THE
ENGLISH CYCLOPÆDIA.

NATURAL HISTORY.

NERITIDÆ.

NERITIDÆ, a family of Holostomatous *Gasteropoda*, having the following characters:—Shell thick, semiglobose; spire very small; cavity simple from the absorption of the internal portion of the whorls; aperture semi-lunate; columellar side expanded and flattened; outer lip acute; operculum shelly, sub-spiral, articulated. At the end of the columella there is an oblong muscular impression, connected on the outer side by a ridge on which the operculum rests; within this ridge the inner layers of the shell are absorbed. Animal with a broad short muzzle, and long slender tentacles; foot oblong, triangular; teeth 7, uncini very numerous. This family includes the genera *Nerita*, *Pileolus*, *Neritina*, and *Navicella*.

Linnæus placed the genus *Nerita* between *Helix* and *Haliotis*, and he divided the genus into the following sections:—

* Umbilicata.

Species: *N. canrena*, *N. glaucina*, *N. vitellus*, *N. albumen*, *N. mammillata*.

** Imperforate, with a toothless lip.

Species: *N. corona*, *N. radula*, *N. cornea*, *N. fluviatilis*, *N. littoralis*, and *N. lacustris*.

*** Imperforate, with a toothed lip.

Species: *N. pulligera*, *N. pupa*, *N. bidens*, *N. viridis*, *N. Virginea*, *N. polita*, *N. peloronta*, *N. albicula*, *N. histrio*, *N. plicata*, *N. grossa*, *N. Chameleon*, *N. undata*, and *N. exuvia*.

We find then, that, in the 'Systema Naturæ,' Linnæus made no marked distinction between the marine and freshwater Nerits.

The *Neritacea* of Lamarck comprise the genera *Navicella*, *Neritina* (Freshwater Nerites), *Nerita* (Marine Nerites), *Natica* and *Janthina*.

Cuvier makes the Nerites (*Nerita*, Linn.) immediately follow *Janthina*, and includes under them *Natica*, Lam.; the Nerits, properly so called (*Nerita*, Lam.; *Peloronta*, Oken); *Velates*, Montf. (*Nerita perversa*, Gmel., a large fossil species); *Neritina*, Lam. and *Clithon*, Montf. (the Crowned Neritines).

M. De Blainville's *Hemicyclostomata*, equivalent to *Nerita*, Linn., comprise the genera *Natica*, *Nerita*, and *Navicella*, or, as he terms it, *Septaria*.

Nerita he divides into the following sections:—

* Right lip toothed. (Genus *Nerita*, Lam.)

A. Species with a single median toothed on the left lip. (Genus *Peloronta*, Oken.) Ex. *Nerita peloronta*.

B. Species with two teeth. Ex. *N. exuvia*.

C. Species with three or four teeth. Ex. *N. lineata*.

** The right lip not toothed. (Genus *Neritina*, Lam.)

D. Species less thick, with the right lip trenchant, and the operculum very oblique. (Genus *Neritina*, Lam.) Ex. *Neritina fluviatilis*.

E. Species whose columellar lip is toothed, and which are provided with spines. Ex. *Nerita canora*.

F. Species with the columellar lip toothed; the two extremities of the right lip prolonged much beyond the aperture, and forming, with the callosity which covers the columellar lip, a sort of auricle produced by the tentacular lobe of the animal. Ex. *N. auriculata*.

NAT. HIST. DIV. VOL. IV.

NERITIDÆ.

G. Calyptroid species, with the upper summit vertical and spired; the last whorl forming the whole base of the shell, and occupied below by a large callosity, which sometimes covers the whole spire. (Genus *Velates*, Montf.) Ex. *N. perversa*.

H. Patelloid species, which are elongated, non-symmetrical, with a dorsal summit, and not spired. (Genus *Pileolus*, Sow.) Ex. *N. altavillensis*.

M. De Blainville observes that this genus is formed of marine and fluviatile species, which led Lamarck to subdivide it into two genera, according to the thickness of the shell, which is greatest in the first, and the denticles on the right lip, which are entirely null in the second. M. De Blainville's observations lead him to the conclusion that the species are still more easily distinguished by the sculpture (guilochis) of the external surface of the operculum than by any other character. He remarks that Lamarck enumerates 17 species of Marine Nerits, which are all from the equatorial and southern seas, and 21 River Nerits, or *Neritina*, two of which only are European, and the others belonging to America and Asia.

M. De Blainville states that only two fossil Nerits are known and two *Pileoli*. But immediately afterwards he says that DeFrance reckons five species of fossil Nerits, two of which are analogues (Italy) according to Brocchi; and five species of *Neritina*, two from the same country, and four *Pileoli*.

M. Rang adopts the arrangement of M. De Blainville, and condemns Lamarck for generically separating the marine and freshwater Nerits. M. Rang says that there are many species of fossil Nerits.

Mr. Swainson places the family *Naticidae* between his *Turbidae* and *Trochidae*, making it consist of the following sub-families and genera. His arrangement is, he says, founded on the shells only, from ignorance of the animals of the major part:—

Sub-Family 1. *Naticina*. Sea-Snails.

Genera: *Natica*, Lam. (with the sub-genera *Naticella*, *Globularia*, *Mamillaria*, *Sigaretus*, *Naticaria*, *Lacuna*, *Leucotis*).

Sub-Family (1) *Neritina*. Nerits.

Genera: *Nerita*, Linn. (with the sub-genus *Neritopsis*, Gray); *Neritina*, Lam. (with the sub-genera *Clithon*, *Velates* (*Velates*), *Pileolus*, and *Navicella*). ('Malacology'.)

Dr. J. E. Gray makes the *Neritidae* the sixth family of his *Podophthalma*, and places it between the *Fissurellidae* and the *Ampullariada*. Dr. Gray's *Neritidae* comprise the following genera:—*Nerita*, *Pileolus*, *Culana*, *Neritina*, *Clithon*, *Dostia*, *Velates*, and *Navicella*.

Adanson appears to have been the first to make known the animal of a *Nerita*, and Cuvier afterwards, in his 'Anatomic Comparée,' gave an outline of it. M. De Blainville has added some further details in the zoology of the *Uranie*, from individuals brought home by Messrs. Quoy and Gaimard, who, in the 'Zoology of the *Astrolabe*,' thus follow out those details.

The Nerits are marine or freshwater animals, a modification of habit which Messrs. Quoy and Gaimard think sufficient for establishing a simple division between these molluscs, which Lamarck erroneously in their opinion separated into two genera—*Nerita* and *Neritina*; for their organisation is entirely similar. Thus the *Nerite*, with a comparatively thick shell, which is very rarely furnished with an epidermis, are always found in the sea; and the *Neritina* of Lamarck, whose shell is more delicate and almost constantly covered with an epidermis,

are always inhabitants of fresh water: a single instance of one of these *Neritina* having wandered into the sea, they may, they say, perhaps have had to cite. The *Nerita* have a particular and distinctive appearance: they pass a part of their life out of the water without ever returning to a distance from it. Those which haunt streams or marshes may adhere to the leaves of trees, but without going on land. Those which are found on land are carried there by *Paguri* or by some accident. Marine *Nerita* are also seen at the mouth of rivers; and Messrs. Quoy and Gaimard remark that these are transitions which nearly all the molluscs undergo without suffering much.

The genus *Nerita* is described separately. (NERITA.)

Neritina has the shell rather thick at the aperture, but extensively abraded inside; outer lip acute, inner straight, denticulated; operculum obely, with a flexible border, slightly toothed on its straight edge.

N. pulligera has the shell ovate, slightly striated, blackish-brown; the outer lip dilated, thin, white within, the margin acute, the inner border yellowish; the inner lip toothed. (Lam.)

This fine species is uniform chestnut, with the striae of growth strongly marked; these converge on the spire, which is covered by the right lip.

The animal has long delicate tentacles, which are yellowish soiled with brown. The head and sides of the foot are yellow, spotted with brown and black. The under part of the foot is reddish.

The operculum is large, of an apple-green colour, with black transverse bands proceeding to converge towards the spire: its contour has a reddish line. ('*Astrolabe*.')

Neritina pulligera.
a, shell and animal; b, operculum.

The drawing from which Messrs. Quoy and Gaimard have figured this species was made at Umata in the island of Gasm. They state that there are also *Nerita pulligera* at Vanikoro. They found on the trees dead shells whose spire was always corroded, and they inquire whether they had been brought there, or whether the animal had died after having ascended the trees. They state as a remarkable fact, that in a great number of individuals of this species they found in the liver a small knot of worms, some of which were not less than 17 lines in length. They were pointed at both ends, like *Lumbrici*, or Round Worms.

Pilularia has the shell limpet-like above, with a subcentral apex; concave beneath, with a small semilunar aperture, and a columellar disc, surrounded by a broad continuous peristome. The species are only known as fossils.

Upwards of 100 recent species of *Nerita* and 70 species of *Neritina* have been described. The fossil species of *Nerita* amount to 60, and of *Neritina* to 20. *Nerita* is found in the Lias, and *Neritina* in the Eocene Formation.

Naricella.—With the exception of the disposition of its operculum and of the muscles of attachment to the shell, the animal may be said to be nearly similar to that of *Nerita*. Its head is large, convex, notched, a little auriculated anteriorly, carrying two long and very pointed tentacles, having the eyes at their base, on a rather elongated pedicel. The foot is regularly oval, and does not overborder the shell; at its union with the mantle, near its root, it presents a remarkable beak-like, which is due to the internal disposition of the operculum. It is pale-yellow below, deeper upon the sides, with spots of deep-brown, as is the case with the head and the ocular peduncles; only the tentacles have a smoked colour, with black and very delicate longitudinal striae. Mantle light yellow.

The form, and especially the position, of the operculum of *Naricella*, are so unusual, that it may be said that it is not a true operculum, and that it is situated in the foot. But it is an evident operculum, and its place is, as in all the Cephalous Molluscs which are provided with that organ, above the foot. Its form is subquadrilateral; it is adhered throughout its lower surface, free on its upper surface, and terminated behind by a cartilaginous part, by means of which it increases. It is carried, as in the *Nerita*, by a very small appendage of the foot, which overborders it a little behind. But that which renders it so unusual is, that the foot, which is really subtracheal, that is, only attached below the body, is united, nearly throughout the rest of its length, to the visceral mass by the continuation of the skin which envelopes it; whence it results that the operculum seems to be contained in a sort of pouch situated between the foot and the viscera, and whose aperture, in the form of a transverse slit, is at the superior extremity of the body. This disposition of the operculum

of the *Naricella*, says M. De Blainville, prevents it from really serving the ordinary purpose of one.

N. elliptica. Shell ovate, elliptical; sub-epidermis greenish-brown, smooth, shining, squamously spotted with white and cerulean; the apex recurved, subprominulate beyond the margin. (Lam.)

The number of species of *Naricella* (all recent) recorded is 20.

Naricella elliptica.

a, animal in the shell, seen from below; b, operculum.

The genus *Natica*, sometimes made the type of a family (*Naticidae*), has been included with the *Neritidae*.

Messrs. Quoy and Gaimard remark, that the *Naticæ* are animals to which their foot gives a remarkable aspect. It is a long oval lamella, ordinarily squared in front, oval behind, and doubled; anteriorly, where it is widest, it is a thick escutcheon, a little auriculated, which ascends on the front of the shell, which it covers, at the same time that it hides all the head of the animal, of which ordinarily nothing but the tentacles appear; a groove on each side indicates the two parts of the foot.

The posterior escutcheon, which is less considerable, supports the operculum, which it overborders in order to cover the left lip and the extremity of the shell. There are individuals in which it has the same size as the foot, from which it is distinguished by a circular groove. Thus, observe these zoologists, throughout their development the *Naticæ* resemble a mass of flesh, on the summit of which one perceives a part of the shell. The operculum, although very large, is not apparent; placed transversely, it is hidden by the extremity of the shell, which contains the mass of viscera. A very small muscle binds all this development of flesh to a rather slight columella. The rest of the animal, which is but slightly spiral, offers nothing remarkable.

N. melanostoma has the shell oval, ventricose, convex-depressed thin, white, zoned with yellow; spire somewhat prominent; lip blackish-brown, umbilicus semi-closed. (Lam.) Length 15 lines; breadth 11½ lines.

Operculum membranous; paucispiral on the left border; the rest of its lamellæ obliquely transverse. Colour deep chestnut-brown lighter on the edge.

Natica melanostoma.

a, shell with animal seen from above; b, animal out of the shell; c, operculum.

It has been found at Tonga, the Moluccas, and many other places.

Found by Messrs. Quoy and Gaimard some fathoms deep. Species of the genus have been captured creeping on the shore like the *Nerita* on rocks and sea-weed, and from the surface to the depth of 40 fathoms on mud and sandy mud, in estuaries and in tidal rivers.

Dr. J. E. Gray makes the *Naticidae* the first family of his second section, *Eriophthalma* (*Edriophthalma* ?), of his second order *Phytophaga*. Under the *Naticidae* he comprises the following genera:—*Natica*, *Neverita*, *Nacca*, *Cepatia*, *Polinices*, *Mammilla*, *Cernina*, *Globulus*, *Naticina*, *Cryptostoma*, *Stylina* (?), *Radula* (?), and *Neritopsis*. In Woodward's 'Manual of the Mollusca' the *Naticidae* include the genera *Natica*, *Sigaretus*, *Lamellaria*, *Narica*, and *Velutina*.

Ninety recent species of *Natica* have been recorded. They are inhabitants of the Arctic Seas, Great Britain, the Mediterranean and Caspian Seas, India, Australia, China, Panama, and the West Indies. The fossil species amount to 260.

Sigaretus has 26 recent and 10 fossil species.

Lamellaria has 5 recent and 2 fossil species.

Narica has 6 recent and 4 fossil species.

Velutina has 4 recent and 3 fossil species.

In Forbes and Hanley's 'British Mollusca' the following species of *Neritidae* and *Naticidae* are enumerated as British:—*Neritina fluviatilis*, *Natica monilifera*, *N. nitida*, *N. sordida*, *N. Montagu*, *N. Helicoides*, *N. pusilla*, and *N. Kingii*.

NERIUM (from *νῆρος*, humid, the habitat of the species), a genus of Plants belonging to the natural order *Apocynaceae*. It has a hypocrateriform corolla, the orifice surmounted by lacerated multifid processes; segments of the limb contorted; the filaments are inserted into the middle of the tube; the anthers sagittate, adhering by the middle to the stigma; it has two ovaries, a filiform style dilated at the apex, and an obtuse stigma.

N. odoratum has linear-lanceolate leaves, three in a whorl; the segments of the calyx erect; appendages of the corolla filamentous; the anthers bearded at the point. The flowers red or white, with an agreeable musky scent. The bark of the root and the sweet-smelling leaves are supposed by native Indian doctors to act as powerful repellants applied externally. The root, taken internally, acts as a poison.

N. Oleander, Common Oleander, has lanceolate leaves, three in a whorl being beneath, the segments of the corona trifid. It is a native of the Indies, in humid places, but has now become wild in the south of Europe, by the side of streams and the sea-coast. The flowers are rather large and of a bright-red colour. This species contains a great quantity of gallic acid, and a decoction of the leaves or bark forms an acrid stimulating wash, much employed by the poor people in the south of France to cure cutaneous disorders. The peasants in the neighbourhood of Nice use the powdered bark and wood of the Oleander to poison rats. Several cases are also recorded of death from having eaten meat roasted on a spit of Oleander wood.

All the species of Oleander are very showy when in blossom. They thrive well in a light rich soil; and cuttings strike root freely in a moist situation. All of them require a good deal of heat to flower well in this country.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

NERVOUS SYSTEM. This system constitutes one of the most essential and characteristic parts of the animal frame. It consists of two portions, the Cerebro-Spinal and the Sympathetic, or Ganglionic, each of which, although possessing many things in common, is distinguished by many peculiarities of structure and function.

The Cerebro-Spinal system includes the brain, spinal chord, and the nerves proceeding from these organs. It is through the medium of this part of the nervous system that the functions of mind, sensation, and volition are performed. This part was called by Bichat the Nervous System of Animal Life. The Sympathetic, or Ganglionic, portion was named by Bichat the Nervous System of Organic Life. These names however involve theories which are not confirmed by recent researches. The sympathetic system consists essentially of a chain of ganglia connected by nervous chords, which extends from the cranium to the pelvis along each side of the vertebral column, and from which nerves pass to the abdominal, thoracic, and pelvic viscera.

When examined under the microscope the tissue of which the whole nervous system is composed, may be separated into two elements, the Vesicular and the Fibrous. The vesicular nervous matter is gray or cineritious in colour and granular in its texture, containing nucleated nerve-vesicles, and is largely supplied with blood. The fibrous nervous matter is, on the other hand, usually white, and composed of tubular fibres, although in some parts it is gray, and consists of solid fibres; it is also less vascular than the preceding. The former is more immediately associated with the mind, and is the originating seat of the force manifested in nervous actions; while the latter is simply the propagator of impressions made on it. The union of these two kinds of matter constitutes a Nervous Centre, and the threads of fibrous matter which pass to or from it are called Nerves. The smaller nervous centres are termed Ganglia; the larger ones are the Brain and Spinal Chord.

The Tubular Fibre is a tube composed externally of a fine transparent homogeneous membrane, very much resembling the sarcolemma of muscle. Nucleated cells may however be occasionally seen in it, as in *fig. 1*, which represents a portion of the sciatic nerve of a frog. This may be termed the tubular membrane of nerve. The contents of this tube consist of a soft, semi-fluid, whitish, pulpy substance, which is readily pressed out of its cut extremity. This is termed by

Fig. 1.

Schwann the white substance, *Fig. 2* is a nerve, that is, a sheath containing a number of nervous filaments branching and receiving branches from another adjacent to it. *Fig. 3* is a portion of nerve in which the sheath has been removed and the fibres and smaller fasciculi of filaments separated from each other.

Fig. 3.

Fig. 2.

The researches of Kölliker on the intimate structure of the nervous tissue are the most recent, and we subjoin his general account of the nerve-fibres as given in the translation of his 'Histology' by Messrs. Busk and Huxley:—

"The Nerve-Tubes, or Fibres, also termed primitive tubes, or primitive fibres of the nerves, are soft, fine, cylindrical filaments, having a diameter of 0.0005"—0.01"; they constitute the principal part of the nerves and of the white substance of the central organs, although they are not wanting in the greater part of the gray substance of the latter and in the ganglia. When examined in the recent state and by transmitted light, they appear as clear as water, transparent, and with simple dark contours; by reflected light—glistening, opaline, like fat, in larger quantities together, white, and for the most part their appearance does not indicate that they are composed of different constituent parts. But it is readily seen upon the application of various methods, that they consist of three entirely distinct component structures, viz. of a delicate coat, and a viscid fluid, in the centre of which is a soft hut elastic fibre.

"The Coat, or Sheath, of the Nerve-Fibres (Limitary Membrane, Valentin) is an excessively delicate, flexible hut elastic, perfectly structureless, and transparent membrane, which, in quite unaltered nerve-fibres, except in certain situations, is altogether invisible. But on the application of suitable reagents, at least in the thicker fibres of the nerves and of the central organs, it comes readily into view, corresponding, in its chemical characters, in all essential particulars, with the sarcolemma of the muscular fibres. In the finest fibres of the peripheral as well as of the central nervous system, the existence of this membrane has not yet been demonstrated, and it must consequently, for the present, be left undecided whether these fibres possess sheaths or not.

"Within the structureless sheath lies the Nerve-Medulla, or Pulp (Medullary Sheath of Rosenthal and Purkinje; White Substance of

Schwann), in the form of a cylindrical tube, closely and exactly surrounding the central fibre. In the recent nerve-fibre this substance is perfectly homogeneous, fluid, but viscid like a thick oil, and, according to the light by which it may be viewed, transparent and clear, or whitish and pearly, and it is obviously to it that the peculiar glistening appearance of the nerve is due. The nerve-pulp is rapidly and invariably altered by the application of cold water, of most acids, and of many other re-agents; the change consisting principally in a coagulation of it, which takes place gradually from without to within, sometimes involving the entire thickness, sometimes only its outermost layer. In the latter case are produced the well-known nerve-fibres with double contour lines, or in which the medullary sheath is externally coagulated to a greater or less extent, remaining fluid internally—in the former case with the contents apparently wholly grumous and opaque. The coagulated nerve-medulla in fact seldom appears homogeneous, but most generally grumous, granular, and as if composed of separate irregular larger and smaller masses; and, upon the application of acetic acid, as if formed of minute, separate, or reticularly-united rods. The nerve-pulp is also altered very readily by pressure. It sometimes escapes from the ends of the tubes, or from lateral protrusions or ruptures of the sheath, forming larger or smaller drops of every imaginable shape—regularly spheroidal, clavate, fusiform, cylindrical, filamentary, or of the most bizarre figures—which likewise coagulate, either on the surface merely or throughout, and thence, like the nerve, appear with a double contour, or half or wholly grumous. But within the fibres also its structural conditions alter, for instead of being continued through them as before—as a cylinder of uniform size—it accumulates in places into larger masses. In this way are produced the frequently-described varicose nerve-fibres, in which the medullary sheath presents sometimes minute bead-like enlargements; sometimes various-sized irregularly-distributed nodosities, or even, in places, complete interruptions. All these forms, in which the sheath frequently participates, but in which the central fibre takes no part, arise artificially, and are developed most readily in the finer fibres with more delicate sheaths, such as are found in the central organs.

"The Central or Axis-Fibre of the nerve-tubes (Primitive Band, Hensen; Cylinder Axis, Purkinje) is a cylindrical or slightly-fattened filament, which in entire and unaltered nerve-fibres is as little recognizable as the sheath, being surrounded by the pulp, and possessing the same refractive power; whilst it comes readily into view when the fibre is torn or treated with various re-agents; and it may thus be recognized as a constant structure, sometimes in the interior of the fibre and sometimes isolated. Under natural circumstances it is pale; most generally homogeneous; more rarely finely granular or striated, bordered by straight or occasionally by irregular pale contour lines; and it is generally everywhere of uniform thickness. It is distinguished from the medullary sheath especially by the circumstance that although soft and flexible, it is still not fluid and viscous, but elastic and solid, something like coagulated albumen, with which it also appears to agree in most of its chemical characters. This axis-cylinder exists in all nerve-fibres without exception, even in the finest, and invariably presents the same characters, except only that it is sometimes thicker, sometimes more slender, according to the size of the fibre itself.

"The Nerve-Fibres in which the three structures above described can be distinguished, and which we would designate as the Medullated, or Dark-bordered, constitute, it is true, the greater proportion of those existing in the body; but besides these there are still some forms requiring more particular description. These are the nerve-fibres in which there exists no trace of a medullary sheath, whilst they have an outer sheath and contents, sometimes identical with the axis-fibre of the other kind of nerve, sometimes similar but more clear. These non-medullated nerve-tubes occur, in the first place, as continuations to the other sort, where the latter are in connection with nerve-cells; and also as more elongated independent fibres, representing the so-called processes of the nerve-cells of authors; and, lastly, at the terminations of the dark-bordered nerves. They may again be arranged in several subdivisions, distinguished respectively by their having, or not having, nuclei, and more or less transparent, more or less consistent contents. It must also be added that the dark-bordered fibres differ extremely—partly in respect of the delicacy or firmness of their structure, and partly in their diameter, which varies from 0.006" to 0.01" or more, so that they may be distinguished into fine and coarse, delicate, or firm fibres; from which it is evident that the nerve-fibres, notwithstanding their general tubular character, still differ pretty widely from each other in various respects.

"The Nerve-Cells (Accessory Corpuscles, Belegungskörper, Nerve-Corpuscles, Valentini) are nucleated cells, occurring in great numbers in the gray or coloured substance of the central organs, in the ganglia, and occasionally also in the trunks and peripheral expansions of the nerves (retina, cochlea, vestibule). The nerve-cells are covered externally by a delicate structureless membrane, which in the cells of the ganglia (ganglion-cells, globules, corpuscles) may be demonstrated easily, but with great difficulty in those of the central organs; the application of re-agents however will suffice to show pretty distinctly that the membrane exists around the larger cells even in these situations, whilst in the smallest, just as in the finest nerve-fibres, no

membrane has yet been observed, although one probably exists. The contents of the nerve-cells are a soft but tenacious elastic substance which, besides the nucleus, consists of two elements; firstly, of a clear homogeneous light-yellowish or colourless matrix, upon which the physical properties of the contents depend, and which is a protein-compound; and, secondly, of minute granules of different kinds. In the colourless nerve-cells these present the form of uniform, roundish, for the most part minute and pale, more rarely darker and larger corpuscles, dispersed throughout the entire contents of the cell, and imbedded in the tenacious matrix; whilst in the coloured cells, instead of these granules, more or less yellowish, brown, or blackish corpuscles occur. The latter are most usually of a larger size, and are placed, closely aggregated, in a mass near the nucleus; in other instances, they nearly fill the entire cell, giving it the aspect, in all respects, of a brown or blackish pigment-cell. In the midst of these contents lies the nucleus, for the most part as a very clear spheroidal vessel with distinct walls, perfectly transparent contents, and one, or more, rarely several, large opaque nucleoli, which occasionally exhibit a cavity.

Fig. 4.

Ganglion-Globules, with their processes, nuclei, and nucleoli.

"a, from the deeper part of the gray matter of the convolutions of the cerebellum. The larger process is directed towards the surface of the organ; b, another from the cerebellum; c, d, others from the posterior horn of gray matter of the dorsal region of the chord. These contain pigment which surrounds the nucleus in c. In all these specimens the processes are more or less broken. Magnified 500 diameters. (From Todd and Bowman.)

"The size of the nerve-cells varies very much; like the fibres, they occur as large, small, and middle-sized. The extreme dimensions of the cells are 0.002"—0.003" and 0.05"—0.06". The nuclei, which for the most part are in proportion to the cells, measure from 0.0015"—0.003"; the nucleoli 0.0005"—0.003". The nerve-cells, moreover, are distinguished according as they are: 1, thin- or thick-walled, of which the former are found almost wholly in the spinal chord and brain; and 2, as they are independent cells, or are furnished with pale processes, of which they may have one, two, or several (uni-

Fig. 5.

A, vesicular and fibrous matter of the laminae of the cerebellum. a, ganglion-globule; b, very minute nerve-tubes traversing a finely granular matrix, in which are numerous rounded nuclei, c.

B, blending of the vesicular and fibrous nervous matter in the dentate body of the cerebellum. a, ganglion-globule, with its nucleus and nucleoli; b, nerve-tube, slightly varicose, in close contact with the ganglion-globule; b', a smaller nerve-tube. These parts all lie in a finely granular matrix interspersed with nuclei, c. (From Todd and Bowman.)

bi-multi-polar cells), and which are frequently camified, and the former, in many situations, continuous with dark-bordered nerve-fibres, and even having the nature of non-medullated nerve-fibres. Besides the nerve-cells, there also exist in the gray substance of the higher central organs, as constant constituents, a finely granular pale substance, which has the greatest resemblance to the contents of the cells, and besides this, in places, large accumulations of free cell-nuclei. Similar elements are contained in the retina, and according to Wagner and Robin in the ganglia of the *Plagiostomata*."

The arrangement of these fundamental elements of the nervous system present an almost countless diversity in the various parts of the spinal chord and of the brain. [BRAIN.] The student of anatomy will find the fullest account of these arrangements in Kölliker's 'Manual of Human Histology.'

The nervous matter has been submitted to chemical analysis, but no very important result has hitherto been obtained. The following compounds have been observed from the fatty matters of the brain, which amount to about 5 per cent.:—1, Cerebric Acid, a white substance in the form of crystalline grains, abounding in carbon, and containing a minute proportion of phosphorus; 2, Cholesterin; 3, Oleo-Phosphoric acid, a peculiar fatty acid containing about 2 per cent. of phosphorus in the form of phosphoric acid; and 4, traces of olein, margarin, and fatty acids. The following table has been drawn up by L'Heritier from his own researches. The numbers in each instance represent the mean of six analyses:—

	Infants.	Youths.	Adnlts.	Aged Persons.	Idiots.
Water	82.79	74.26	72.51	73.85	70.93
Alhmen	7.00	10.20	9.40	8.65	8.40
Fat	3.45	5.30	6.10	4.32	5.00
Osmazome and Salts	5.96	8.59	10.19	12.18	14.82
Phosphorus	0.80	1.65	1.80	1.00	0.85

The varying amount of phosphorus has been supposed to stand in some connection with the mental powers. This view must however at present be deemed merely hypothetical. The nerves, according to L'Heritier, contain more alhmen, less solid and more soft fat, than the brain.

Lehmann, in the third volume of his 'Physiological Chemistry,' is obliged to admit that at present our knowledge of the chemical composition of nervous matter throws no light upon the functions of this system. This may serve as a reuke to those who so readily attribute nervous function to the action of physical and chemical causes. "But however forcibly," says Lehmann, "we may be compelled to admit the incapacity of chemical assistance to explain the actions of the nervous system, chemists will not suffer themselves on that account to be deterred from further investigations; for they must be well aware that, without a careful examination of the chemical phenomena presenting themselves in the nervous system, they can never succeed in tracing nervous actions to definite physical laws."

The nerve-fibres proceed uninterruptedly from their origin in the nervous centres—the ganglia—to their destination. In the whole of their course there is no branching, or anastomosis, or union with the substance of any other fibres. The nerves seem to terminate at their peripheral extremities in different ways. Those which have been

Fig. 6.

A, nerve from the finger, natural size, showing the Pacinian corpuscles.
B, unusual form from the mesentery of the cat, showing two included in a common envelope; a, b, are the two nerve-tubes belonging to them.
C, another from the same, showing an offset from the central cavity, containing a branch of the nerve.
D, rare form from the mesentery of the cat, showing two corpuscles placed in succession on a single stalk, and furnished with the same nerve-tube, which resumes its white substance in the interval between them. (From Todd and Bowman.)

noticed are as follows:—1, In loops. In this case each fibre, after supplying the tissue on which it is found, turns back, and probably pursues its way to a nervous centre. This mode of termination has been observed in the internal ear, in the papillae of the tongue, in the pulp of the tooth, and in other parts. 2, In plexuses. It has been stated by many observers that nerves terminate in this way on the serous membranes. 3, In free ends. This seems to be the case in the retina. [EYE.] It has also been observed in the Pacinian corpuscles. These bodies, so called from Pacini their discoverer, are found in the human subject in great numbers in connection with the nerves of the hand and foot, but they also exist sparingly on other spinal nerves and on the plexuses of the sympathetic, though never on the nerves of motion. In the mesentery of the cat they may be almost always detected by the naked eye, being pellucid oval grains rather smaller than hemp-seeds.

A (fig. 6) gives a correct idea of their relation to the nerves in the palm and sole. In the human subject they vary from the 10th to the 20th of an inch. The structure of these bodies is highly singular. They consist, first, of a series of membranous capsules, from thirty to sixty or more in number, inclosed one within the other; and, secondly, of a single nervous tubular fibre inclosed in the stalk, and advancing to the central capsule, which it traverses from end to end.

Fig. 7.

Pacinian corpuscle from the mesentery of a cat; intended to show the general construction of these bodies. The stalk and body, the outer and inner system of capsules, with the central cavity, are seen.

a, arterial twig, ending in capillaries, which form loops in some of the inter-capsular spaces, and one penetrates to the central capsule; b, the fibrous tissue of the stalk, prolonged from the neurilemma; n, nerve-tube advancing to the central capsule, there losing its white substance, and stretching along the axis to the opposite end, where it is fixed by a tubercular enlargement. (Todd and Bowman.)

In the above figure (7), which exhibits the general structure, the ten or fifteen innermost capsules may be observed to be in contact with one another, while the rest are separated by a clear space containing fluid.

Respecting the function or use of these corpuscles much has been written. Pacini himself regarded them as connected with the function of animal magnetism. Mr. Huxley, in a Paper in the second volume of the 'Quarterly Journal of Microscopical Science,' suggests that they are homologous with certain bodies described by Savi in the *Torpedo*, and with the ampullae or muciparous canals of Rays and Sharks. He says, "We have only to conceive a single hair developed in one of these ampullae, and taking the place of the clear gelatinous matter, to have a vibrissa, such as is met with in almost all the *Mammalia* about the lip and eyebrow; and I conceive that the vibrissae are in fact the most complex and fully-developed forms of this series of cutaneous organs. Now the vibrissae are without doubt delicate organs of touch, and the mucous canals of fishes appear to be very probably of the same nature; but when we come to the Savi and Pacinian bodies, and to the corpuscula tactus, two possibilities arise—either they may be still the instruments of a modified sense of touch, or they may be merely rudimentary representatives of the more completely formed organs." In a note, he adds, "The auditory labyrinth is constructed on precisely the same plan as the muciparous canals of fishes, and the eye

on that of a vibrissa, as might readily be demonstrated; so that all the organs of sense are to be regarded as modifications of one and the same plan."

The development of the elements of the nervous system has been observed by Kölliker. The nerve-cells, wherever they may occur, are nothing else than transformations of the so-called embryonic-cells; some of which simply enlarge, whilst others throw out a varying number of processes, and are, at all events in part, connected with nerve-fibres.

Many nerve-cells also appear, at a subsequent period, to increase by division; at all events, I do not know how otherwise to explain the frequent occurrence of two nuclei in the nerve-cells of young animals, especially in the ganglia; and the cells connected by communicating filaments, which have been noticed by various observers.

The peripheral nerve-fibres all originate on the spot, but their subsequent development proceeds in such a way that the central extremities always precede the peripheral. With the exception of the extremities of the nerves, they are developed from fusiform nucleated cells, which are nothing else than modifications of the primordial formative cells of the embryo, and are conjoined into pale, flattened, elongated, nucleated tubules or fibres 0.001"—0.003" broad. Now, at first the nerves consist only of fibres of this kind, and of the rudiment of the neurilemma, being gray or dull white, like the sympathetic filaments; subsequently, in the human embryo at the fourth or fifth month, they always assume a whiter colour, and the proper white or medullary substance continues to be more and more developed in them. Of the three possible modes of development of this substance propounded by Schwann, one only in the present state of things can come into question, that namely, as to whether the medullary sheath is a structure deposited between the membrane and the contents of the embryonic nucleated fibres; in which case the contents of the latter would become the axis-fibre. But besides this, the medullary sheath may originate in what did not occur to Schwann, namely, a chemical metamorphosis of the external portion of the contents of the embryonic-fibres; and the axis-fibre may be only the remainder of those contents which has not undergone a fatty metamorphosis. It is difficult to determine which of these two views is correct. Direct observation shows only this much, that the contents of the pale embryonic fibres invariably, by degrees obtain dark contours, and ultimately present the aspect of a true dark-bordered fibre, whilst it teaches nothing with respect to the proper origin of the white substance. Since however it can be proved that the fibres, whilst they undergo this change, do not alter in size, the supposition I have expressed would still appear the more correct.

"The development of the terminations of the nerves, which appears in some respects to present conditions different from those exhibited in the trunk, may be readily traced in the tails of the larvæ of the naked *Amphibia*. We there find, as is mentioned by Schwann, the primary rudiments of the nerves to be pale branched fibres, measuring 0.001"—0.002", which here and there anastomose, all finally terminating in free fibrilla of the finest kind, measuring 0.002"—0.001." There is no difficulty in showing that these fibres arise from the coalescence of fusiform or stellate cells, for, in the first place, such cells may be seen, in part still in close opposition with but independent of them; in part more or less connected by means of their processes; and, secondly, cell-nuclei occur at the divisions of the fibres, which are there somewhat dilated; and, at all events in young larvæ, with them are associated the well-known angular vitelline corpuscles, with which, at first, all the cells of the embryo are filled. At first the number of pale embryonic nerves is very small, and limited to a few short trunks closely applied to the muscular structures in the tail; but they are gradually developed in the direction from the centre towards the periphery, farther into the transparent portion of the tail, new cells being continually added in connection with the existing trunks, whilst the latter themselves, almost in the same manner as the capillaries of these larvæ, unite directly by delicate offsets."

On the general question of the functions of the elementary parts which have been described, Kölliker makes the following observations:—

"As regards the two elementary portions of the nervous system, anatomical investigation shows, that all its divisions which preside over the higher functions, contain gray substance in greater or less quantity, as in the sympathetic, the ganglia of the spinal and cerebral nerves, and in the spinal chord and brain; whilst the nerves which act only as a conducting apparatus contain nothing but nerve-fibres. This being admitted to be the attribute of the gray substance, it may further be inquired whether it presents differences in its structure, as it does in its functions. With respect to this I would remark as follows: The largest nerve-cells are met with in situations from which motory effects proceed, as in the anterior horns of the spinal chord, amongst the fibres of the anterior roots, in the medulla oblongata, at the points of origin of the motor cerebral nerves, in the cortical substance of the cerebellum, the pons variolii, and crura cerebri; whilst the smallest cells are found in the sensitive regions, as in the posterior horns of the spinal chord, the corpora restiformia, and quadrigemina. There does not however, appear to be any constant relation between the size of the cells and the existence of

sensitive or motor functions; for, in the ganglia of the cerebro-spinal nerves and of the sympathetic, and in the optic thalami, both sorts of fibres arise in one place from small, and in another from large cells. It seems, therefore, as in the case of the nerve-fibres, that there are large and small motor cells, as well as sensitive cells of various dimensions, a fact which is confirmed by comparative anatomy, as the large bipolar cells in fishes are manifestly sensitive. No essential difference can be pointed out between sensitive and motor cells, whether the latter be of uniform or of different size, and in particular the variations existing between such cells are not greater than those between the motor cells in different localities. Even the cells in the cortical substance of the brain, to which physiologists assign the mental manifestations, with our present means of research, exhibit no perceptible peculiarities. The nerve-cells however may be divided into those which are in direct connection with nerve-fibres, and those which are not thus connected, but independent. The former, of course, are to be especially regarded as sensitive and motor; with respect to the latter, anatomy to some extent affords no information, inasmuch as that they present no processes as in the sympathetic ganglia, and in some situations in the brain. As regards those furnished with processes, particularly the many-rayed cells, which in many situations undoubtedly are not prolonged into nerve-fibres, it might be considered certain that they—both larger and smaller, by means of their processes which fulfil the functions of nerves, and whether the latter anastomose or not—bring different regions of the central organs into mutual connection, and participate in the reflex phenomena, the sympathies, and other modes of association of the functions. Cells of this kind exist in the spinal chord and brain everywhere in very large quantities, but not in the ganglia; although it is not from this intended to imply that no reflex actions are performed in those bodies.

"Respecting the nerve-fibres, anatomy is not in a position to point out any difference in them, between the sensitive and motor nerves; a circumstance however which physiologically can afford no reason to ascribe identical functions to them. As regards the various sizes of the nerve-fibres, the numerous changes in diameter undergone in their course by all the cerebro-spinal nerves, very obviously indicate that these proportions have no relation to the functions of the fibres in general. Nevertheless, I do not look upon these relations of size as altogether of little consequence, and in particular does the attenuation of the fibres, where they extend through gray substance, appear to me to be important, as also their diminution at their origins and terminations. It is however difficult to perceive the physiological import of these facts. Were it the case that in the nerve-fibres the axis-cylinder alone was the conducting, and the medullary sheath an insulating substance, and could it be proved that the medullary sheaths were wanting in the attenuated portions, the peculiar activity of the nerve-fibres in these situations (the transverse conduction in the spinal chord, the acuteness of sensibility at the terminations, &c.) would be satisfactorily explained. It is well known that such a notion has already been entertained by various writers, and its conception has usually proceeded upon the idea that a close alliance or identity exists between electricity and the nervous force, and the medullary sheath abounding in fatty matter has from this point of view been regarded as an insulator. But first, it is anything but demonstrated, that the nerves possess no other active force but electricity; and secondly, there is nothing to indicate an absence of the medullary sheath, and a free condition of the axis-fibres in many peripheral extremities of the nerves (skin, muscles), and in those portions of the central organs (spinal chord) in which a transverse conduction is evident. The question always remains, whether the medullary sheath, although not altogether, yet at all events partially, may not insulate more or less, according to its thickness. Since however this membrane is wanting not only in many terminations of nerves, where an insulating conducting faculty might not be required, but also in other situations, as in the *Invertebrata*, and the nerves of *Petromyzon* generally, as well as in the processes of the nerve-cells which certainly act as nerves, in the central organs of the higher animals, and in the finest nerve-fibres in those situations (brain), the notion that such is its effect in the dark-bordered nerves loses all ground of support. It would seem to me, that the medullary sheath represents nothing more than a protective soft envelope for the tender central fibre."

Although the possession of a nervous system is a distinguishing feature of the higher animals, the structural traces of its existence are not found in a large series of truly animal beings. It would appear in these cases that the function of both the nervous and muscular systems are carried on by the same tissues. Nor do these functions in the lower animals distinguish them from plants, for we find the protoplasm in the interior of the cells of plants endowed with the same power as the tissues of the polyp or jelly-fish. The possession therefore of a nervous or muscular system, or the performance of functions supposed to be dependent on these organs, is not a characteristic distinction of the animal world.

It is in the higher *Radiata* that we find the first definite indications of the existence of a connected nervous system. It is probable that such exists in all the *Acalephæ*, although the softness of their tissues renders it difficult of detection. According to Ehrenberg, two nervous circles may be detected in the *Medusæ*; one running along the margin

of the mantle and furnished with eight ganglia, from which filaments proceed to the eight red spots which he supposes to be eyes; whilst the other is disposed around the entrance to the stomach, and is furnished with four ganglia, from which filaments proceed to the tentacula. A nervous ring has also been detected by Professor Agassiz in *Sarcia*, one of the Naked-Eyed Pulmogrades; and he states that it is entirely composed of ganglionic cells. In *Berœ*, it is affirmed by Dr. Grant that a nervous ring exists round the mouth, furnished with eight ganglia, from each of which a filament passes towards the other extremity of the body, while others are sent to the lips and tentacula. In the *Echinodermata* however its manifestations are much less equivocal. In the *Asterias*, for instance, a ring of nervous matter surrounds the mouth, and sends three filaments to each of the rays; of these, one seems to traverse its length, while the two others are distributed on the caecal prolongations of the stomach. In the species examined and figured by Tiedemann, no ganglionic enlargements of this ring appear to exist, and it seems not improbable that, as in the *Medusa*, the entire ring is composed of vesicular nervous matter; but this element is usually collected into distinct ganglia, which are found at those points of the ring whence the branches diverge, the number of the ganglia being always equal to that of the rays. In those species which possess ocelli at the extremities of the rays, the nervous chord proceeding towards each swells into a minute ganglion in its neighbourhood. In the *Echinus* the arrangement of the nervous system follows the same general plan; the filaments which diverge from the oral ring being distributed (in the absence of rays) to the complicated dental apparatus, whilst others pass along the course of the vessels to the digestive organs. The transition between the *Radiata* and *Articulata*, presented by the *Holothuria* and *Sipunculus*, is peculiarly well marked in the nervous system of these animals; for the ring which encircles the mouth is here comparatively small, but a single or double non-gangliated filament traverses the length of their prolonged bodies, running near the abdominal surface (which is their situation in the articulated classes) and giving-off transverse branches.

When we compare the character of the nervous system of these Radiated classes with that of the higher animals of more heterogeneous structure, we find that every segment of the body which is similar to the rest is connected with a ganglionic centre that seems to be subservient to the functions of its own division alone, and to have little communication with, or dependence upon, the remainder; these centres being all apparently similar to each other in their endowments.

Among the Molluscous classes there is no radiate or longitudinal multiplication of parts, the only repetition being on the two sides of the median plane. It is chiefly in the organs of animal life that this bi-lateral symmetry is observable, the symmetry of their nutritive apparatus being obscured by the unequal development of its different parts; and the predominance of the latter in their organisation impresses itself (so to speak) upon their nervous system, which is not formed until a late period of development, and which shows a want of constancy in the relative position of its centres, that is, in striking contrast with the uniformity of the plan which is so obvious in the nervous systems of *Articulata* and *Vertebrata*. Of these centres there are typically three pairs:—1. The Cephalic Ganglia, which lie either at the sides of the œsophagus, or above it; and may be either disjoined, although connected by a commissure, or fused into one mass, which is usually bi-lobed; this gives off nerves to the labial and olfactory tentacula, to the eyes, and to the muscular apparatus of the mouth; and upon either of these nerves accessory ganglia may be developed. 2. The Pedal Ganglia, which are commonly fused into one mass which is situated below the œsophagus, and are connected with the cephalic ganglia by a commissural band on each side, forming a ring which encircles that canal; though, in the *Nudibranchiata* and some other Gasteropoda, the pedal ganglion of each side is fused into one mass with the corresponding cephalic ganglion: from the pedal ganglion are given off nerves to the foot, and also to the organs of hearing, when those are not actually lodged in them, as frequently happens. 3. The Parieto-Splanchnic Ganglia, which are usually found in the posterior part of the body, and are connected by commissural bands both with the cephalic and with the pedal ganglia: these give off nerves to the muscular and sensitive parietes of the body, to the shell-muscle or muscles, to the branchial apparatus, and to the heart and large vessels. The function of these is divided, in the higher *Mollusca*, between two or more pairs of ganglia; and the proper visceral or sympathetic system becomes more distinct from it. [MOLLUSCA.]

The nervous system of the *Mollusca* becomes gradually more complicated as we ascend from the lower to the higher forms. It is in the *Cephalopoda*, which stand at the head of the Molluscan series, that we find an approach towards the structure of the Vertebrate animals. [CEPHALOPODA; NAUTILIDÆ.]

The plan on which the nervous system is distributed in the sub-kingdom *Articulata* exhibits a remarkable uniformity throughout the whole series, whilst its character gradually becomes more elevated as we trace it from the lowest to the highest divisions of the group. It usually consists of a double nervous chord, studded with ganglia at intervals; and the more alike the different segments, the more equal are these ganglia. The two filaments of the nervous chord are some-

times at a considerable distance one from the other, and their ganglia distinct; but more frequently they are in close apposition, and the ganglia appear single and common to both. That which may be regarded as the typical conformation of the nervous system of this group is seen in the ganglionic chord of *Scolopendra*, or in that of the larva of most insects, such as that of *Sphinx ligustri*. Here we see the nervous chord nearly uniform throughout, its two halves being separated however at the anterior portion of the body; the ganglia are disposed at tolerably regular intervals, are similar to each other in size (with the exception of the last, which is formed by the coalescence of two), and every one supplies its own segment, having little connection with any other. The two filaments of the chord diverge behind the head to inclose the œsophagus; above which we find a pair of ganglia that receive the nerves of the eyes and antennæ. We shall find that, in the higher classes, the inequality in the formation and office of the different segments, and the increased powers of special sensation, involve a considerable change in the nervous system, which is concentrated about the head and thorax. In the simplest Vermiform tribes, on the other hand, we lose all trace of separate ganglia, the nervous chord passing without evident enlargement from one extremity to the other. Whatever may be the degree of multiplication of the ganglia of the trunk, they seem but repetitions one of another; the functions of each segment being the same with those of the rest. The cephalic ganglia however are always larger and more important; they are connected with the organs of special sense; and they evidently possess a power of directing and controlling the movements of the entire body, whilst the power of each ganglion of the trunk is confined to its own segment. The longitudinal gangliated chord of *Articulata* occupies a position which seems at first sight altogether different from that of the nervous system of Vertebrated animals, being found in the neighbourhood of the ventral or inferior surface of their bodies, instead of lying just beneath their dorsal or upper surface. From the history of their development however, and from some other considerations, it has been suggested that the whole body of these animals may be considered as in an inverted position; the part in which the segmentation is first distinguished in insects being the real equivalent of the dorsal region in *Vertebrata*, and that over which the germinal membrane is the last to close in being homologous with the ventral region. This view applies also to the position of the 'dorsal vessel,' which would then be on the ventral side of the axis, as in *Vertebrata*. Regarded under this aspect, the longitudinal nervous tract of *Articulata* corresponds with the spinal chord of Vertebrated animals in position, as we shall find that it does in function.

When the structure of the chain of ganglia is more particularly inquired into, it is found to consist of two distinct tracts; one of which is composed of nerve-fibres only, and passes backwards from the cephalic ganglia over the surface of all the ganglia of the trunk, giving off branches to the nerves that proceed from them; whilst the other includes the ganglia themselves. Hence, as in the *Mollusca*, every part of the body has two sets of nervous connections; one with the cephalic ganglia; and the other with the ganglion of its own segment. Impressions made upon the afferent fibres, which proceed from any part of the body to the cephalic ganglia, become sensations when conveyed to the latter; whilst, in correspondence to these, the consensual impulses, operating through the cephalic ganglia, harmonise and direct the general movements of the body, by means of the efferent nerves proceeding from them. For the lower reflex operations, on the other hand, the ganglia of the ventral chord are sufficient; each one ministering to the actions of its own segment, and, to a certain extent also, to those of other segments. It has been ascertained by the careful dissections of Mr. Newport, to whom we owe all our most accurate knowledge of the structure of the nervous system in articulated animals, that of the fibres constituting the roots by which the nerves are implanted in the ganglia, some pass into the vesicular matter of the ganglion, and, after coming into relation with the vesicular substance, pass out again on the same side; whilst a second set, after traversing the vesicular matter, pass out by the trunks, proceeding from the opposite side of the same ganglion; whilst a third set run along the portion of the chord which connects the ganglia of different segments, and enter the nervous trunks that issue from them, at a distance of one or more ganglia above or below. Thus it appears, that an impression conveyed by an afferent fibre to any ganglion, may excite motion either in the muscles of the same side of its own segment, or in those of the opposite side, or in those of segments at a greater or less distance, according to the point at which the efferent fibres leave the chord. And as the function of these ganglia is altogether related to the locomotive actions of the segments, we may regard them as so many repetitions of the pedal ganglia of the *Mollusca*; their multiplication being in precise accordance with that of the instruments which they supply. [INSECTA; CRUSTACEA.]

Proceeding to the Vertebrated Series we find their Nervous System constitutes a far more important portion of the entire organism than it does in any Invertebrated animal; and that, in its most characteristic forms, it combines the locomotive centres of the *Articulata* with the sensorial centres of the *Mollusca*, possessing in addition two organs, the Cerebrum and Cerebellum, to which nothing distinctly analogous can be detected in any of the inferior classes. That which may be regarded as the fundamental portion of the nervous system in

Vertebrata is the Cranio-Spinal Axis, which consists of the medulla spinalis, or spinal chord, of its anterior prolongation, termed the medulla oblongata, and of the chain of sensory ganglia, which forms the superior continuation of the latter. The whole of this axis lies above the alimentary canal, and there is consequently no oesophageal ring, like that of Articulated and Molluscous animals; but the two lateral strands of the cranio-spinal axis still diverge from each other as they enter the cranium, so as to leave the space which is termed the fourth ventricle. This cavity communicates anteriorly with the third ventricle, which separates the lateral halves of the anterior portion of the sensorial apparatus; and posteriorly with the spinal canal, which intervenes between the two lateral halves of the spinal chord. This last however, like the space between the lateral halves of the ventral chord in the higher *Articulata*, is nearly obliterated in man and the *Mammalia*, although sufficiently distinguishable in Fishes. The spinal chord consists of a continuous tract of gray matter, inclosed within strands of longitudinal fibres; and it may thus be regarded as analogous to the ganglionic chain of the *Articulata*. Below the medulla oblongata its endowments appear nearly similar throughout, for all the nerves which proceed from it are distributed to the sensory surfaces and to the locomotive organs. In some *Vertebrata*, whose form resembles that of the *Articulata* (such as the eel and serpent), there is no difference in the size or distribution of the several pairs of nerves, as no extremities are developed; but in other cases, the size of the trunk, proceeding to the anterior and posterior extremities, is much greater than that of the nerves given off from the other segments of the chord; and the quantity of gray matter at their roots is correspondingly increased. In these trunks, both afferent and efferent fibres are bound up; but they separate at their roots, or junction with the spinal chord—the afferent being connected with the side of the chord nearest the surface of the back—and the motor with that next the viscera. Both these roots have two sets of connections; some of each enter the gray substance of the chord, in which they seem lost, whilst others are continuous with the fibrous portion of the chord, and are thus put in connection either with other segments or with the encephalic centres. In this respect, then, there is a precise correspondence between the spinal column of *Vertebrata* and the ventral chord of insects; and in the former, as in the latter, experiment indicates that each segment of the chord has a certain degree of independence, reflex actions being excitable through it, so long as the circle of afferent and motor nerves, and their ganglionic centre, are in an active and uninjured state, even though it be completely separated from all the rest. At the upper portion of the spinal chord however, there is a series of ganglionic enlargements, having several distinct functions. From the medulla oblongata proceed the chief nerves which are subservient to the respiratory actions, and also those concerned in mastication and deglutition; so that this may be regarded as combining the respiratory and the stomato-gastric ganglia. Above, or in front of this again, we find auditory, optic, and olfactory ganglia, corresponding to the various subdivisions of the cephalic ganglia in the *Invertebrata*; these receive trunks from their respective organs of sensation, and may probably be regarded as sensorial centres, or seats of consciousness for the impressions which they severally transmit. The cranio-spinal axis constitutes the whole nervous system of *Amphioxus*, in which there seems nothing that in the least resembles a cerebrum, or cerebellum; and among the cyclostome fishes generally, the condition of this apparatus is but little higher, save as regards the larger development of the sensory ganglia.

But in all higher *Vertebrata* we find superimposed (as it were) upon the sensory ganglia the bodies which are known as the Cerebral Hemispheres or Ganglia; whilst superimposed upon the medulla oblongata we find the Cerebellum. The former constitute the mass of the brain in the *Mammalia*; covering in and obscuring the sensory ganglia so completely, that the fundamental importance of these is by no means generally recognised. In fishes however the proportion between the two sets of centres is entirely reversed, the rudiments of the cerebral hemispheres being usually inferior in size to the optic ganglia alone. The intermediate classes present us with a succession of gradations from the one type to the other, as regards not merely the size of the cerebrum, but also its complexity of structure; and a very close relation may be seen between the degree of development which it exhibits and the degree of intelligence of the species. It is a point which is especially worthy of note, that no sensory nerves terminate directly in the cerebrum, nor do any motor nerves issue directly from it; and there seems a strong probability that there is not (as was formerly supposed) a direct continuity between any of the nerve-fibres distributed to the body and the medullary substance of the cerebrum. For whilst the nerves of special sense have their own ganglionic centres, it cannot be shown that the nervous fibres of general sense, which either enter the cranium as part of the cephalic nerves, or which pass up from the cranio-spinal axis, have any higher destination than the ganglionic masses termed thalami optici, which undoubtedly form part of the group of sensorial centres. So the motor fibres which pass forth from the cranium, either into the cephalic nerve-trunks, or into the motor columns of the spinal chord, cannot be certainly said to have an origin higher than the corpora striata; which, like the thalami, are most accurately to be regarded

as ganglionic centres, possessing considerable independence of the cerebrum, though formerly regarded as mere appendages to it. And we shall find strong physiological ground for the belief that the cerebrum has no communication with the external world otherwise than by the sensori-motor apparatus which ministers to the automatic actions; receiving through the sensory ganglia that consciousness of external objects and events, which is the spring of its intellectual or emotional operations; and communicating its voluntary determinations to the motor part of the same system, to be worked-out (so to speak) by it through the instrumentality of the muscles upon which it plays. The cerebellum, in like manner, presents a great difference in relative development in the several classes of *Vertebrata*; being in the lowest a mere thin lamina of nervous matter on the median line, only partially covering in the fourth ventricle; whilst in the highest it is a mass of considerable size, having two lateral lobes, or hemispheres, in addition to its central portion. It is connected with both the anterior and the posterior columns of the spinal chord; and experiment leads to the belief that its chief office is to combine the individual actions of different members into the complex and nicely-balanced movements required for progression of various kinds, and in man for the execution of the various operations which his intelligence prompts him to undertake. (Carpenter.)

The part of the nervous system of the *Vertebrata* which is subject to most alteration is the Brain. The chief differences in its form depend on the degree in which the hemispheres of the cerebrum and cerebellum are developed. In fishes these are usually smaller than the ganglia on the origin of the optic nerves; but ascending in the scale they become more and more predominant in size over the rest of the nervous centres, and appear to have a certain relation to the development of intelligence in the animal. In the highest animals and in man the lobes of the cerebrum and cerebellum are by far the largest of all the nervous organs; their surfaces are convoluted and furrowed, the quantity of the gray matter upon them augmented, and the complexity of their structure greatly increased. But as a special article is devoted to this subject [BRAIN], it need not be further considered here; for similar reasons we shall here treat of only the general phenomena and laws of the actions of the nerves as they are observed in man, and the cerebro-spinal system only in reference to the nerves of common sensation and motion; referring for the description of the special senses to the articles EYE, EAR, NOSE, and TONGUE, and for the peculiar influence of the nervous system in the most important organs, to the articles devoted to them. [HEART; STOMACH.]

The constant functions of the cerebro-spinal nerves are—to convey impressions made on the points in which they are distributed, to the brain, where they are perceived as sensations, or to the spinal chord, where they are perceived without sensation; and to convey the influence of the will from the brain, or some involuntary influence from it or the spinal chord, to the muscles by which some motion is to be performed. The influences that thus pass to and from the brain are conveyed through distinct nervous filaments, though the filaments subservient to each are generally inclosed in the same sheath, and appear to form a single and simple nerve. The filaments which convey impressions to the nervous centres are called sensitive, centripetal, or afferent; while those conveying impressions from the centres to the muscles are named motor, centrifugal, or efferent filaments.

The spinal chord, in which all the nerves of the trunk have their apparent origin, is composed of two lateral halves, symmetrical in form and size, and united together by a part of their inner surfaces at the median line. The outer portion of the chord is composed of white nervous matter, the inner of gray, an arrangement the reverse of that of the brain, in which the cortical substance is gray, and the medullary or central white. Each lateral half of the spinal chord is again obscurely divided by superficial furrows into an anterior and a posterior column, and a smaller middle portion between them. All the nerves by which sensitive impressions pass arise from the groove between the posterior and middle columns, and all those (with the exception of the spinal accessory nerve) by which the excitants to muscular motion are conveyed arise from the groove between the anterior and middle columns. They all arise by what are called roots, that is, by a number of fine nervous threads or narrow bands attached to the grooves, and passing for a short distance into the substance of the chord, which, as they proceed outwards, converge and unite into a single chord or nerve. There is an important distinction however between them: the roots of the posterior or sensitive nerves have a ganglion at their union just where they are leaving the vertebral canal, while those of the anterior or motor nerves unite without any ganglion into a single chord, which passes over but does not communicate with the ganglion on the posterior roots. Beyond this ganglion the anterior and posterior roots unite in a common sheath, in which their filaments, though they continue distinct, are indiscriminately mixed; and in this manner they proceed through the varied branchings of the sheath to nearly all parts of the body, conveying the power of perceiving impressions to all, and the power of motion to the muscles and probably a few other tissues.

Nearly the same mode of origin and distribution, and the same distinctness of office, are found in the nerves that have their centre in the brain, in which those of the fifth pair [BRAIN] are almost exactly analogous to the spinal nerves. But in the other cerebral nerves there

is less regularity of origin, the nerves of peculiar sensation having no muscular nerves corresponding to them, the seventh nerve, or portio dura, being exclusively motor, without any corresponding sensitive root, &c. Thus, of the nerves proceeding from the brain, some are in all their course sensitive only; others are (except for the occasional connection of some of their branches with branches of the fifth) entirely motor; others (part of those of the fifth) mixed, that is, containing in a common sheath both sensitive and motor filaments, like all the nerves derived from the spinal chord.

The following table will give the student an idea of the functions of the cerebral nerves:—

Nerves of Special Sense	} Olfactory. Optic. Auditory. Part of Glosso-Pharyngeal. Lingual branch of 5th.
Nerves of Common Sensation	
Nerves of Motion	} Greater portion of 5th, and part of Glosso-Pharyngeal.
Mixed Nerves	
	3rd, 4th, lesser division of 5th, 6th, Facial, and Hypoglossal.
	Pneumogastric and Accessory.

The conveyance of those impressions which produce common sensation is the property exclusively of those nervous filaments which arise from the posterior columns of the spinal chord and their continuations in the brain. To possess this power, their connection with the brain, either directly or through the medium of the spinal chord (which, in this view, may be regarded merely as a collection of a vast number of the nervous filaments which have their centre in the brain), must remain uninjured. Hence, when any sensitive nerve is cut through, all the parts to which its filaments are distributed beyond the place of division are rendered perfectly insensible. The nearer to the brain that the injury is inflicted, the more extensive is the destruction of sensibility. When the spinal chord is injured by fracture of the vertebrae, or by disease, or any other means, all the parts whose nerves come out from the portion below that which is destroyed, become insensible; they lose also all power of voluntary motion, but for the present we shall consider the sensitive filaments and their functions only. If the posterior roots of a nerve be divided, all the parts supplied by that nerve lose their sensibility; or if a nerve be divided in any part of its course, then all the parts supplied by branches given off between the point of division and the brain retain their sensibility, while those which are supplied by branches given off in the other part of the nerve mere distant from the brain are rendered insensible. These facts prove that the influence of an impression upon the distal or peripheral extremity of a nervous filament can only be conveyed to the brain so as to produce sensation through a continuity of nervous tissue, and only through the very filaments that are impressed; and that there is no such communication of adjacent filaments, that if one is injured, another can convey the impression made on it, as in the circulation, by the anastomosis or communication of the bloodvessels, when one is obliterated, the blood which should traverse it passes through another. The same facts evidently explain also many of the phenomena of partial paralysis.

If that part of a divided nerve which is still connected with the brain be stimulated, the same sensation is perceived as if the stimulus were applied to all the parts in which the branches that the nerve gives off below the division are distributed. This is shown in the sensation which every one must have felt on striking the inside of the elbow (the 'funny bone,' as it is commonly called); the tingling pain that the blow produces, and which appears to have its seat in the inner side of the fore arm and hand, and in the little and ring fingers, is owing to the filaments of the ulnar nerve (which passes behind the elbow) being distributed to those parts, and to the sensation being always referred to the peripheral termination of the filament, in whatever part of its course it is irritated. It is of course impossible to experiment upon a single nervous filament, but the accuracy with which the imagined seat of sensation produced by irritating a bundle of filaments accords with their distribution leaves no doubt of the fact just mentioned. The nearer to the brain that the stimulus is applied, the more extended is the sensation; hence in disease of the spinal chord, pain is often felt in all the parts supplied with nerves coming off from the chord below the diseased portion, and the pain of dividing a nerve is felt over all the parts to which its branches are distributed. The same circumstance gives rise to the apparently strange ideas which those who have lost a limb entertain that they still possess it, till by their sight or some other means they correct the erroneous impressions of their sense of touch. For example, the constant cry of a patient who has just lost his leg, while the stump is being dressed, is that his attendants are squeezing his knee, or cutting his foot, or injuring some other part of the limb, which he cannot believe has been cut off. The reason is, that when those filaments of the nerves in the stump which are destined for the knee are touched, the knee seems to be touched; when those which are going to the foot are injured, the foot appears to suffer. So deceptive are these sensations, that even years after the loss of a limb, or for the rest of their lives, persons occasionally endeavour to perform some act with the stump which they were accustomed to do with the part they have lost. From the same circumstance of the sameness of sensation, whatever be the part of a nervous filament to which the stimulus is applied, arises the well-known feeling of the foot having fallen asleep, when the sciatic nerve has been pressed upon, and the peculiar

character of the pain in many cases of *tic dolooureux*, in which the trunk of a nerve being diseased, the pain is referred to all the parts to which its filaments are distributed.

The laws deduced from these facts, and which are of great importance in the explanation of many diseases of the nervous system, are briefly these:—The impressions producing sensation always pass from the circumference of the distribution of the nerves to the centre; they are always centripetal, and their centre, the seat of sensation, is the brain. They can pass only through the tissue of the nervous filaments to which they have been applied, and whose connection with the brain must therefore be unimpaired. The sensation is the same on whatever part of the nervous filament the impression is first made, and it is always referred to the peripheral end of the filament.

If the connection of the nerve with the brain be broken, the same impression may pass along its filaments to the part where its continuity is destroyed, but it will produce no sensation; though when the spinal chord remains, its passage may be indicated by the phenomena of reflex motion, which will be presently considered. It is chiefly through the medium of the nerves of common sensation that we become acquainted with all that the contact of other palpable bodies teaches, as their form, size, hardness, heat, &c. For the perception of these properties we must suppose a peculiar condition of nervous matter; for although the laws under which impressions are conducted through all the sensitive nerves to the brain are the same, yet the nerves of peculiar sensation, as the optic [EYE] and the auditory [EAR] are no more capable of perceiving the impressions of contact of non-vibrating bodies, than the nerves of the limbs, &c., are of perceiving light and sound. If the retina be touched in an operation on the eye (as in the experiments which M. Magendie has often made in operating for cataract), the sensation produced is that of a brilliant flash of light; if the auditory nerve be electrified, the sensation is that of a sudden loud noise; but in neither case is pain produced, unless the nerves of common sensation, with which parts of the eye and ear are supplied, be irritated at the same time.

Our ideas of the form and size as well as of the hardness of bodies are dependent in some degree on another sense, which is peculiarly connected with the muscles [MUSCLE], and is called Muscular Sensibility. By it we know what degree and extent of muscular force we exert at any given time. Thus, if the hand grasps a ball, we estimate its size by the degree in which the fingers are extended to inclose its circumference, for the mere impression of its contact on the fingers would be the same whether the ball were large or small; we estimate its weight by the muscular exertion which we feel it necessary to make to prevent it from falling; and its hardness by the degree of exertion which is sufficient or insufficient to make an impression on its exterior. In like manner, if the body be larger than the hand can grasp, then (unless we can see it) we estimate its size by the distance through which the hand moves in passing over the whole surface, and its form by the differences of position in which, in thus passing over it, the hand is from time to time placed. It is only the smaller differences in the form of the surfaces of bodies, their smoothness and roughness, and other similar characters, that are estimated by the touch alone. Thus, when a sensitive part (as the hand) is placed or moved with a certain force on the surface of a body, we know that it is smooth if all the hand receives the same sensation, or rough if the sensation of contact is perceived at points distant from each other. In like manner, from the extent of surface touched, we form our ideas of the sharpness or obtuseness of bodies.

Perceptions of temperature are also the peculiar attributes of the nerves of common sensation, but they do not admit of our forming very accurate ideas of the heat of bodies, because our sensations depend rather on the rapidity with which heat is abstracted from or added to our bodies, than on the quantity which we lose or receive. Hence we feel marble, which conducts heat rapidly, as if it were much colder than a slowly-conducting carpet of the same temperature; and when the difference of temperature between the hand or any other part of the body and that which it touches is very great, we lose all power of judging, and cannot directly tell whether it is in contact with (for example) ice or boiling water. Peculiar states of the circulation in and around the nerves give rise to very different sensations of heat, as in fever or in shivering, in which, though the skin feels as if it were burning or freezing, the actual temperature of the surface does not in either case differ more than five or six degrees from that which is natural to it.

The acuteness of the common sensibility of parts probably depends, *ceteris paribus*, in the healthy state, on the closeness with which they are beset with the termination of sensitive nervous filaments. E. H. Weber ('Annot. Anatom. et Phys.') has suggested a mode of estimating the degrees of sensibility of different parts of the surface of the body by touching two adjacent points of it at the same instant, and observing at what distance from each other the two contacts can be discerned as two distinct impressions. This may be effected by putting small pieces of cork on the points of a pair of compasses, and pressing both at the same instant on the part to be examined; the angles which the legs of the compass form will thus measure the distances at which the two impressions are distinguished or are confounded into one. By this method of examination it is found that the tip of the tongue is the most sensible of all the surface of the body, being able to distinguish

two impressions when the distance between the points on which they are applied is not more than 1-20th of an inch, a result which might have been anticipated, from the accuracy with which the tongue perceives and estimates the characters of the smallest portions of foreign matter in the mouth, and from the great share which the sense of touch takes in what we confound in the general idea of taste. The balls of the fingers can distinguish double impressions from 1-12th to 1-4th of an inch apart; the palm at about half an inch, and other parts of the skin at various greater distances. Applied to the skin at the back of the neck, of the upper arm, the thigh, and some other parts, each double impression are confounded into one when the points touched are upwards of two inches asunder.

Numerous circumstances have the power of modifying or increasing the sensibility of parts, giving rise to varieties of agreeable and painful sensations. Most parts moreover have certain sensations peculiar to themselves; thus no other time than the skin is ever the seat of the sensations of tickling, or itching, or burning heat, &c.; the muscles alone feel fatigue; the pain of disease in different tissues is as varied as any other of its phenomena. Certain parts also are insensible to any but particular impressions; the tendons and other similar tissues may be cut or burnt, or in any way injured without exciting any sensation, unless they are pulled or twisted, or subjected to any other of those mechanical influences which it is their office in the animal economy to resist. Other parts again, as most of the internal organs, the bones and cartilages, are insensible during health, but in disease excite severe and peculiar pain. For all these differences however no explanation is yet known. It is known that certain nerves (the motor) never, under any circumstances, convey sensible impressions; that others (the nerves of the sympathetic system) are, if ever, only occasionally conductors of sensations; that others (the nerves of the peculiar senses) convey only the impressions of those agents for the reception of which certain organs are peculiarly adapted; and that others have the constant office of conveying impressions of contact, heat, &c.; but upon what differences of structure or arrangement these varieties of function depend no reasonable opinion can at present be formed.

Many of the phenomena illustrative of the mode of conduction of the nervous influence in the sensitive nerves are repeated in the motor filaments, with this difference, that while in the sensitive nerves impressions always proceed from the circumference to the centre, or from the termination of the nervous filament in any tissue, to its termination in the brain or spinal chord; in the motor nerves the impressions always pass in the opposite direction, that is, from the centre to the circumference, or from the brain or spinal chord to the muscle or other contractile tissue. When the motor filaments of a nerve are irritated in any part of its course, no pain is felt, but the muscles to which it is distributed contract; when a similar nerve is cut through (or otherwise prevented from conveying the nervous influence), all the muscles to which the filaments that pass off from it, beyond the injured portion, are distributed, lose the power of being acted upon by the will, and very soon of being excited by any stimulus, while those from between the injured part and the brain retain their power. If the end of that portion of a divided motor nerve which is still connected with the nervous centre be irritated, no perceptible effect follows; if the end of the other portion, which is now separated from the brain, be irritated, the muscles to which its filaments proceed will for a time continue to contract. The same observations on the necessity of a continuity of nervous substance, on the absence of any communication between adjacent filaments, by which one might assume the office of another, and on the sameness of effect, whatever part of a nervous filament is irritated, may be made of the motor as of the sensitive filaments. As in by far the greater number of nerves, sensitive and motor filaments are contained within the same sheath, the phenomena, which have been described separately, will, in the case of laceration or other affection of such nerves, be combined. Thus when the nerve of any limb is irritated, sudden pain is felt and coincident convulsions ensue; when a similar nerve is divided, the limb becomes both senseless and motionless; if the upper part of the divided nerve (that still connected with the brain) be irritated, pain is felt, but no motion is excited; if the lower part be irritated, convulsions of the limb take place, but no pain is felt.

Of the nature of the influence which, passing along the nerves, excites motion, and of the manner in which it is set in motion, nothing whatever is known. Through some nerves it can be transmitted at will, and the muscles supplied with these are therefore called voluntary; through others the will has no influence in sending the excitant to motion, and the involuntary muscles to which they pass are entirely removed from any connection with the mind, except in the excitement of violent passion or grief, or other exalted mental affection. Whatever stimulus is applied to the motor nerves, the same effect is produced; whether it be the stimulus of the will, or of any mechanical, chemical, or electrical application, the same muscular contraction, varying only in degree, is produced. The mind alone has the power of determining the strength and extent of muscular contraction, and this it effects by an operation which it scarcely appreciates; for even one who knows accurately the position and the mode of action of each muscle cannot, except in certain cases, order the act of a single muscle, but to produce a certain kind or strength of motion

is obliged to exert coincidentally all the muscles that can minister to that motion. Thus there are two muscles, at least, that bend the fore arm, and no person can make one of them act while the other remains inactive; the will can only determine certain effects, but it cannot determine the muscles by which they shall be accomplished.

In all the phenomena hitherto considered, the mind takes a part; but in some circumstances an impression passes along a sensitive nerve to the nervous centre, and although no sensation may have been produced, an influence is in return conveyed back from the centre through a motor nerve, and motion is produced, either in the muscles adjacent to the part first impressed, or in those of some other part of the body. The phenomena of this class are those of what is called the Reflex Function; a term which is derived from the idea that the impression, passing centripetally, is reflected from the centre as soon as it arrives there, and made to pass from it centrifugally.

For the occurrence of these reflex actions, it is essential that the nerves acted upon should retain their connection with the spinal chord or with the brain. The spinal chord is sufficient for some of these actions, and the power is therefore often spoken of as if it belonged exclusively to it; but it is evidently possessed by the whole cerebro-spinal axis. Thus, if the hind leg of a reptile or any other animal be separated from the body, and the skin of any part of it be irritated, no motion of its muscles will ensue; but if the leg be allowed to retain its connection with that part of the spinal chord from which its nerves come out, the same irritation of the skin will produce convulsive contractions of the muscles. In the first case the impression on the skin, if it passed along the sensitive nervous filaments at all, was lost at their cut extremity; in the second, it passed through them to the spinal chord, and thence either it or some other influence returned immediately through the motor nerves to the muscles.

On this property of reflecting the impressions received from sensitive to motor nerves, many of the muscular motions which were formerly regarded as instinctive or sympathetic, and many others of the most important phenomena, depend. Thus when light falls on the retina, the impression received by the brain is instantly reflected through the third nerve, and the iris, without any effort of the will, contracts; and if the light be very strong and sudden, the eyelids involuntarily wince, as they do before any expected injury. In like manner a stimulus applied to the nose excites involuntary sneezing, food, or any other substance in the fauces or pharynx, excites the involuntary act of swallowing, and still more an irritation of the larynx is reflected from the medulla oblongata, and excites in all the respiratory muscles involuntary coughing. In all these cases sensation coexists with the reflection of the impression through the motor nerves; but sensation is by no means essential to the phenomena; on the contrary, in the most marked examples the centripetal impression is not perceived by the brain. Thus the sphincter muscles are constantly maintained in a state of contraction under the influence which passes unfelt from the spinal chord; and all the motions occurring in decapitated animals (in which the reflex actions are more remarkable than under any other circumstances) must probably be regarded as unaccompanied by sensation, since exactly similar phenomena occur in persons suffering from some forms of paralysis, and who can never feel the impression on the skin upon which the involuntary motions instantly follow. In the case of reflection from the optic nerve to the nerves of the iris, and in most of those in which the sensitive nerves pass directly to the brain, sensation is produced with the reflex action; but in all the cases where the centripetal nerves pass to the spinal chord, the reflex actions take place as well, or even more certainly, after the removal of the brain. The spinal chord is essential for a reflex action in the nerves that pass out from it; the brain for a similar action in its own nerves: in the first case sensation is not involved, in the second it generally is.

Mr. Grainger ('Observations on the Spinal Chord') believes that the impressions which produce reflex actions, and those which pass to and from the brain in sensation and voluntary motion, are not conveyed by the same sets of nervous fibres. He considers that there meet in the spinal chord four sets of nervous filaments: one passing only to the exterior white matter, and then ascending to the brain, to which they convey sensations; a second, corresponding to these, which pass from the brain along the exterior white matter of the chord, and thence to the muscles, for the conveyance of the influence of the will to them. These two sets are the same as the commonly described sensitive and motor filaments; the others are analogous to these, but are supposed to be subservient only to the reflex actions; they pass to and from the chord with the others, but instead of being continued up with them to the brain along the exterior of the chord, penetrate into its substance, and lose themselves in its central gray matter—the recipient and reflector of the impressions which they convey. The observations of the course of the filaments of the nerves, where they pass into the spinal chord, upon which this very ingenious view is founded, have not yet been sufficiently confirmed to establish its truth beyond doubt; but it still affords the most intelligible explanation of the manner in which impressions, passing apparently through the same filaments, in some cases produce sensation, and in others none; and in which, for certain purposes, organs supplied with nerves from the cerebro-spinal axis are yet usually removed from the influence of the brain.

It deserves particular remark, that in the cases in which the impression is conveyed only to the spinal chord, as in beheaded animals, the motions that result from this reflected influence evince design. They are in fact instinctive. Thus, when a bird's or any other lower animal's (as a frog's) head is cut off, the body endeavours to escape, and evinces method in its attempts; if a limb is touched, it is drawn away from the contact; if a part of the body is irritated, the foot will sometimes be raised in an endeavour to remove the source of irritation. These actions are similar to those of monsters born without brains, many of which have been known to cry, to take milk, and perform many other instinctive acts. From such facts as these it is inferred that the brainless animals perform all their functions unconsciously. We can however draw a distinction between the functions performed under the influence of the action of the nerves of special sense (the sensory ganglia) and those performed by the ganglia supplying the stomach, heart, lungs, and other organs.

Of the nature of the agent which, passing along the nervous filaments, produces sensation or excites motion, nothing satisfactory is at present known. The imperceptible velocity of its passage naturally suggested this idea of an electric current, and except by the supposition of the motion, or the vibration of the particles of some such subtle material as electricity or the other imponderable agents are conceived to be, its velocity is scarcely to be accounted for. Some idea may be formed of its rapidity of passage along the nerves to and from the brain, by a rough calculation which the writer lately made, that when a person plays rapidly on the piano, upwards of 1000 distinct movements are performed within the minute; each of which has its time, place, and strength exactly ordered. At the same time that the mind imparts this number of impressions to the muscles, it is receiving not less than 2000 impressions by each of three distinct senses, the eye, the ear, and the touch, and perceives the most minute variations with each. From the similarity of this velocity of the nervous agent, to that of the passage of electricity, and from a few apparent analogies, some have imagined this nervous agent, or fluid, to be identical with the electric; but the grounds for such an opinion are at present few and uncertain, while many evident facts militate strongly against it, as the equal conducting power of all the moist tissues as well as the nervous; the improbability that electric fluid should be isolated in the filaments, the inconstancy of the results of experiments in which a current of electricity is used to replace a removed portion of a nerve, &c.

The more probable theory is that the nervous force is correlative with the forces engaged in the nutrition of the body. We find light and heat necessary to the production of the materials from which the nervous system is formed. These are correlative with the chemical forces brought into action in forming the compounds of our food, as sugar, starch, and protein. The sugar and starch, on the dissolution of their physical conditions in contact with oxygen, yield heat to the body; and it is quite as probable that protein, under the same circumstances, should exhibit muscular and nervous force. At any rate this theory is rendered very probable by a large and increasing number of facts. In animals capable of developing electricity it is clearly correlative with the nervous force. [ELECTRICITY IN ORGANIC BEINGS.]

The nervous force appears to be generated in the brain, spinal chord, and in all parts where there is ganglionic or gray nervous matter, and from these centres distributed to the nerves. Thus, if the trunk of a mixed nerve be divided, that part which is separated from the nervous centre soon loses that which may be called its stock of excitability, while that which remains attached to this centre retains its excitability as if no injury had been inflicted. For the maintenance of the excitability on which the reflex actions depend, the spinal chord alone seems to be necessary; for it is not more rapidly expended after the removal of the brain than when the brain is present. For the maintenance of this excitability for other actions the brain is essential.

Each impression made on the sensitive nerves, and each excitant to motion, may be considered to cause a certain consumption of the nervous influence, which it is the office of the nervous centres to replace; and a healthy condition of the nervous system may reasonably be conceived to depend on a due proportion between the waste and the supply. When the former has been excessive, weakness or fatigue of the senses, or of the power of muscular motion, is produced, which a period of sleep or rest from excitement is necessary to replace. The necessity of such rest is indicated to us by the fatigue at the close of each day, and cannot long be safely resisted; for after the loss of the night's rest, the excitant necessary to produce a certain effect is found to become greater in a rapidly increasing ratio through every hour of the succeeding day. During rest the brain may be considered as producing the excitability by which the nerves may act during the period of exertion; and hence exertion is not less necessary for health than rest; and many disorders show that excitability may, for want of being wasted by exertion, accumulate. Hence much of that which passes under the popular name of nervousness—a condition in which a given excitant produces a greater effect than is natural or healthy; and this (although the use of terms usually applied to material things may give too definite an idea of it) we may reasonably believe to result from an accumulation of nervous influence, as fatigue, or the need of a greater excitement to produce a certain effect, results

from its waste. The influence of exercise of the nerves follows the same rule as that of exercise of the muscles or any other tissue; by it, within certain limits, the power of perceiving impressions and of exciting motion is progressively increased; the excitability of each organ or of the whole system being, within those limits, capable of adaptation to the need of the individual; hence the power by practice of attaining to perfection of touch, or of hearing, or sight, or any other sense. Impressions are distinctly felt by the practised sense which are completely imperceptible to that which has been only casually employed. In like manner, when the organ of one sense is destroyed, and thus one outlet for excitability is closed, the rest acquire increased acuteness; hence the accuracy of the hearing and touch in the blind, of the sight in the deaf, &c.

The study of the functions of the spinal chord in health is especially important in relation to the numerous diseased actions of the nervous system. In the previous remarks we have seen that the spinal chord is the seat of an important series of reflex functions. It must not however be supposed that the spinal chord alone is the seat of reflex functions, the masses of nervous matter which lie at the base of the brain, the medulla oblongata, and the nervous centres giving origin to the nerves of special sense, and the brain itself, are all seats of special reflex functions. These reflex actions more especially presided over by the spinal chord in man, appear to be the expulsive movements of the organs of organic life and the muscular movements of the posterior extremities. These expulsive movements alluded to, and which can be performed independent of any action of the brain or will, as defecation, urination, parturition, and other functions connected with the reproductive processes. These functions are performed in diseased conditions such as apoplexy, and in the anæsthetic state produced by chloroform, or ether, without the consciousness of the individual. So also the movements of the posterior extremities occur as the result of stimulation when the individual is entirely unconscious. Amongst the lower animals muscular movements are manifested in the *Invertebrata* after the removal of the cephalic ganglia, and in the *Vertebrata* after the destruction of the brain. Thus frogs will leap when irritated after their brains are removed, and birds are known to fly after their heads have been cut off. From these facts we may infer that the muscular movements in man, of the lower extremities especially, may be the result of the reflex action of nerves proceeding from the spinal chord, and supplying these parts. It is very certain that the movements of the body are continued in walking whilst the mind is entirely abstracted.

In morbid conditions of this nervous system, the functions of the spinal chord are frequently deranged. In many diseases convulsions occur, which are the result of the derangement of the spinal chord and its nerves. [CONVULSIONS, in ARTS AND SC. DIV.] Convulsive diseases may arise from three causes: 1, from irritation of the excitator nerves; 2, from deranged or morbid conditions of the spinal chord or medulla oblongata; or 3, from a combination of these two. Such conditions of the nervous system are seen in the convulsions of hydrophobia, tetanus, epilepsy, and hysteria. When these diseases destroy life, it is usually by suspending the respiratory movements, the muscles effecting which being fixed by the spasms prevent the ingress and egress of air to and from the lungs.

The Medulla Oblongata [BRAIN] is distinct from the spinal chord and the brain, although it has an intimate relation with both. From this relationship arises one of its special functions, which appears to be, to bring the parts of the nervous system above and below it into intimate connection. It also serves as a centre for the reflex operations of the nerves which issue from it. These reflex actions are connected with the most important functions in the life of animals—Deglutition and Respiration. This explains the fact that the activity of almost every other portion of the nervous system may be suspended, and yet life continue, but should the functions of the medulla oblongata cease, death ensues.

"The chief excitator nerve of the Respiratory Movements, is the afferent portion of the par vagum; but the afferent portion of the fifth pair is also a powerful excitator; and the afferent portions of all the spinal nerves, conveying impressions from the general surface of the body, are also capable of contributing to the excitement necessary for the production of the movement. The chief motor nerves are the phrenic and intercostals, which, though issuing from the chord at a considerable space lower down, probably originate in the medulla oblongata. The motor portions of several other spinal nerves are also partly concerned, as are also the facial nerve, the motor portion of the par vagum, and the spinal accessory. The ordinary movements of respiration involve little action of any motor nerves but the phrenic and intercostal; and it is only when an excess of the stimulus (produced for example by too long a suspension of the aërating process) excites extraordinary movements, that the nerves last enumerated are called into action.

"The acts of prehension of food with the lips, and of mastication, though usually effected by voluntary power in the adult, seem to be capable of taking place as a part of the reflex operation of the medulla oblongata in the infant, as in the lower animals. This is particularly evident in the prehension of the nipple by the lips of the infant, and the act of suction which the contact of that body (or of any resembling it) seems to excite. The experiments provided for us by nature, in

the production of a *microcephalus monstrosities*, fully prove that the integrity of the nervous connection of the lips and respiratory organs with the medulla oblongata, is alone sufficient for the performance of this action; and experiments upon young animals from which the brain has been removed establish the same fact. Thus Mr. Grainger found that upon introducing his finger moistened with milk, or with sugar and water, between the lips of a puppy thus mutilated, the act of suction was excited, and not merely the act of suction itself, but other movements having a relation to it: for as the puppy lay on its side sucking the finger it pushed out its feet in the same manner as young pigs exert theirs in compressing the sow's dug. This action seems akin to many of those by which the lower animals take in their food; and we may thus recognise in the medulla oblongata a distinct centre of reflex action for the reception and deglutition of aliment, analogous to the stomato-gastric ganglia of invertebrate animals. In the movements of deglutition, which as formerly explained are purely reflex, this chief excitor is undoubtedly the adherent portion of the glosso-pharyngeal nerve. It is found that, if the trunk of this nerve or its pharyngeal (but not its lingual) branches be pinched, pricked, or otherwise irritated, whilst still in connection with the medulla oblongata, the movements concerned in the act of swallowing are excited. The same occurs if when the trunk of the glosso-pharyngeal has been divided, the cut extremity in connection with the medulla oblongata is irritated; but little or no muscular contraction is produced by irritation of the separated extremity, whence it is apparent that the glosso-pharyngeal has little or no direct motor power, but acts as an excitor. In this it appears to be assisted by the branches of the fifth pair distributed upon the fauces; and probably also by the branches of the superior laryngeal distributed upon the pharynx. The motor influence, which is generated in response to the stimulus thus conveyed, appears to act chiefly through the branches of the par vagum, which are distributed to most of the muscles concerned in swallowing; but the facial, the hypoglossal, the motor portion of the fifth, and perhaps also the motor portion of some of the cervical nerves, are also concerned in the movement, and may effect it, though with difficulty, after the pharyngeal branches of the par vagum have been divided.

"In the propulsion of the food down the oesophagus, to which the glosso-pharyngeal nerve does not extend, the muscular contraction, so far as it is of a reflex nature, must depend upon the oesophageal branches of the par vagum alone; their afferent portion being the excitor, and their motor portion giving the requisite stimulus to the muscles. The same must be the case in regard to the muscular contractions of the cardiac and pyloric sphincters, and of the walls of the stomach, so far as regards their dependence upon the nervous system at all; but the degree of this is doubtful. It is also through the reflex actions of the medulla oblongata that the aperture of the glottis is regulated (LARYNX; VOICE), and the regulation of the aperture of the iris in the eye is effected." [EYE.]

That part of the brain which gives origin to the olfactory, optic, and auditory nerves, is seen in the lower animals, especially in fishes, to consist of separate and independent ganglia. In the human brain they are not so distinct, but at the base of the brain two ganglionic masses are observed which are called the corpora striata and thalami optici. [BASIS.] The fibres forming these two masses may be readily separated, for we find that, whilst the fibres passing to the corpora striata give rise to none but motor nerves, those that pass to the thalami afford origin to sensory nerves.

The functions of this group of ganglia may be partly inferred from the results of experiments, and these have been chiefly made upon the optic ganglia, or corpora quadrigemina. The partial loss of the ganglion produces temporary blindness in the eye of the opposite side, and partial loss of muscular power on the opposite side of the body; and the removal of a larger portion, or the complete extirpation of it, occasions permanent blindness or immobility of the pupils, and temporary muscular weakness on the opposite side.

"This temporary disorder of the muscular system sometimes manifests itself in a tendency to move on the axis, as if the animal were giddy; and sometimes in irregular convulsive movements. Here then we have proof of the necessity of the integrity of this ganglionic centre for the possession of the sense of vision; and we have further proof that the ganglion is connected with the muscular apparatus by motor nerves issuing from it. The reason why the eye of the opposite side is affected, is to be found in the decussation of the optic nerves. The influence of the operation on the muscles of the opposite side of the body is at once understood from the fact of the decussation of the motor fibres in the anterior pyramids.

"Thus we see that the optic ganglia receive the impressions from the eyes by the optic nerves, convert them as it were into sensations, and also transmit motor impulses to the muscular system, in response to these sensations. Thus they have much analogy to the cephalic ganglia of the lower animals, the greater part of whose purpose seems to be to guide the actions of the beings to which they belong through the sensations which they receive. But with a function which is probably the same, there is this important difference, as to the purpose served by these parts, in the cephalon of man, and of the animals that approach nearest to him, in the conformation of his nervous centres.

"The consensual or instinctive movements which make up nearly the whole of those actions in the *Invertebrata* that are not simply reflex, constitute a comparatively smaller proportion of the actions of the higher *Vertebrata*; these being guided in a much greater degree by intelligence, which reasons upon the sensations, and devises means to gratify the desires created by them. Consequently there is reason to think that the direct action of the sensory ganglia upon the muscles is comparatively seldom exercised in the active condition of the cerebrum.

"There are certain actions however which would seem to take place regularly through this channel. Thus the consensual movements of the eyes, which concur to direct their axis towards the same object, appear to depend upon the impressions made upon the retina, for we do not see these movements taking place with nearly the same exactness in the eyes of persons who have been born totally blind; and in these who have completely lost their sight after having enjoyed the power of vision, we may also perceive that although the two eyes move concertedly from habit, yet that their axes are parallel instead of convergent, so that they do not seem to look at any object but beyond it into vacancy.

"The existence of a Sensation of some kind, in connection with a Muscular exertion, seems essential to the continuance of the latter. Our ordinary movements are guided by what is termed the muscular sense, that is, by a feeling of the condition of the muscle that comes to us through its own sensory nerves. How necessary this is to the exercise of muscular power may be best judged of from cases in which it has been lost. Thus a woman who had suffered complete loss of sensation in one arm, but who retained its motor power, found that she could not support her infant upon it, without constantly looking at it; and that if she were to remove her eyes for a moment the child would fall, in spite of her knowledge that her infant was resting on her arm, and of her desire to sustain it. Here, the muscular sense being entirely deficient, the sense of vision supplied what was deficient so long as it was exercised upon the object, but as soon as this guiding influence was withdrawn, the strongest will could not sustain the muscular action. Again, in the production of vocal sounds, the nice adjustment of the vocal larynx, which is requisite to produce determinate tones, can only be effected in obedience to a mental conception of the tone to be uttered; and this conception cannot be formed unless the sense of hearing has brought similar tones to the mind. Hence it is, that persons who are born deaf are also dumb. They may have no malformation of the organs of speech, but they are incapable of uttering distinct vocal sounds or musical tones because they have not the guiding conception, or recalled sensation of the nature of these. By long training, and by efforts directed by the muscular sense of the larynx itself, some persons thus circumstanced have acquired the power of speech; but the want of sufficiently definite control over the vocal muscles is always very evident in the use of the organ.

"Various other facts might be adduced to show that in man certain movements are as intimately connected with the excitement of sensations in the sensory ganglia as others are with the production of impressions in the ganglia of reflex actions. And it may be further questioned, in the absence of any precise knowledge upon the subject, whether the emotions, when so strongly excited as to act involuntarily on the body, do not operate through this group of ganglia and the fibres proceeding from them.

"There are many analogies between the purely emotional actions of man and the instinctive movements of the lower animals, each following closely upon sensations, without any exercise of the reasoning faculty, and each being performed not merely without the mandate of the will, but often in direct opposition to it. That the emotions, when they thus affect the body, do not operate through the same set of nervous fibres as those which convey the influence of the will, seems proved by this fact—that cases have occurred in which muscles have been paralysed by the will, whilst they remain obedient to the emotions; and vice versa. Thus, in one instance the muscles of one side of the face were palsied in such a manner that the individual could not voluntarily shut his eye nor draw his mouth towards that side, yet when any ludicrous circumstance caused him to laugh, their usual play was manifested in the expression of his countenance; and in another case the muscles were in obedience to the will, but when the individual laughed or cried, under the influence of an emotion, it was only on one side of the face. To these may be added another case in which the right arm was completely palsied, so that the individual had not the least voluntary power over it; yet it was violently agitated whenever he met a friend whom he desired to greet. These and similar cases afford sufficient proof that the direct influence of the emotions on the muscular system operates through a channel distinct from that which conveys the influence of the will; and when we consider how closely the emotions are connected with the sensations which excite them, and their close analogy with the instincts of the lower animals, there seems a strong presumption in favour of the idea that the motor nerves proceeding from the sensory ganglia constitute their peculiar instrument of operation on the body.

"A very characteristic example of the immediate dependence of the action of this class upon sensations, is afforded by the peculiar movements which are excited by the act of tickling."

No one can question the completely involuntary nature of these movements; on the other hand, they are not reflex, for they do not take place unless the irritation is felt.

Now the tickling may produce not merely a variety of semi-convulsive movements, tending to withdraw the body from the source of irritation, but also a tendency to laughter, and an emotional state connected with it. But it would appear that the semi-convulsive movements are immediately excited not by the emotion but by the sensation; for there is a great variation amongst different individuals as to the results of the irritation, the action of laughter being excited in some, without any other effect; whilst in others, spasmodic movements of the extremities take place without any tendency to laughter, indeed with a feeling of extreme distress.

In many Diseases the influence of emotional states are remarkable. In Hydrophobia and Hysteria convulsions are frequently brought on by causes that excite emotional states. In hydrophobia the sight or sound of moving water will sometimes produce frightful paroxysms, whilst in hysteria the sight of one individual labouring under an attack will produce it in another. Many of the phenomena presented by persons in the mesmeric state may be also traced to an excessive activity of the consensual or emotional system, so that slight impressions produce powerful effects. If it is also recollected that such individuals have frequently a morbid desire of gratifying the wishes of those who witness them in the expectation of seeing marvels, a further explanation is afforded of the singular phenomena presented by persons in this state.

The functions of the Cerebellum [BRAIN] have been the subject of much discussion. According to the system of phrenologists [PHRENOLOGY], this organ is the seat of the sexual instinct. This doctrine derives little or no support from comparative anatomy, as there is no correspondence between the size of this organ and the strength of this instinct among the lower animals. Nor does it appear to be always the case that there is a derangement of the sexual instinct where there is disease of this organ. The more probable view of the functions of the cerebellum seems to be that it is in some way connected with the functions of locomotion. Its development in the lower animals corresponds with the variety and energy of the muscular movements, whilst injury to this organ is invariably attended with derangements in the functions of locomotion. From experiments upon all classes of vertebrate animals it has been found that when the cerebellum is removed, the power of walking, flying, standing, or maintaining the equilibrium of the body is destroyed. It does not seem that the animal has in any degree lost the voluntary power over its individual muscles, but it cannot combine their actions for any general movements of the body. Again, it is found that when the cerebellum is diseased, the motor function of the muscles is not destroyed, but that the same want of combining or harmonising the movements of the body result as are observed when the cerebellum is injured.

From what has been previously said, it will be seen that the cerebral lobes, although so important in man and the higher animals, are, after all, not the fundamental portions of the nervous system. They are the last-formed portions of the nervous system, and all the functions of animal life can be carried on without them. But whilst this is the case there is no doubt that the cerebral hemispheres are the seat of all those phenomena which we call intelligence, and which distinguish so greatly man from the lower animals. The substitute for intelligence in the lower animals is what we call instinct. The distinction between actions resulting from the operation of these two principles are very evident. In intelligence there is an intentional and known end produced, as the result of definite ideas; whilst in instinctive actions there are no preceding ideas and no knowledge of the end to be attained. Such actions are purely automatic. Because instinctive actions evince design, it is no proof that the animal exhibiting them is aware of the design. In fact, the great mass of instinctive actions are so perfect, that none of the results of intelligence can equal them. The bee builds its cells with imitable certainty; the *Chalcidodon rostratus* projects from its prolonged snout a drop of water, which strikes the insects that are flying above its head, and thus secures them as its prey. The great majority of the actions of the lower animals are purely instinctive and automatic; and many even of those which possess cerebral lobes lead rather an instinctive than an intelligent life. So even with man, many of the actions of his life are instinctive, especially those which are performed during infancy.

That the cerebral lobes are the seat of Intelligence, seems to be proved in various ways. When they are destroyed the animal or human being is no longer capable of exhibiting the functions of intelligence. At the same time this is not the case when one lobe of the brain only is destroyed, for when this is the case from disease or accident, persons have been known to perform all the ordinary acts of intelligence. This has led to the conclusion that just as all the functions of seeing or hearing can be performed by one eye or one ear, so all the functions of the mind may be performed by one lobe of the brain. The arguments in favour of this view have been well developed by Dr. Wigan in his work on the 'Duality of the Mind.'

In cases of children who are born with a deficiency of the cerebral lobes, we find a deficiency of intellectual activity. In the case of many idiots there is simply a want of size of brain. This is remarkably exemplified in the case of the two Aztec children recently exhibited

in London, whose brains are exceedingly small, and whose want of intelligence corresponds with this deficient development of their brains. It is thus that we find there is some truth in the phrenological axiom [PHRENOLOGY] that the size of the brain is the measure of its power. But this is only true in respect of the gray matter, as there can be little doubt that the vesicular or gray matter of the cerebral lobes is the seat of intelligence. In regard to the human brain it holds good as far as the operations of the understanding are concerned, and persons with large heads are remarkable for the influence they exercise over the judgments and acts of others. In the case however of those intellectual operations which we call Genius, and which seem to take their rise in the feelings and to address the feelings, it is not found that there is any relation between the size of the cerebral lobes and its manifestations, persons manifesting considerable genius possessing but small brains.

It appears to be perfectly true that varieties of mental character accompany varieties in the form of the brain, and that the manifestations of intelligence vary according to the temperament of various individuals.

All the operations of the mind are dependent upon sensations. Without sensation there is no development of intelligence. A blind man has no idea of colour; he has had no impression of colour produced upon his eye, and consequently no idea formed in his mind. The seat of Sensorial Consciousness, as we have seen, is evidently the sensorial ganglia; but in animals without cerebral lobes there can be no impressions produced, such as we call sensations; these are in fact ideas or impressions produced upon the cerebral lobes by the transmission of the impressions upon the sensory ganglia upwards. Thus we find the sensory ganglia producing reflex automatic movements by acting on the spinal chord below, and becoming the source of ideas to the cerebral lobes above. Dr. Carpenter, to whom physiologists are deeply indebted for the masterly manner in which he has investigated the whole of this subject, goes farther than this, and states his opinion that the sensory ganglia constitute the seat of consciousness, "not merely for impressions on the organs of sense, but also for changes on the cortical substance of the cerebrum; so that until the latter have reacted downwards upon the sensorium we have no consciousness either of the formation of ideas or of any intellectual process of which these may be the subjects."

Although it follows from this that animals without cerebral lobes have no ideas, we may suppose that the conditions of their consciousness would produce the feelings of pleasure and pain; and just as these feelings are produced by external impressions, so do ideas of pleasure and pain produce emotional states of the mind, which determine the character of our thought and influence our conduct. The various sentiments and propensities dwelt on by mental philosophers [PHRENOLOGY] seem to take origin in this way,—the activity of the sentiment of Benevolence or Malevolence having for its excitement the idea of an object to be loved or hated, and so on with the other sentiments, and what are called the propensities. "The same view may be applied to the love of Truth, of Beauty, of Sublimity, of Goodness, of Order, of Possessions, of Country, &c., and also to Cheerfulness, Wit, Humour, &c., and to many conditions usually considered as purely intellectual. And in fact the association of sensorial pleasure with any idea or class of ideas gives it an emotional character; so that emotional states are not by any means limited within the categories which most psychologists have attempted to lay down; these being for the most part generic terms, which comprehend certain groups of ideas bearing more or less similarity to each other, but not by any means including all possible combinations."

We have seen how the movements of the body may be influenced by impressions made upon the sensory ganglia, and we can now see how it is that ideas may become the source of movements. In persons who are 'ticklish' it is not necessary to tickle them to make them laugh, but the mere idea of tickling produced by pointing the finger will set them off. Thus throughout the whole series of emotional ideas they may be recalled without sensations so as to produce movements. Such movements may or may not be under the control of the will. That they are not always so, that there is frequently an antagonism between the emotions and the will, Dr. Carpenter regards as evidence that the seat of the emotions is different from that of the will. It also sometimes happens that muscles paralysed to volitional will act under the influence of emotional impulses, and vice versa. This subject is fraught with lessons of practical value. In the education of the human being it becomes of the utmost importance so to cultivate the will that it may control those tendencies to impulsive action which are the result of the various emotional states. Excessive indulgence in particular feelings constantly lead to those conditions of insanity which are known by the name of Monomania. [INSANITY, in ARTS AND SC. DIV.] In certain forms of hysteria, and in habitual stammering we have also instances of the loss of control of the will over muscular actions, brought on by emotional states.

The result of the activity of the cerebral lobes in the way we have pointed out, is to produce what are called the Intellectual Powers. To these we can only briefly refer. Thus the first in order of these is called the Association of Ideas, which consists in the production of such a connection between two or more ideas, that the consciousness of the one tends to bring the other before the mind—one idea, or set

of ideas, tending to the production of other ideas. This is called *Suggestion*. The activity of this power lies at the foundation of the intellectual qualities of man. It is owing to this association of ideas that he is enabled to trace the relation of cause and effect. It is through this same power of associating ideas that he is enabled to separate those things which differ, and to combine those things which are alike; and thus to Classify, and also to arrive at general facts, from the investigation of special ones. It is also by means of this power that he is enabled to put his ideas into new forms, and to produce those results which are called *Imagination*.

When the consciousness is specially directed to the changes going on in the sensorium, whether these are produced by objects from without, or by the operation of the brain itself, the act is called *Attention*. This condition may be either produced by an effort of the will, or it may occur as the result of the irresistible attraction of the object or train of thought going on in the cerebrum. Memory occurs when past states of consciousness are reproduced by the association of ideas. From what we know of the exercise of this faculty, it would appear that every sensory impression is registered in the cerebral organisation, whether individuals are conscious of it or not. Thus persons will entirely forget for days and weeks, or even longer periods, facts which are nevertheless duly registered in their minds. An extraordinary case of this kind is related, in which a poor woman, during the delirium of fever, was discovered to be repeating passages from the Psalms in Hebrew. When she recovered she was quite unconscious of any knowledge of Hebrew, but in the early part of her life she had lived in the family of a clergyman who was in the habit of repeating frequently in her hearing parts of the Psalms in Hebrew. In this instance the woman must have acquired her knowledge unconsciously. Memory is either voluntary, when it is called *Recollection*, or it is automatic, reproducing ideas without the direct interference of the will.

When we attend to our own mental operations a very different class of ideas is called up from those which are produced by external objects. This class of ideas is entirely dependent on the intellectual powers, and they have no relation to sensations, but are the original source of all our knowledge. To this class of ideas we may refer the Beliefs in our own present existence, in our past existence, and in our personal identity; the Belief in the external and independent existence of the causes of our sensations, the Belief in an efficient cause for all things around us, the Belief in the stability of the order of nature, and in our own free will. Amongst those elementary modes of thought which arise from the constitution of our minds we must rank the ideas of Truth, Beauty, and Right; and closely connected with these are the ideas connected with the being and attributes of Deity.

Upon the sensational and intellectual ideas thus brought before the mind, all acts of what is called *Reasoning* are founded. These consist for the most part in the aggregation and collocation of ideas, the resolution of compound ideas into simple ones, and the combination of simple ideas into general expressions. In these processes the faculty of Comparison, by which the connection and relation of ideas are perceived, is exercised; also that of Abstraction, by which we separate and isolate particular qualities of an object; and Generalisation, by which the qualities of an object or objects which are alike are brought together.

One of the most interesting and important points in connection with the function of the cerebral hemispheres is the influence of what we call Will, not only on the intellectual powers, but on the whole of the functions of the nervous system. We have seen that the functions of the spinal chord, the medulla oblongata, and the sensory ganglia, are to a certain extent under the influence of the will, whilst on the other hand we find them constantly acting automatically and independently of any control on the part of the will. What the real nature of the will is presents a difficulty not yet overcome, and perhaps never will be, and we can only speak of the conditions of its action. In order that the will may act it appears necessary that there should be in the first place a distinct idea of the object to be attained, and secondly, that there should be a belief in the possibility of attaining it by the means employed. It is also found that, *ceteris paribus*, the degree of intensity with which the will acts, is in proportion to the concentration of the attention upon the effort it is making. It is a curious fact, and one which Dr. Carpenter has recently pointed out, that the influence of the will in the production of muscular effort may be superseded or supplanted by the simple Dominance of Ideas. This condition is seen in persons who are what is called 'electro-biologised,' or in the mesmeric trance. Persons in this state are readily brought under the dominion of a single idea, suggested by the operator from without, and in consequence of the attention being thus concentrated, they are capable of performing feats of strength of which they are otherwise quite incapable. Just as the will by its influence can produce, by its activity, a paralyzing effect on muscular activity, arising from emotional or other causes, so a dominant idea in this condition will entirely suppress the action of the muscular system. Persons are told they cannot open their eyes, and they do not; that they cannot move, and they remain fixed. In the condition brought on by the electro-biologist, as they call themselves, and in the induced sleep of the mesmerist, none of the phenomena can be traced to this cause. This extends not only to their corporeal condition, but also to their mental states. The three conditions necessary to produce the phenomena which have so greatly astonished the world seem to be:—

First, a condition of the cerebral lobes in which, without the consciousness of the individual, they readily come under the influence of ideas suggested by others from without. Secondly, the dominancy of these ideas in the mind, so as to preclude all interference with them on the part of other ideas. Thirdly, an intensification of the nervous energy in the production of the effects upon the muscular system or mind resulting from the dominancy of the idea suggested. (Carpenter, 'Human Physiology.' Carpenter, in 'Quarterly Review,' 1854.)

In states quite independent of those induced for the sake of amusement by electro-biologists and mesmerists, the same condition of the brain comes on. Thus, in what is called *Reverie*, persons are influenced by external sensations, without the controlling influence of the will. This is called *day-dreaming*. What is called *Absence of Mind* is also a condition in which the mind is acting automatically. Sleep-Walking is also a natural occurrence, and in this state persons display much the same phenomena as under the mesmeric and other influences. [SOMNAMBULISM.] In *Dreaming* we have another instance of the same general condition, in which there is no control of the will. Here however the person is under the influence of his own suggestions, although not unfrequently the course of the dream may be dependent on suggestions from without. [SLEEP.] The diseased conditions known as *Delirium* and *Mania* are also other instances in which the cerebral lobes are as it were abandoned to the influence of suggestion, without the control of the will. [INSANITY, in ARTS AND SC. Div.]

It is from conditions like these that it is concluded that in all those states in which the directing power of the will over the current of thought is suspended, the course of action is determined by some dominant idea, which for the time has full possession of the mind, and from which the individual has no power of withdrawing his consciousness. So that we here see that the influence of the idea is similar to that of the sensation, or the excitant in producing movements. Dr. Laycock proposes to call actions thus produced *Ideomotor*. The following diagram, after Dr. Carpenter, will afford a complete view of this series of actions:—

A proper estimate of the functions of the Will will at once show that it is of all the faculties possessed by man the one which most distinguishes him, and influences his character. From it in a great measure arises his moral and religious character. His habits, his Feelings, his sense of Right and Wrong, are dependent for their development and their varied character in different individuals upon the way in which they have been acted upon by the will. It is the possession of will that constitutes man a free agent, and gives him the sense of responsibility.

"From the time when the human being first becomes conscious that he has a power within himself of determining the succession of his mental states, from that time does he begin to be a free agent; and in proportion as he exerts that power, does he emancipate himself from the domination of his constitutional or automatic tendencies. It is a principle now recognised by all the most enlightened educators, that the development of this power of self-control ought to be the object of all nursery discipline; and the process of its acquirement is very gradual. When an infant is excited to a fit of passion by some unpleasant sensation, its nurse attempts to restore its equanimity by presenting some new object to its attention, so that the more recent and vivid pleasurable impression may efface the sense of past uneasiness. As the infant grows into childhood, the judicious parent no longer trusts to mere sensory impressions for the diversion of the passionate excitement, but calls up in its mind such ideas and feelings as it is capable of appreciating, and endeavours to keep the attention fixed upon these until the violence of the emotion has subsided; and recourse is had to the same process whenever it is desired to check any tendency to action which depends upon the selfish propensities—appeal being always made to the highest motives which the child is capable of recognising, and punishment being only had recourse to for the purpose of supplying an additional set of motives when all others fail. For a time this process of external suggestion may need to be continually repeated, where there are strong impulses whose unworthy character calls for repression; but if it be judiciously adopted, and consistently persevered in, a very slight suggestion serves to recall the superior motives to the conflict. And in further space, the child comes to feel that he has himself the power of recalling them, and of controlling his urgent impulses to immediate action. The power of self-control, thus usually acquired in the first instance in regard to those impulses which directly determine the conduct, gradually extends itself to the habitual succession of the thoughts; and in proportion as this is brought under the direction of the will, does the individual

become capable of forming his own character, and therefore truly responsible for his actions. It must not be forgotten however, that the power of self-control may be turned to a bad as well as to a good account; and that the value of its results will entirely depend upon the direction in which it is employed. The thoughts may be so determinatively drawn away from the higher class of motives, the suggestions of conscience so habitually disregarded, and the whole attention so completely fixed upon the gratification of selfish or malevolent propensities, that the human nature acquires far more of the Satanic than of the Divine character; the highest development of this type (if the term may be permitted) being displayed by those who use their power of self-control for the purposes of hypocrisy and dissimulation, and cover the most malignant designs under the veil of friendship.

"Such men (whose portraiture is presented by our great dramatist in the character of Iago) show us to what evil account the highest intellect and the most powerful will may be turned when directed by the baser class of motives; and we cannot but feel that they are far more degraded in the moral scale than those who, having never learned to control their animal propensities, and being unconscious of the very existence of a higher nature within themselves, simply obey the promptings of their automatic impulses, and are rather to be considered as ill-conditioned automata than as vicious men. Of this latter class, some, from original constitution and early influences of the most degrading kind, seem altogether destitute of anything but a brutal nature; such ought to be treated as irresponsible beings, and as such restrained by external coercion from doing injury to society. But this class is small in proportion to that of individuals who act viciously simply because they have never been led to know that any other course is open to them, or to feel any motive that might give them a different impulse. With these the object should rather be to awaken the higher parts of the moral nature, 'to find out the holy spot in every child's heart,' and to develop habits of self-control in the manner just described, than to subjugate by external restraint; and the success which has attended this method, in the hands of those who have judiciously applied it, is sufficient evidence of its superiority; many of the most apparently-debased natures having been thus elevated to a grade which it seemed at first impossible they could ever attain. From the Satanic or positively and wilfully evil type of human nature, in which the highest powers are turned to the worst account, we are thus conducted through the brutal or negatively evil type, towards that higher aspect of humanity which is presented by those who habitually keep before them the Divine ideal, and who steadily endeavour to bring their whole nature into conformity with it. This is not to be effected by dwelling exclusively on any one set of the motives already referred to, as those which the truly religious man keeps before his mind. Even the idea of duty, operating alone, tends to reduce the individual to the subservience of a slave, rather than to induce in him that true mastery over himself which consists in such a regulation of his emotions and propensities, that his course of duty becomes the spontaneous expression of his own higher nature; but it is a most powerful aid in the acquirement of that regulation, by the fixation of the thoughts and affections on 'things on high,' which is the best means of detaching them from all that is earthly and debasing. It is by the assimilation, rather than by the subjugation, of the human will to the divine that man is really lifted towards God; and in proportion as this assimilation has been effected, does it manifest itself in the life and conduct; so that even the lowliest actions become holy ministrations in a temple consecrated by the felt presence of the Divinity. Such was the life of the Saviour; towards that standard it is for the Christian disciple to aspire." (Carpenter, 'Human Physiology,' page 848.)

In the previous view of the Nervous System we have not spoken of the Sympathetic Nerve.

The system of the great Sympathetic Nerve is that whose branches are distributed to all the organs of organic life, the heart, lungs, digestive canal, and glands, &c., chiefly following the course of the blood-vessels, bearing numerous and large ganglia in all parts of their course, and communicating with the brain and spinal chord or their nerves only by few and small filaments. The parts to which the branches of the sympathetic nerve are distributed have but vague if any sensibility, unless under peculiar circumstances of disease; and the motions which some of them possess are usually quite independent of the mind. Numerous experiments of irritating the ganglia of the sympathetic to see whether it produces pain, have had unsatisfactory results; nor would any results of apparent insensibility be conclusive, because the ganglia might, like part of the brain, be insensible to injury, though fully capable of perceiving the impressions transmitted to them through their nerves. But the pain of the diseases of internal organs is amply sufficient to prove their sensibility, though it does not determine whether the impression of pain is conveyed through filaments of the sympathetic system or through those few of the cerebro-spinal system which are mingled with the former in the common sheath. In the same manner, in extraordinary cases, the brain and spinal chord have an evident influence on the motions of the organs supplied by the sympathetic nerve, as in the effects of strong passion and other mental affections on the circulation, the digestive functions, &c. The impressions conveyed from the viscera to the brain and spinal chord may also be reflected either to the voluntary muscles, as

in the convulsions of children with disordered digestion, or to the involuntary muscles, as in the increased rapidity of pulse, the sickness, &c., which occur in various diseases.

In the natural state however, the organs chiefly supplied by the sympathetic nerves are entirely independent of the cerebro-spinal system, and will maintain their actions for a time even after their removal from the body. Thus the peristaltic motion of the intestines, the contractions and dilations of the heart of some animals, and some other similar actions, will continue for a considerable time after they are separated from the body, or after all the nerves passing to them have been divided. Many other facts prove also that the internal organs are much less dependent on the influence of the sympathetic nerve than the external animal organs are on that of their cerebro-spinal nerves: severe irritation of the sympathetic nerves, such as, if applied to the cerebro-spinal motor nerves, would excite sudden and violent convulsions of their muscles, gives rise to but weak and slow contractions of the viscera; and these follow at perceptible intervals after the application of the stimulus, so that it is often difficult to say whether the irritation has exerted any influence at all.

The office of the numerous ganglia placed in the course of the sympathetic nerves is perhaps the most obscure point in the whole range of physiology. Some have regarded them as so many brains, by which impressions are received through the branches of which each ganglion is the centre, and from which excitements to motion are sent out; others have believed that they exercise a power of isolating the organs they supply from the influence of the mind or of obstructing the constant passage of impressions to and from the brain; and many other functions have been supposed to be performed by them; but for each and all the evidence is altogether unsatisfactory.

The Sympathetic Nerve, or system of nerves, has received its name from the idea that it is of ultimate importance in the phenomena of what is called sympathy, in which one part of the body is affected in consequence of some peculiar condition of another. A great number of the phenomena which were formerly regarded as the effects of sympathy are now more clearly explained by the reflecting action of the cerebro-spinal axis; many others depend on some generally operating influence, as a peculiar condition of the blood, &c.; and in those that remain it is questionable whether the sympathetic system of nerves exercises any peculiar power. The universality of its distribution among the viscera is the only ground on which it can be believed to possess this property of exciting impressions or actions in one, in consequence of being itself excited by the condition of another.

It exerts a more evident influence in the various secretions of the glands and other surfaces which it supplies. In some instances the excitant to secretion is conveyed primarily from the brain, either directly, as in the flowing of tears in grief, &c., or by a reflex action, as in the tears that flow when the mucous membrane of the nose is irritated, or as in the flow of saliva in a strong irritation of the membrane of the mouth, in the sweating of fear or of great agony, &c. In the more constant secretions the influence of the sympathetic nerves is in some degree assumed; but there are sufficient facts to prove that their injury is very soon followed by a suppression or modification of the secretion in the organ to which the injured nerves are destined. The cerebro-spinal nerves also exercise an influence on the secretion and nutrition of the parts which they supply; but its amount is indistinct, in consequence of the interruption of other circumstances favourable to those processes, by the same injury which cuts off the secretory power of the nerves, as the loss of exercise of the muscles, &c.

(The literature upon the Nervous System is very extensive. In the preceding article we have almost exclusively consulted the works of Dr. Carpenter, whose several physiological works contain by far the best account of the physiology of the Nervous System with which we are acquainted. The following are the works of Dr. Carpenter which have been consulted and used in this article:—'Principles of Human Physiology,' 4th edition, 1853; 'Principles of Comparative Physiology,' 4th edition, 1854; 'Principles of Physiology, General and Comparative,' 3rd edition, 1851; 'Manual of Physiology,' 1846. The best account of the Histology of the Nervous System will be found in Kölliker's 'Manual of Human Histology,' translated for the Sydenham Society by Messrs. Busk and Huxley. The following works may also be consulted with great advantage on both the structure and functions of the Nervous System:—Valentin, 'Text-Book of Physiology,' translated by Brinton; Müller, 'Physiology,' translated by Baly; Marshall Hall, 'Memoirs on the Nervous System,' Newport, article 'Insecta,' in 'Cyclopædia of Anatomy,' Noble, 'On the Brain,' Todd, 'Anatomy of the Brain and Spinal Cord,' Kirks and Paget, 'Handbook of Physiology,' Unzer and Prochaska, 'On the Nervous System,' translated by Laycock for the Sydenham Society.)

NERVOUS TISSUE. [NERVOUS SYSTEM.]

NE'SEA (Lamouroux), a genus of Corallines.

NESOTRAGUS. [ANTILOPE.]

NETTLE, a name applied to various plants. The true Nettles are various species of the genus *Urtica*, well known for their stinging properties, which are owing to the presence of an acrid poisonous secretion that in some Indian species is so dangerous as to cause excruciating pain and even death. Dead-Nettles are species of *Lamium*,

monopetalous plants belonging to *Labiata*, and wholly inert. The Nettle-Trees belong to the genus *Celtis*, also destitute of stinging properties, but having leaves resembling those of some kinds of *Urtica*. [*Urtica*; *Lanum*.]

NEUROLITE, a Mineral occurring massive. Its texture is imperfectly foliated. Fracture uneven. Hardness 4-25. Brittle. Colour greenish-yellow. Opaque, or only translucent on the edges. Specific gravity 2.476. Before the blow-pipe it gives out water, becoming snow-white and fusible, but does not melt; with carbonate of soda it fuses slowly into a transparent glass, of a slightly yellow colour, which on cooling cracks in various directions.

It is found at Stanstead, in Lower Canada, and appears to form a vein about two inches wide. The following is an analysis by Dr. Thompson:—

Silica	73.00
Alumina	17.35
Lime	3.25
Magnesia	1.50
Peroxide of Iron	0.40
Water	4.30

—99.80

NEUROPTERA (from *νεῦρον*, a nerve, and *πτερόν*, a wing), one of the orders into which the class *Insecta* is divided. The insects composing this order may be distinguished by the following characters:—wings, four in number, membranous, generally naked, and more or less transparent, but sometimes hairy; the mouth is usually fitted for mastication, or furnished with mandibles and maxillæ; the larvae are provided with six legs, and are active; their metamorphosis is variable, but is usually semi-complete. The character which gave rise to the name, namely the minute reticulation of the nervures of the wing, will also in most instances serve to distinguish the insects of the present order from others. The May-Fly and Dragon-Fly afford familiar examples.

The order *Neuroptera* is divided by Latreille into three sections, to which he applies the names *Subulicornes*, *Planipennes*, and *Plicipennes*.

Subulicornes contains the Dragon-Flies (*Libellula*, Linn.) and the *Ephemera*. The larvae of these insects are carnivorous, and live in the water, respiring by means of appendages situated on the sides or extremity of the body; the pupæ also live in the water, but leave that element to undergo the final transformation. In the perfect insect the wings are always reticulated, and when at rest are in some species horizontal, in others vertical; the compound eyes are very large and prominent; and the ocelli, or simple eyes, are two or three in number; the mandibles and maxillæ are covered by the labrum and labium; the antennæ are short, slender, and subnate.

The Dragon-Flies (*Libellulidae*) have the four wings of equal length, the tarsi three-jointed, the antennæ very small and resembling minute bristles, the eyes extremely large, and generally approximated above; the fore part of the head, or what might be termed the face, has an inflated appearance; the legs are rather small, and the abdomen is elongated, sometimes cylindrical, and sometimes depressed, and terminated by membranous appendages. The larvæ and pupæ, both of which are active, nearly resemble the perfect insect in general form, and are remarkable for the great development of the labial apparatus, which is elongated and dilated at the extremity, and covers the fore part of the head like a mask.

The *Libellula* are divided into three genera of Fabricius. Those species which have the wings extended horizontally when at rest, the head almost globular, the eyes very large and meeting on the vertex, an elevation in front and close to the eyes, and the abdomen depressed, form the genus *Libellula* as restricted by that author.

The second genus (*Anaxa*, Fab.) is chiefly distinguished by the cylindrical form of the abdomen and its greater proportionate length. The wings are as in *Libellula*, and the head is of the same globular form.

In the third genus (*Agrion*, Fab.) the wings when at rest are elevated perpendicularly; the head is transverse, and the eyes are widely separated. Examples of each of these genera are found in this country.

The second division of the *Subulicornes*, or the family *Ephemeroidea*, is distinguished from the *Libellulidae* by the comparative softness of the parts of the mouth, they being of a membranous character in the insects of the present family, and the parts less defined; the tarsi are 6-jointed; the inferior wings are much smaller than the upper, and in some are absent; the abdomen is terminated by two or three long and hair-like appendages. They form the genus *Ephemera*, according to Linnaeus, and were so called on account of their short term of life, that is, in the imago or perfect state.

The *Ephemera*, or May-Flies, Latreille states, usually appear at sunset, in fine weather in summer and autumn, on the banks of rivers, lakes, &c. and sometimes in such remarkable numbers, that after their death the surface of the ground is completely covered with them, and in certain districts on the continent they have been collected in cart-loads for manure.

These insects collect together in great numbers in the air, and fly in an undulating manner, constantly ascending and descending, and have a very beautiful appearance. The males are distinguished from the females by the abdomen being furnished with two articulated hooks at the extremity, and apparently the anterior legs and the

terminal filaments of the abdomen are larger in this sex; the eyes are also larger. In some there are four compound eyes, two of which are elevated and larger than the others.

The female insect deposits her eggs in the water, and these are collected together in a mass, after which it dies, the duration of life in the perfect state being very short in both sexes. When however we trace them through the transformations, we find their existence is in reality a long one, for in the larva and pupa state some of them exist for two or three years. During this time they are generally hidden, at least in the day-time, in the mud or under stones; sometimes in horizontal holes in the banks of rivers.

The species of *Planipennes* have the antennæ composed of numerous joints, always larger than the head; the mandibles are well developed, and the posterior wings are nearly equal in size to the superior; they are either naturally extended or have the anterior portion simply folded beneath: the reticulations of the wings are very distinct, and they are naked; the maxillary palpi are usually filiform, or slightly thickened at the apex, shorter than the head, and 4-jointed.

This section is divided into four families:—

1st. The *Panorpidæ*, the species of which are distinguished by all the tarsi being 5-jointed, and the anterior portion of the head drawn out in the form of a snout or proboscis.

It consists chiefly of the Linnaean genus *Panorpa*, which is now divided into the following genera:—*Nemoptera*, Latreille; *Bittacus*, Lat.; *Panorpa* proper, and *Boreus*, Lat.

The *Panorpa communis* of Linnaeus is a common insect in hedges and in woods. It is about three-quarters of an inch in length, black; the snout and apical portion of the abdomen red; the clytra are irregularly spotted with black.

Of the genus *Boreus* we also have an example in this country; the *B. hyemalis*, a small insect, which is found usually in moss, and during the winter season.

2nd. The *Myrmeleconidæ*.—In this family the antennæ are more or less suddenly incrassated at the apex; the head is transverse, and the eyes project considerably; there are six palpi, of which the labial are usually the longest, and thickened at the apex; the first segment of the thorax is small; the anterior and posterior wings are equal, elongated, and when closed meet at an angle like the roof of a house; the abdomen is usually elongated, and furnished at the apex in the male sex with two appendages; the legs are short. These insects are found in the warmer portions both of the Old and New World: they form two genera according to Fabricius, *Myrmeleon* and *Ascalaphus*. The curious habits of the larva of the *Myrmeleon Formicarius*, a European insect, though not found in this country, have often attracted the attention of the naturalist. This insect is of a grayish colour, and short and broad form; the head is small, and furnished with a large pair of sharply-pointed mandibles, which serve both to seize its prey and to extract the juices upon which it lives. [MYRMELEON.]

The third family consists of the *Hemerobiidæ*, which are chiefly distinguished from the last group by their filiform antennæ; they moreover differ in having only four palpi. In some (the genus *Hemerobius*) the wings when closed meet at an angle, as in the *Myrmeleons*, whilst in others (*Sembla*) they are horizontal.

Hemerobius perla is common in our gardens, and is often seen flying about the filices, especially towards the evening. It is rather more than half an inch in length, of a green colour, and has transparent wings with numerous green nervures; its eyes resemble small globes of gold; when touched it emits a very disagreeable odour.

To the fourth family Latreille applies the name *Termitinæ*; it includes those Neuropterous Insects which have a semi-complete metamorphosis; they are terrestrial and active, and are either carnivorous or gnawers in all their states.

The *Mantiapæ*, which Latreille places in this division, differ much from other insects of the order in having large anterior legs formed like those of the *Mantida*; their tarsi have never more than four joints; the mandibles are strong, and the wings have no folds; the inferior pair are either smaller or equal to the superior wings in size.

Besides the genus *Mantiapa*, this family includes *Raphidia*, *Termes*, and *Pococæ*.

The last family of the *Planipennes* is the *Perlidae*, in which the tarsi are 3-jointed, and the mandibles almost always small and partly membranous; the inferior wings are wider than the others, and are folded when not in use. This family contains the genera *Perla* and *Neumera*. The larvæ of the *Perla* live in the water, and inhabit sheaths which they construct by joining together various substances by means of a silken web which they spin.

The insects belonging to the third section, the *Plicipennes*, are well-known to anglers by the name of Caddis-Fly, and in the larvæ state they are called Caddis-Worm, or Cadew-Worm. They constitute the genus *Phrygania* of De Geer, and have been raised to the rank of an order by Meunier. Kirby and Spence and Dr. Leach, being the order *Trichoptera* of their system.

The *Phryganiæ*, or Caddis-Flies, are distinguished from other Neuropterous Insects by the absence of mandibles and in the structure of their mouth; in fact they evince an approach to the Lepidopterous Insects as well as in some other characters; the wings are semi-transparent, and when closed meet at an angle, like the roof of a house; they are usually hairy, hence the name *Trichoptera*; the

posterior wings are longitudinally folded, and usually broader than the anterior pair; the head is small, and furnished with two simple eyes situated on the vertex, besides the ordinary compound eyes; the antennæ are very long and thread-like, and composed of very numerous indistinct joints; the palpi are four in number; the maxillary palpi have often five joints in the females, and the labial palpi are 3-jointed.

Caddis-Fly (*Phrygania*).

1, Larva of a species of *Phrygania*, magnified; 2, case inhabited by the larva; 3, the pupa, magnified; 4, the perfect insect with the wings expanded; 5, ditto, with the wings in the ordinary position when the insect is at rest.

The larva, or Caddis-Worm, always lives in the water, and incloses itself in a cylindrical case, open at both ends, and formed of pieces of stick, small shells, and various other substances, which the insect joins together by a silken web. It never quits this case, but when it wishes to move it protrudes the fore part of the body, which is furnished with six tolerably long legs, and crawls about with the case attached to the hinder part, it being held by means of two hooks situated on the last segment of the abdomen. The form of the larva is nearly cylindrical, but slightly compressed. The head and first three segments of the body (which in fact constitute the thorax) are coriaceous; the remaining segments are soft. When about to change into the pupa state the larva fixes its tube to some substance in the water, and closes the ends. The transformation is what is termed complete, the pupa resembling the perfect insect, except in having the wings imperfectly developed, and also in having two hooks on the fore part of the head, by means of which it makes its escape from the case, that it may swim to some dry situation when about to assume the perfect state.

The *Phryganiæ* are very numerous, and M. Pictet states that they abound more in the northern than in the southern parts of Europe. Their larvæ being always aquatic, they are generally found near the water; they fly chiefly in the evening, and are not unfrequently seen in immense numbers. The author just quoted, M. Pictet, has published a quarto volume with numerous plates, in which, after giving a detailed account of the anatomy and habits of these insects, he traces very many of them through all their stages. In this work, which is one of the most perfect monographs ever published, the *Phryganiæ* are divided into eight genera, as follows:—

1. *Phrygania* proper.—Distinguished by the superior wings having some transverse nervures near the bifurcation of the principal nervure, the posterior wings folded; the antennæ setaceous, and equal in length to the wings; maxillary palpi but slightly pubescent; those in the males 3-jointed, and those of the female having 5 joints; the terminal joint is ovate, and shorter than the two preceding taken

together. Of this genus upwards of 30 species are known in Europe, some of which are the largest of the *Phryganiæ*.

2. *Mystacida*, Latreille.—Anterior wings straight and elongated, having a few transverse nervures; posterior wings much folded; antennæ setaceous and slender, longer than the wings; maxillary palpi 5-jointed in both sexes, long and pubescent.

3. *Trichostoma*, Pictet.—Anterior wings short, without transverse nervures; posterior wings but slightly folded; antennæ comparatively thick and short, the basal joint very hairy; maxillary palpi 3-jointed in the male, the terminal joint stout, and more densely clothed with hair on the apical portion than at the base.

4. *Sericostoma*, Latreille.—Anterior wings without transverse nervures; posterior small, and but slightly folded; antennæ stout and short, and having the basal joint long and thick; the maxillary palpi in the male shaped like the bowl of a spoon, and uniting to form a rounded muzzle. The larvæ of the species of this genus inhabit a case which approaches to a conical form, and is more or less curved; it is composed of pieces of sand and small stones joined together. The perfect insect is slow in its movements.

5. *Rhyacophila*, Pictet.—Anterior wings without transverse nervures; posterior wings straight, of the same form as the anterior pair, and almost destitute of folds; antennæ moderate; maxillary palpi 5-jointed in both sexes, the second joint almost as short as the first, and the terminal joint ovate; abdomen often terminated by coriaceous appendages. This genus contains many species, all of which are of small size.

6. *Hydropsyche*, Pictet.—Anterior wings without transverse nervures; posterior wings folded; antennæ slender; maxillary palpi 5-jointed in both sexes, the terminal joint almost equal in length to the other joints taken together, and very slender. This is also a numerous group. The larvæ live almost always in running waters. The perfect insect is often spotted.

7. *Psychomyia*, Latreille.—Anterior wings straight, pointed, and without transverse nervures; posterior wings resembling the anterior, and not folded; antennæ moderate; maxillary palpi 5-jointed in both sexes, the terminal joint long and slender.

8. *Hydroptila*, Dalman.—Anterior wings attenuated and pointed, very hairy, and with the nervures indistinct; posterior wings resembling the anterior, not folded; antennæ short and filiform; maxillary palpi 5-jointed in both sexes, the terminal joint ovate.

NEUROPTERIS. [COAL-PLANTS.]

NEUTRIA. [HYSTRICIDÆ.]

NEWFOUNDLAND DOG, a well-known and fine variety of the Dog, seldom seen in a state of purity, when it is comparatively small, but very muscular and strong, and generally black. The large, and it must be confessed, handsome dogs, which are so often seen in this country, and pass for Newfoundland Dogs ("dogs"—it is Colonel Hawker, if we recollect right, who so designates them—"as big as a jackass, and as hairy as a bear"), are very different from the compact and moderate-sized animals which, in their native country, are employed in drawing sledges and little carriages laden with wood, fish, or other commodities. Some of these true Newfoundland Dogs make admirable retrievers. The great and less pure English Newfoundland Dogs, so to speak, are also employed in the field for the same purpose with great success. One of the leading qualities of both, when so broken in, is the gallant manner in which they will face and penetrate cover, however thick and rough, in pursuit of the lost object. Whether it be furze, hramble, or blackthorn, in they dash, and almost always persevere till they have recovered the lost piece of game. As water-dogs they are above all praise. Their zeal, their devotedness, their entire abandonment of self when they rush to the rescue of some drowning wretch, are admirable; to be sure, in their eagerness to save, they sometimes encumber those with help who do not need it; and there have been instances where they have nearly destroyed the swimmer by their kindness. Directly they see anybody, or indeed any animal whatsoever, struggling in the water, in they jump, and seem to think that it is their duty never to leave them till they have got them out. They have been employed most successfully in wrecks, and will work against the most heavy sea—not always with success however. There is a case on record where the compact frame and indomitable courage of a hull-dog succeeded in carrying him through breakers which proved fatal to the Newfoundland breed. During a heavy gale a ship had struck on a rock near the land. The only chance of escape for the shipwrecked was to get a rope ashore, for it was impossible for any boat to live in the sea then running. There were two Newfoundland dogs and a bull-dog on board. One of the Newfoundland dogs was thrown overboard with a rope tied round him, and perished in the waves. The second shared a similar fate; but the hull-dog fought his way through that terrible sea, and, arriving safe on shore, rope and all, became the saviour of the anxious people on the wreck.

The Newfoundland Dog is confiding, very sagacious, and capable of the warmest attachment to his master. The attacks of little dogs are generally either coolly looked down upon, as if hardly understood, or treated with marked contempt; but there are exceptions to this lofty behaviour. We saw a harmless and very affectionate pug receive his mortal hurt from one of these dogs, and that without the slightest provocation on the part of the poor little pug. This however was a

bad-tempered exception to the general rule; and the Newfoundland Dog may notwithstanding be pronounced to be as generous as he is brave.

NEWT. [AMPHIBIA.]

NICKEL. This metal was first described by Cronstedt in 1751. For all purposes the metal may be obtained in a state of purity by the following process:—Roast the native sulphuret of nickel to expel the sulphur and oxidise the metal; dissolve the residue in a mixture of four parts of sulphuric acid and one part of nitric acid moderately diluted with water. Evaporate the clear solution till crystals are formed, which are sulphate of nickel, of a fine emerald-green colour; re-dissolve these, and separate any copper they may contain by a plate of iron, and add excess of ammonia, which dissolves the oxide of nickel and any oxide of cobalt that may be mixed with it. To the clear solution add potash dissolved in water, which throws down hydrate of nickel of a green colour, and this, after washing and drying, is to be mixed with black flux, and reduced into the metallic state by a strong heat in a wind-furnace.

Nickel has the following properties:—It is of a white colour with a yellowish tint. Its lustre is considerable, and it is both malleable and ductile. Like iron, it is attracted by the magnet, and may, like it, be rendered magnetic at common temperatures, but it loses this power when heated to 630° Fahrenheit. The specific gravity of fused nickel is about 8.28, and by hammering it is increased to almost 9.0. It is nearly as hard as iron.

Nickel suffers little or no change by exposure to air and moisture at common temperatures. It is very difficult of fusion, but melts at a lower temperature than iron; at a red heat it absorbs oxygen gradually from the air, and also decomposes water at this temperature. Nitric acid is the only acid which readily acts upon nickel. Nickel occurs in meteoric iron and aerolites. [AEROLITES.]

The uses of nickel are very limited, and until within a few years it was scarcely employed at all; but it is now very usefully employed, and, to a considerable extent, in forming an alloy with copper and zinc, known by the name of German silver. Its oxides impart a green colour to glass and porcelain.

The ores of nickel are as follows:—

Sulphuret of Nickel, Capillary Nickel.—This occurs in regular hexagonal capillary crystals. Primary form a rhomboid. Colour brass-yellow or grayish; lustre metallic. Hardness, scratches mica, and is scratched by felspar. Opaque; brittle. It is soluble in nitric acid, and before the blow-pipe, when strongly heated, gives a malleable and metallic button. It occurs in Wales, Cornwall, Saxony, &c. The following is an analysis by Arfwedson:—

Sulphur	34.26
Nickel	64.35

—98.61

Arseniuret of Nickel, Copper Nickel.—It occurs crystalline, botryoidal, reniform, and amorphous. Primary form a right rhombic prism. Structure compact, fibrous. Fracture uneven, conchoidal, splintery. Hardness 3.0 to 5.5. Colour yellowish and grayish-red. Lustre metallic. Opaque. Specific gravity 7.655. Before the blow-pipe on charcoal it emits an alliaceous smell, and melts. It is found in Cornwall, Saxony, Bohemia, &c., and also in South America. The analysis by Pfaff gives:—

Nickel	45.90
Arsenic	46.42
Iron	0.34
Lead	0.56
Sulphur	0.80

—97.02

Sulpho-Arseniuret of Nickel, Nickelglanz, Gray Nickel.—It occurs massive. Its structure is granular. Fracture uneven. Easily frangible. Colour pale lead-gray. Opaque. Specific gravity 6.129. It is found in Sweden and in the Harz, &c. An analysis of a specimen from Looe, in Nelsingland, by Berzelius, which was mixed with some Mispickel, gave:—

Nickel	29.9
Arsenic	43.4
Sulphur	19.3
Cobalt	0.9
Iron	4.1

—97.6

Silicates of Nickel, Pimelite.—It occurs massive, and investing other minerals. Colour apple-green or yellowish-green. It is earthy, dull, opaque, soft and greasy to the feel. It is infusible before the blow-pipe, but becomes of a dark-gray colour. It is found in Sweden and the Harz. It was analysed by Klaproth, and gave:—

Silica	35.00
Oxide of Nickel	15.62
Alumina	5.10
Lime	0.40
Magnesia	2.25
Water	37.91

—96.23

Arsenate of Nickel.—It occurs powdery on the surface of arseniuret of nickel, and massive. Colour greenish-white and green. Opaque. It is found in Allionnet, Helse, &c. Analysis by Stromeyer:—

Arsenic Acid	36.97
Oxide of Nickel	37.35
Water	24.32

—98.64

NICOTIANA, a genus of Plants belonging to the natural order *Solanaceae*. The species of this genus are called Tobacco. Tobacco was the name used by the Caribbees for the pipe in which they smoked it, but this word was transferred by the Spaniards to the herb itself. The genus *Nicotiana* contains about 40 species, most of them yielding tobacco for smoking, and many of them cultivated in the gardens of Europe. The name *Nicotiana* was given these plants after Jean Nicot, of Nîmes, in Languedoc, who was an agent of the king of France at Portugal, and there procured the seeds of the tobacco from a Dutchman who had procured them in Florida. Nicot sent them to France in 1560.

The species of *Nicotiana* are most of them herbs, rarely under-shrubs, and generally clothed with clammy hairs or down. The flowers are terminal, racemose, or paniced, and of a white, green, or purplish colour. The calyx is 5-cleft, permanent; corolla funnel- or salver-shaped, divisions 5, plicate and spreading; stamens 5, as long as the tube of the corolla; anthers debiscing lengthwise; stigma capitate; capsule 2-celled, 2-valved, valves bipartite; seeds minute, numerous.

N. Tabacum, Common Virginian or Sweet-Scented Tobacco, is an herbaceous plant, with acuminate oblong-lanceolate sessile leaves, lower ones decurrent; throat of corolla inflated, segments of the limb pointed. This plant is a native of the West Indies, where it first became known to the Spaniards, and of Virginia, where the English first became acquainted with its properties. Of the various species it is that which is most commonly cultivated in gardens as an ornament. It is also largely cultivated in Europe for the purpose of smoking. The other species are however in some cases preferred. Sebrank has described a large number of varieties of the common tobacco, varying in the size and form of their leaves, as well as the colour and form of their corollas. This species is the one most commonly employed for making tobacco and cigars. [TOBACCO, in ARTS AND SC. DIV.]

N. macrophylla, Orinoco Tobacco, is an herbaceous plant, with ovate-acute leaves clasping the stem; throat of corolla inflated, segments short, pointed. It is a larger plant than the last, the stem rising from 5 to 7 feet high. It is a native of America, and is frequently used for smoking, under the name of Orinoco Tobacco; it is however inferior to the last; the milder Havannah cigars are said to be made from it.

N. rustica, English Tobacco, has an herbaceous square stem, with petiolate ovate quite entire leaves; tube of corolla cylindrical, longer than the calyx; segments of the limbs roundish, obtuse. This plant is a native of Europe, Asia, Africa, and America. It is called English Tobacco because it was the first species that was introduced into this country for growth; it was then brought from America. It grows very well in this climate, and in some places is almost naturalised. It is known in France as *Tabac Pausse*, in Germany as *Bauern-Tabak*, and in Spain as *Tabaco Cimaroso*. This plant grows on the coast of the Mediterranean, and thence finds its way into India, where it is highly valued. The tobaccos of Salonica and Latakia, which are much esteemed, appear to be the produce of *N. rustica*. From the extensive range of climate and difference of situation which this plant occupies, its characters suffer considerable change; hence a number of varieties have been described. In the shops this tobacco is known as Turkish.

N. Persica, Shiraz Tobacco, is an herbaceous plant, clothed with clammy down, with the leaves of the root oblong, those of the stem acuminate and sessile; corolla salver-shaped, with a long tube, and rather unequal segments. This plant is a native of Persia, and furnishes the famous Shiraz Tobacco. This tobacco is milder than that produced by the *N. Tabacum*, and but a small quantity is consumed in this country. The English smoke more of the strongest tobacco than any nation in the world.

There are several other species of tobacco which are used for smoking in the places where they naturally grow. *N. quadrivalvis* has capsules with four valves; it grows near the Missouri River, and is there smoked by the natives. *N. multivalvis* has capsules with many valves; it is cultivated by the Indians on the Columbia River for smoking. It is a fetid plant, and the calyx, the most fetid part, is selected by the Indians for smoking. *N. nana*, a small species of tobacco, is a native among the Rocky Mountains of North America, and is smoked by the Indians. *N. repanda* is a native of Cuba, and is said to furnish the tobacco for making the small cigars known as Queen's.

NIDULARIACEÆ, a sub-order of Plants belonging to the order *Gasteromycetes*, the alliance *Fungales*, and the class *Thallophytes*. It includes the genera *Nidularia*, *Cyathus*, *Crucibulum*, *Sphaerobolus*, *Thelebolus*, and *Atractobolus*.

NIGELLA (from *niger*, black, because of the colour of the seeds), a genus of Plants belonging to the natural order *Ranunculaceæ*. It has 5 coloured petal-like spreading sepals. The petals small, from

5 to 10, hilabiate, with a hollow nectariferous claw. The capsules more or less connected together, terminated by the elongated styles opening in the inside, many-seeded. The leaves are capillary, multifid, often surrounding the flowers like an involucre, and finely cut like fennel. The flowers are solitary on the tops of the stems or branches. The species are erect annual smoothish herbs. The species are vulgarly known by the names Devil in a Bush and Devil in a Mist.

N. sativa has ovate-obtuse anthers; capsules muricated, united up to the very point into an ovate fruit, terminated by 5 erect styles; the stem erect and rather hairy; flowers naked. The seeds are angular, aromatic, subacid, and were formerly used instead of pepper; and have also been employed as carminatives. It is the *Μελανθιον* of Hippocrates, 'Steril.' 675, and of Dioscorides, 3, 93; the *Githex* of Pliny, 20, 17.

N. arcensis has pointed anthers; from 5 to 7 styles circinate-ly revolute, outwardly smooth; capsules connected below the middle into an obovate fruit, which is narrowest at the base. It has a smooth stem, with diverging branches. It is a native of middle and southern Europe in corn-fields, also in the north of Africa. The seeds are sometimes used instead of those of *N. sativa*, but they are not so aromatic, neither have they so pleasant a smell. Both species are employed in the adulteration of pepper.

(Lindley, *Flora Medica*; Fraas, *Synopsis Plantarum Floræ Classicæ*.)

NIGHT-HERON. [NYCTICORAX.]

NIGHT-JARS. [GOAT-SUCKERS.]

NIGHTINGALE. [PHILOMELA.]

NIGHTSHADE, DEADLY. [ATROPA.]

NIGRIN, a Mineral consisting principally of oxide of titanium, and containing about 14 per cent. of iron. It resembles *Menaccanite* in colour, lustre, and appearance of the fractured surfaces. It occurs in Ceylon and in Transylvania.

NIKA, a name given by M. Risso to a genus of Macrurous Crustaceans. [PALEMONIDÆ.]

NIMA, a genus of Plants belonging to the natural order *Simarubaceæ*. It has hermaphrodite flowers, a 5-parted permanent calyx, 5 oblong petals, 5 stamens with filaments dilated at the base; the 5 ovaries are connected together, pilose, and seated on the thick disc beneath the petals. The embryo is large, without albumen. The species are trees, with alternate imparipinnate leaves, having four pairs of serrated leaflets. The flowers are disposed in panicle corymbæ.

N. quassioides is a native of Nepaul, in a valley near the town called Thankot. It has elliptical oblong leaflets, which are acuminate and serrated. The corymbæ are trichotomous. It is as bitter as the quassia of South America.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*.)

NIPADITES (Bowerbank), a genus of Fossil Fruits from Sheppey.

NIPPLEWORT. [LAPSAÑA.]

NISSO'LIA (in honour of William Nissole, a French botanist), a genus of Plants belonging to the natural order *Leguminosæ*. It has a campanulate calyx, a papilionaceous corolla, and 10 monadelphous stamens. The legume is stipitate, one- or few-seeded. The species are climbing shrubs, with imparipinnate leaves.

N. ferruginea has from 7 to 11 leaflets, which are alternate, oblong, mucronate, and clothed with rusty velvety down; beneath, the flowers are panicled, monadelphous, and the legume straight and rather velvety. The flowers are violaceous. It is a native of Guyana, and exudes from its stem a red transparent gum that has a powerful astringent flavour. It is also known by the name of *N. quiriata*.

None of the species of this genus are European, nor are they of use in art or science. A mixture of loam and peat is the best soil for them, and young cuttings will strike root in sand under a bell-glass in heat.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*.)

NISUS. [FALCONIDÆ.]

NITELLA, a genus of Plants belonging to the natural order *Characeæ*. It is characterised by the whole plant being more or less pellucid; the cells are tubular, not invested with a secondary layer of smaller cells as in *Chara*; the reproductive organs consist of globules and nucules, mostly seated on the terminal whorl, and axillary.

Four species of this genus have been described inhabiting Great Britain.

N. translucens has an elongated flaccid pellucid glossystem, with the branches of the whorls spreading, elongated; the nucules and globules approximate, on the smaller ramuli scarcely bracteated. It grows in deep and stagnant ponds, but is by no means a common plant in Great Britain. It is the largest of the British species, and best adapted for the examination of the curious currents, which are obvious in the whole of the family to which it belongs. [SAP.]

N. flexilis has a stem 1 to 2 feet long, smooth, flaccid, somewhat glossy and pellucid. It is not unfrequent in lakes and still waters. The nucules are often solitary. The stem, like that of *Chara*, is often incrustated with carbonate of lime. Hassal thinks this constitutes the only distinction of Agardh's *N. opaca*.

N. nidifica has single stems, smooth below, flaccid, somewhat glossy and pellucid; the nucules and globules separate. It is a native of the salt-water ditches in the south and east of England.

N. gracilis has smooth, glossy, pellucid stems, with whorls of the branches compound, the segments acute, the bracts wanting. This is

a small delicate and elegant species, but probably not distinct from *N. flexilis*. In fact it may be questioned whether all these species are not varieties of one.

(Hassal, *Freshwater Algae*; Smith, *English Botany*; Babington *Manual of British Botany*.)

NITIDULA, a genus of Insects belonging to the Clavicorn family of the *Coleoptera Pentamera*.

NITRE. [POTASSIUM.]

NO'BIA. [CIRRIPEDIA.]

NOBLE. [ASPIDOPHORUS.]

NO'CTHORA, F. Cuvier's name for the Douroucoul, a quadrumanous animal of the New World, with several characters that remind the observer of some of the *Lemuridæ* (the Loris especially) of the ancient continent and its islands. Indeed Dr. Horsfield and Mr. Vigors observe ('Zool. Jour.' vol. v.) that to the philosophic inquirer "it will equally be a Lemur among the Monkeys, or a Monkey among the Lemurs."

Humboldt, who first gave a detailed and clear account of this curious form, sees in it, and with good reason, an approximation to the Slow Lemur, or Loris *Parsesux* of the French (*Lemur tardigradus* of the south of Asia), and the physiognomy and features, particularly the eyes, well justify the comparison. So far it would seem to represent in America the *Lemuridæ* of the Old World; but the teeth are the same with those of the Sajous (*Simia apella*, *S. capucina*, &c., Linn.), according to F. Cuvier, who observes, that if the canines were small and little in the individual examined by him, it was because that individual was a female. The diameter of the small intestines was extremely small, and the cæcum simple and only about two inches deep, and sensibly smaller than the stomach.

The organs of motion do not present anything very particular; the four extremities or hands are formed exactly like those of the Sajous, except that the animal does not extend the fingers of the fore hands, which remain raised as F. Cuvier has represented them (see the cuts). The nails are long, narrow, chaunelled (en gouttières), and a little hooked: the tail is very moveable, but not prehensile, though the animal can turn it over its back, or round its neck or its legs. The pupil of the eye is round, and the eyes themselves are very large and without any accessory organ.

Profile of the Douroucoul.

Fore hands of the Douroucoul.

The external ear is much developed and very like that of the *Simia* generally. The aperture of the nostrils is not wide. The mouth is very large and without cheek-pouches. The fur is soft, thick, and of a silky nature. The interior of the hands presents areas formed of very fine striae, always parallel and ordinarily circumscribed the one within the other. Vulva grandis externæ vulvæ canum simillima. Under each axilla a teat.

The habits of this creature are entirely nocturnal. It spends the day in sleep, folded up with the head hidden between the fore legs; but as soon as the brightness fades into twilight the animal awakes to activity. The eyes, which, if exposed to the full brilliancy of day, are darkened with excess of light, for the iris is then closed completely, perform their office as the shades of night approach, and the pupil then dilates nearly to the size of the eye.

Humboldt informs us that, in a state of nature, the Douroucoul hunts small birds, and also, especially, insects: it eats all sorts of vegetables, but is particularly fond of bananas, sugar-cane, the fruit of

the palms, the nuts of the *Bertholletia*, and the seeds of the *Mimosa* *Japa*. They do not live in societies, but pass their time together in pairs. Their nocturnal cry (muh-muh) resembles that of the Jaguar, and the whites who visit the missions of Oromooko call it Titi-Tigra. Its voice is of extraordinary power and volume when considered in relation to its size. Besides the Jaguar-like cry it has two others, one a species of moaning (ei-aiou), and a very disagreeable sound (quer-quer). Its throat swells when it is irritated, and the animal then resembles in its dilatation and posture a cat attacked by a dog.

Humboldt's specimen, which he kept for five months, was lethargic during the day, sleeping from nine in the morning to seven at night (whence the species is called *Nons Dormillon*). Sometimes it would begin to slumber at daybreak, and always selected the most shady places; and, like squirrels and weasels, passed readily through small holes and openings. If roused during the day, its large eyes, which at night resembled those of the owl, were lustreless; and when it was wrapped up in the soundness of sleep, its mouth might be opened and its teeth examined with impunity. It was very fond of flies, and sometimes would even hunt for them on a dull day, capturing them with great skill. It drank but little, and sometimes passed twenty or thirty days without taking any liquid. It was kept at night in Humboldt's bed-room, notwithstanding the belief of the natives, that the Douroucouli will tear out the eyes of sleeping persons. In a state of nature it is generally caught by the natives when sleeping in some hollow tree by day, and the male and female are often taken together.

P. Cuvier's Douroucouli was very mild in temper, which he attributes to the sex. He fed her on milk, biscuit, and fruit. Humboldt could not familiarise his.

P. Cuvier observes that the genus of which the Douroucouli is the type received the name of *Aotus* because the absence of external ears appeared to be its dominant character. This name, he remarks, can hardly be applicable to the animal now before us.

The affinities of this curious form to the Sajons and Loris among the *Quadrumanes* are shown by its fondness for insects, its nocturnal habits, and various parts of its organization. The last-named habits, its cat-like cries and appearance when excited, and other points, indicate its relation to the *Ferez*: Mr. Swainson notices this approach to the ferocious quadrupeds, and makes this the genus by which we are conducted from the *Cebidae* to the *Lemuridae*. In his 'Classification' he places the form in the latter group, between *Tarsius* and *Galopithecus*.

It is found in South America. Humboldt saw the species in the forests bordering the Casiquiare and the woods at the base of Mount Duida; also in the vicinity of the cataracts of the Maypures.

Noctilio tringula.

NOCTILIO. [CHEIROPTERA.]

NOCTILUCA, a genus of Animals usually referred to the class *Acalypse*. [ACALEPHEA.] One species only of this genus has been described *N. miliaris*. It occurs occasionally in prodigious numbers around the coasts of England, and is the most frequent cause in this part of the world of the phosphorescence of the ocean. It was first discovered by M. Suriray in 1850.

According to M. Suriray the *Noctiluca* is a spherical gelatinous mass, provided with a long filiform tentacle or appendage, presenting a

mouth, an oesophagus, one or many stomachs and ramified ovaries, and thus possessing a certain complexity of organisation. De Blainville confirmed Suriray's account, and placed *Noctiluca*, without doubt most erroneously, among the *Diphydæ*. On the other hand, Van Beneden Verhaeghe and Doyère, denying the relation of *Noctiluca* with the *Acalephe*—and conceiving its organisation to be of a much more elementary character—relegated it to the *Rhizopoda*.

To this doctrine M. De Quatrefages also attaches the weight of his authority in his valuable essay 'Observations sur les Noctiluques,' published in the 'Annales des Sciences Nat.' for 1850. M. De Quatrefages does not admit the existence of any true mouth or intestinal canal, and considers that the so-called stomachs are nothing but 'vacuoles' similar to those observed in the *Rhizopoda* and *Infusoria*.

Krohn was the first to describe the long cilium which proceeds from the mouth of *Noctiluca*. Mr. Huxley has recently described this animal in the 'Quarterly Journal of Microscopical Science.' (Vol. iii.) He says—

"*Noctiluca miliaris* may be best described as a gelatinous transparent body, about 160th of an inch in diameter, and having very nearly the form of a peach—that is to say, one surface is a little excavated, and a groove or depression runs from one side of the excavation half way to the other pole (échancrure, Quatrefages; Frauenbusenähnliche Einbucht, Krohn). Where the stalk of the peach might be, a filiform tentacle, equal in length to about the diameter of the body, depends from it, and exhibits slow wavy motions when the creature is in full activity. I have even seen a *Noctiluca* appear to push repeatedly against obstacles with this tentacle.

"The body is composed of a structureless and somewhat dense external membrane, which is continued on to the tentacle. Beneath this is a layer of granules, or rather a gelatinous membrane, through whose substance minute granules are scattered without any very definite arrangement. From hence arises a net-work of very delicate fibrils, whose meshes are not more than 1-3000th of an inch in diameter, and these gradually pass internally—the reticulation becoming more and more open—into coarser fibres, which take a convergent direction towards the stomach and nucleus. All these fibres and fibrils are covered with minute granules, which are usually larger towards the centre."

After describing minutely the structure of this creature, Mr. Huxley concludes—

"Not only does all I have observed lead me to believe that *Noctiluca* has a definite alimentary cavity, but I am inclined to think that this cavity has an excretory aperture distinct from the mouth. The funnel-shaped depression in the post-oral area in fact always appeared, when I could obtain a favourable view, to be connected with a special process of the stomach. On one occasion I observed the sides of this process to be surrounded by fusiform transversely-striated fibres or folds; I could not determine which.

"Krohn states that he repeatedly saw the egesta voided 'in the neighbourhood of the groove of the body,' but he could not determine at what exact point, and he inclines to think it must have taken place through the mouth.

"I am equally unable to bring forward direct evidence on this point, and my belief in the existence of a distinct anus is founded simply on the structural appearances.

"In front of and above the gastric cavity is the nucleus, described by Verhaeghe and Krohn. This is a strongly-refracting oval body of about 1-460th of an inch in length, which, by the action of acetic acid, assumes the appearance of a hollow vesicle. The anterior radiating fibres pass from it; the posterior from the alimentary canal.

"Quatrefages and Krohn consider that a process of fissiparous multiplication takes place in *Noctiluca*; both of these observers having found double individuals, though very rarely. According to the latter writer, division of the body is preceded by that of the nucleus. I have not had the good fortune to meet with any of these forms, and the only indication of a possible reproductive apparatus which I have seen consisted of a number of granular vesicular bodies, of about 1-2000th of an inch in diameter, scattered over the surface of the anterior and inferior part of the body.

"Such is what repeated examinations leads me to believe is the structure of *Noctiluca*; but if the preceding account be correct, it is obvious that the animal is no *Rhizopod*, but must be promoted from the lowest ranks of the *Protozoa* to the highest.

"The existence of a dental armature, and of a distinct anal aperture, are structural peculiarities which greatly increase the affinity to such forms as *Colpoda* and *Paramacium*, indicated by Krohn. *Noctiluca* might be regarded as a gigantic *Infusorium* with the grooved body of *Colpoda*, the long process of *Tracheliu*, and the dental armature of *Nausula* united in one animal.

"On the other hand, the general absence of cilia over the body, and the wide differences in detail, would require the constitution of at least a distinct family for this singular creature."

In the same volume of the 'Microscopical Journal' is an account of this creature by Dr. Woodham Webb, of Lowestoft.

NOCTUA. [STRIGIDÆ.]

NOCTUA, a genus of Insects belonging to the Nocturnal *Lepidoptera*, to which the Red Under-Wing Moths belong.

NOCTULE. [CHEIROPTERA.]

- NODDY. [BOOBY.]

NOLANA (so named by Linnaeus, from 'nola,' a little bell, on account of the bell-shaped form of the corolla), a genus of Plants belonging to the natural order *Nolanaceae*. It has a 5-cleft calyx; a campanulate 5-lobed 5-plicate corolla; 5 stamens adhering to the tube of the corolla, nearly equal; the anthers are 2-celled, debiscing lengthwise. The seeds are roundish, with a membranous testa, and fleshy copious albumen. The species are herbs; natives of Peru and Chili; usually annual. Leaves alternate, quite entire. The flowers are solitary, pedunculate, and of a showy blue colour.

N. prostrata, Prostrate Nolana, has a prostrate stem; ovate-oblong leaves; a pyramidal calyx, with triangularly sagittate segments, furnished with spur-like processes at the base. It is a native of Peru, but grows freely in this country in the open air. In France poultry are fed upon it, and are so fond of it that Persoon proposed to call it *N. gallinacea*.

N. paradoxa has prostrate hairy stems; ovate-obtuse pilose leaves; the segments of the calyx triangular; the corolla campanulately funnel-shaped; the drupes cumulated, 1-seeded. It is a native of Chili, on the sea-shore about Concepcion. The flowers are blue.

The species of *Nolana* are only valuable as ornamental plants; they are showy when in blossom, and are much like some of the trailing species of *Convolvulus*. The seeds should be sown in a gentle hot-bed in the spring, and the plants when of sufficient size, or about the middle of May, should be finally transplanted to the open ground, where they will flower and ripen seed; or the seeds may be sown at once in the open border in a warm sheltered situation.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*.)

NOLANACEÆ, *Nolanads*, a natural order of Plants, having erect or prostrate stems; alternate leaves without stipules. Flowers usually showy; calyx 5-parted, valvate in æstivation; corolla monopetalous, with a plaited æstivation usually thickened in the tube; stamens 5, equal, inserted into the tube, alternate with the segments of the corolla; anthers oblong, 2-celled, bursting longitudinally; pistil composed of several carpels, either distinct with a single style, or partially combined into several sets, with a single style seated on a succulent disc; stigma somewhat capitate. Fruit inclosed in the permanent calyx, constructed like the pistil; pericarp woody, often a little succulent; seeds ascending, solitary; embryo curved with either straight or double cotyledons in the midst of a small quantity of albumen; radicle next the hilum. This little order is remarkable for the various modes in which its carpels are disposed without ever being consolidated. In one genus there are but 5, and they are distinct; in another there are 20 combined in fours, in a third the combination is irregular though the number remains 20, and in others they are all wholly distinct. The species are all South American, and chiefly from Chili. Their uses are unknown. There are 6 genera and 35 species.

(Lindley, *Vegetable Kingdom*.)

NONATELLIA, a genus of Plants belonging to the natural order *Rubiaceæ*, the tribe *Guettardeæ*, the sub-tribe *Morindeæ*. It has a calyx with an ovate tube, and a 5-toothed permanent limb; a tubular funnel-shaped corolla, with the tube as if it were gibbous, and a 6-lobed limb; the stamens 5, almost inclosed; the stigmas (2?) obtuse; the fruit a globose drupe, furrowed, containing 5 coriaceous 1-seeded pyrene; the albumen horny. The species are shrubs or small trees with glabrous downy oval-oblong leaves, and the stipules combined together more or less, or free. The flowers are white and arranged in a panicle-formed or corymbose thyse.

N. officinalis, Asthma Bush, has ovate acute glabrous leaves, the stipules combined into a 4-toothed sheath, the panicles corymbose; the involucre small, 3-leaved under each flower. It is a native of Guyana, in forests and sterile places. All the parts of this plant, when bruised or dried, give out a slight aromatic odour. The creoles in Guyana call this plant *Azier à L'Asthme*, and it is said to have a powerful influence in subduing attacks of asthma.

There are several other species of *Nonatelia*, all natives of America, but none are used in the arts or as medicines.

(Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

NONIONI'NA, a genus of Fossil *Foraminifera*.

NONTRONITE, a Mineral consisting of Silicate of Iron. This mineral occurs in small nodules imbedded in an ore of manganese. Its colour is pale or greenish-yellow. Fracture earthy. Dull. Opaque. Unctuous to the touch, and very tender. It is found in the department of Dordogne in France, in the arrondissement of Nontron. The following is an analysis by Berthier:—

Silica	44.0
Peroxide of Iron	29.0
Alumina	3.6
Magnesia	2.1
Clay	1.2
Water	18.7

— 93.6

NORFOLK ISLAND PINE. [ARACARIA.]

NOROPS. [IGUANIDÆ.]

NOSE is one of the external apertures of the respiratory system and the organ for the sense of smell. The portion of the nose by which odours are perceived lies deep back in the cavity to which the

external apertures of the nostrils lead; the portion which is prominent upon the face serves merely as the apparatus for inhaling the air which is impregnated with the odour. The most essential parts of the organ are the olfactory nerves, which come off from the olfactory bulbs of the brain [BRAIN], and passing through numerous holes in the ethmoid bone, which is situated between the orbits and above and behind the nostrils, ramify on the extended surfaces of that bone and the turbinated bones which form on each side the chambers of the nose. The sensitive terminations of the nerves are placed on the surface of a delicate and very vascular membrane which lines the whole cavity of the nose, and which is constantly kept moist by the secretion of a small quantity of mucus, in which the odoriferous particles are caught and for a time retained.

The sense of smell varies considerably, both in degree and in kind, in different animals. It is evidently possessed by insects and many others of the lower animals, but the organs by which they exercise it are unknown. In the higher animals its degree of acuteness is in general marked by the extent of surface of the ethmoid and turbinated bones, over which the olfactory nerves are distributed. In man this surface is proportionally smaller than in other animals, in most of which, besides occupying the greater part of the interior of the face, it is increased by peculiar branchings and convolutions of the thin layers of the bones. Each species has also a sense of smell in some degree peculiar to itself; thus herbivorous animals, though possessing the most delicate power of discerning the differences of vegetable odours, have no evident faculty of discriminating those of most animal substances; while the carnivora, on the other hand, can scarcely distinguish any others than the last. Each species has a fine sensibility for those substances which are of the greatest importance to its own existence, and thus obtains at once a knowledge of their presence in places concealed from all the other senses. Man possesses the sense of smell for a very large number of substances, but not in a very acute degree for any of them. The difference appears the greater between him and other animals in consequence of the neglect of the exercise of this sense which is common (except for particular purposes) in civilised society; but the American Indians and some of the northern Asiatic tribes, by their constant practice in hunting, are said to have acquired a power of scent scarcely inferior to that of the dog.

The olfactory nerve is appropriated exclusively to the sense of smell, and is incapable of perceiving pain or any other sensation. Of the peculiarities by which in different animals it is capable of perceiving only certain odours, we know no more than of the nature of those odours themselves, of whose existence we have no other evidence than that of the sense which they affect.

The sense of smell serves as an adjunct to that of taste, and is subservient in most instances to the same purpose, of providing proper and avoiding injurious food for the sustenance of the body. By it many animals seek out their food, and all select from that which they obtain; and much of that compound sensation which we regard as taste is really due to the smell, as for instance the sensation of the flavour of aromatic substances, which is completely lost by closing the nostrils while we are eating them.

For the full perception of odours it is necessary that the particles charged with them should be drawn with some force into the nose, and we may stand for some time in a very strongly-smelling atmosphere without perceiving it if we breathe only through the mouth. The most acute sensation is obtained by the sudden inhalation of a large quantity, or by a succession of short and quick inspirations. [BRAIN; NERVOUS SYSTEM.]

NOSEAN, a Mineral identical with Haüyne. [HAÜYNE.]

NOSTOCACEÆ. [ALGÆ.]

NOTACANTHA, a family of Insects belonging to the order *Diptera*.

NOTACANTHUS, a little-known genus of Arctic Fishes belonging to the section *Acanthopterygii* and to the family *Scomberidae*.

NOTAMIA. [CELLARIEÆ; POLYZOÆ.]

NOTHOSOMUS. [FISH.]

NOTIDANUS. [FISH.]

NOTONECTA, a genus of Insects belonging to the family *Hydrocorisæ*, of the order *Hemiptera*. *N. glauca*, the Water-Boatman, is one of our commonest insects. It is about half an inch long and swims upon its back in order the better to seize its prey.

NOTOPTERUS, a genus of Fishes belonging to the family *Clupeidæ*.

NOVACULI'NA. [SOLENIIDÆ.]

NOVACULITE, a name for a kind of Clay-Slate. [SLATE.]

NOWD. [TRIOLÆ.]

NUCIFRAGA, a genus of Birds known by the name of Nutcracker. One species is a native of Britain. Its classification is difficult. Some of its habits, and the worn appearance of the tail-feathers from climbing about the branches of trees, together with the nesting in hollows of trees, indicate a relationship to the *Picidæ*. Its manners, which are said to resemble those of the Jay, and other circumstances, connected with its food and organisation, bring it into alliance with the Crows, to which family it is generally referred by ornithologists, and so placed as to approximate either to the Woodpeckers or Starlings. Mr. Vigors considers it as assimilating to the latter family, and especially to the genera *Cassicus* and *Barita*. Mr. Swainson makes it

a subgenus of *Corvus* in his sub-family *Corvinae*, placing it immediately after the subgenus *Pica*, and immediately before the genus *Barita*. Prince C. L. Bonaparte arranges it also under the sub-family *Corvinae*, among which it occupies the last place in his 'Geographical and Comparative List,' whilst it immediately precedes the sub-family *Sturninae*. Mr. Yarrell ('British Birds') places it at the end of the Crows, and immediately before the Woodpeckers. Sir W. Jardine ('British Birds') arranges the genus between the Magpie and the Jay. In Temminck's arrangement its place is between the Jays and the Chonghs ('Pyrrhocorax').

The bill is conical, longer than the head, straight, the upper mandible having the culmen rounded, overhanging the lower, both terminating in an obtuse and depressed point; nostrils basal, round, open, concealed by hairs directed forwards. Toes, three before and one behind, the two outer being united at their base. Tarsus longer than the middle toe. Wings long and pointed, the first quill shortest, the fourth and fifth longest. (Gould.)

This genus is generally considered to comprehend only two known species: *N. Caryocatactes* and *N. Acniopila*, which bears a considerable resemblance to it, though it is clearly a distinct species, described and figured in Mr. Gould's 'Century of Birds from the Himalayan Mountains.' Prince C. L. Bonaparte and Mr. Audubon, include the *Corvus Columbianus* of Wilson in the genus *Nucifraga*.

N. Caryocatactes (the *Corvus Caryocatactes* of Linnaeus; *Caryocatactes* of Willughby; *Cassio Noix* of the French; *Ghiandula Nucifraga* of 'Stor. degl. Ucc.'; *Nocciolaja* of Sav. ; Kurz and Langehnüblger *Nussknacker* of Brehm; Tannen Heher (Pine Jay) oder Türkischer Holzschreyer of Frisch; *Notwecka*, *Notkraka*, of the Swedes; *Noddekrige* of the Norwegians; *Notkraake* of Bruunich; *Nussrabbe* of Meyer; and *Alderyn y Cnau* of the Welsh, the *Nutcracker*. Size about that of the Jackdaw, but the tail is longer. Plumage reddish amber-brown; the body, with the exception of the head and rump, dappled with large white spots which occupy the centre of each feather; wings and tail blackish, shot with green; the feathers of the latter (except the two middle ones) tipped with white. Bill and legs brownish-black. Sexes, as in the crows generally, nearly alike. The female is, if anything, a little smaller and her plumage less lively.

The manners of the Nutcracker are said by those who have observed it to resemble in some degree those of the Jay, and some of its habits those of the Woodpeckers. Like the former it feeds on nuts and berries, as well as on the seeds of the pine, of which it appears to be very fond; and like the latter it climbs the trunks and branches of trees, tapping the bark with its bill to start the insects and their larvæ that may lurk beneath, and devour them. They are said to crack nuts much in the same way with the Nuthatch. The nest is formed in the hollows of trees, which the bird is supposed to enlarge after the manner of the Woodpeckers. The eggs are five or six in number, of a yellowish white or gray, with a few spots of bright gray-brown. Temminck states that it sometimes devours young birds and eggs.

Nutcracker (*Nucifraga Caryocatactes*).

It inhabits central Europe. The bird is a rare visitor to Great Britain, and does not appear to have been seen in Ireland. The only one Pennant ever heard of was killed near Mostyn in Flintshire. Montagu mentions one that was killed in Kent, and states that one was seen by an accurate observer near Bridgewater. He also notices two others, which were shot in 1804, one in Devon, the other in Cornwall. Mr. Selby mentions one that was seen in Netherwitton Wood in Northumberland. Mr. Rodd of Penzance gave Mr. Yarrell information of one that was seen on a tree on the banks of Hooe Lake. It is recorded by Dr. Moore as having been shot in Devonshire

near Washford Pyne Moor. Another is said to have been noticed at Pepper Harrow Park, Lord Middleton's seat. Mr. Macgillivray gives instances of its having been shot in Scotland.

Temminck records varieties of pure white, or yellowish white, with deeper spots; sometimes with the wings and tail white.

NUCLEOBANCHIATA, M. De Blainville's name for his fifth order of his second section of his second sub-class (*Paracephalophora Monica*).

M. Rang, who has illustrated the anatomy of some of the families, makes the *Nucleobranchiata*, in his arrangement, the first order of Cuvier's class *Gasteropoda*, and comprises under it some of the *Heteropoda* of Lamarck and the family *Pterotracheæ* of De Férussac.

The following character of the order is given by M. Rang:—

Animal furnished with a foot compressed into the form of a fin, with an acetabulum or sucker (ventouse) on its superior border. Branchiæ pectinated. Both sexes comprised in the same individual.

Often a shell, which is spiral, has a very large aperture, and is vitreous and very fragile.

An operculum sometimes.

M. Rang observes that the Molluscs which he had already, in an anatomical memoir on the genus *Atlanta*, proposed to assemble under the name of *Nucleobranchiata*, borrowed from M. De Blainville, are all pelagic animals which are often met with on the surface of the sea in calm weather, swimming in an inverted position by the aid of their foot, which is compressed into a fin. They never creep, but they have the power of fixing themselves (to floating bodies only) by spreading upon them the sucker of their ventral fin, and at the same moment making a vacuum. The shells are very much sought after in collections on account of their extreme rarity.

Two families, according to M. Rang's arrangement, constitute the order *Nucleobranchiata*.

1. *Pterolidae* (*Pterotracheæ*, Férussac; *Nectopoda*, Blainville; *Urobranchia*, Latreille).

Animal elongated, straight, and horizontal; one or more fins; branchiæ forming, with the other viscera, a nucleus on the dorsal part.

Shell sometimes present, and when it is, incapable of containing more than a very small part of the animal.

Pterolæ (*Pterotrachea*, Forsk.; *Pteroloides* and *Sagittella*, Les.).—Animal very much elongated, gelatinous and transparent, terminated behind by a tail more or less long and pointed; mouth situated at the extremity of a proboscis, and including an apparatus proper for mastication (?). No tentacles, or only two tentacular rudiments carrying the eyes at their external base; one or more fins; nucleus exposed, protected only by a membrane, and always situated below and behind the ventral fin; termination of the intestinal canal and of the organs of generation in a tubercle on the right side.

No shell. (Rang.)

The *Pterolæ* are very common animals in the seas of the warm and temperate zones, and are remarkable for their extreme transparency, which is often interrupted by golden spots.

Pterolæ Frederici.

The other genera in this family are *Carinaria* [CARINARIA], and *Cardiopoda*.

2. *Atlantidae*.

Animal furnished with a well-developed shell, into which it can retire; gills contained in a dorsal mouth-cavity; lingual teeth similar to *Carinaria*. The shell symmetrical, discoidal, sometimes closed by an operculum.

The following genera belong to this family:—

Atlanta, 15 species. [ATLANTA.]

Porcellia (fossil). 10 species.

Bellerophon (fossil). 70 species.

Cyrtolites (fossil). 13 species.

Maclurea (fossil). 5 species.

NUCLEOLITES. [ECHINIDÆ.]

NUCLEUS. [SEED.]

NUCULA. [POLYDONTA.]

NUDIBRANCHIATA, a family of Gasteropodous Mollusca, characterized by the possession of distinct, external, and uncovered gills. The species of this family are all marine, and with few exceptions small in size. They are sometimes with other forms of animals called Sea-Slugs, arising from the fact that, like land-slugs, they are destitute of shells. Their body is usually elongated and soft, and attached throughout its whole length to the foot, or disc, upon which they crawl. They are not unfrequently covered with a cloak, which in some is strengthened with calcareous spines. The head is anterior, and frequently indistinct, bearing one or two pairs of tentacles, the

upper pair of which are placed on the cloak when it is present, and behind them the eyes are situated. But the characteristic peculiarity of these molluscs is the appendages that constitute their breathing organs, placed upon the back, always symmetrically, in plumes, tufts, or papillae, either forming a circle on the central line, or arranged in rows upon the sides.

None of the Nudibranchiate *Mollusca* appear to have been known to the ancients, and even up to the time of Linnaeus they remained, with one or two rare exceptions, entirely unnoticed. In the twelfth edition of his 'Systema Naturae' only seven species were described, scarcely any of which had come under his own observation in a living state. They were placed by him in the class *Vermes*, and referred to the genera *Doris*, *Scyllaea*, and *Tethys*. Otho Frederic Müller paid more attention to them; twelve species are characterised in his 'Zoologia Danica Prodomus,' most of which were afterwards figured with fuller descriptions in the 'Zoologia Danica.' The number of species introduced into the latter work is fourteen. Otho Fabricius has also excellent descriptions of two or three of these molluscs in his 'Fauna Gronlandica.' Other authors contributed a little to increase the number of species; but it was not until the appearance of the celebrated 'Mémoires' of Cuvier, in the 'Annales du Muséum,' that much attention was drawn to this subject. These formed a new era in their history, and the dissections there given furnished the groundwork for those more correct views of their affinities which that distinguished naturalist carried out in the 'Règne Animal,' where the order *Nudibranchiata* was first instituted for their reception. Even at that time however very few species were known, and it is to be regretted that Cuvier was obliged to have recourse to specimens preserved in spirits for his descriptions. So far as their anatomy was concerned this disadvantage was not greatly felt, but the figures and descriptions of their external forms were in consequence very imperfect. The position of this group in relation to the testaceous tribes, from which they had been kept apart in the Linnaean arrangement, began now to be generally acknowledged. Their affinities were further illustrated in the celebrated 'Histoire Naturelle des Animaux sans Vertèbres' of Lamarck, and in the 'Manuel de Malacologie' of Blainville; each of which contributed something to the knowledge of their physiology and relations, but not much to the number of species.

Although little had been done up to this time by British naturalists in augmenting the species of this beautiful family, they have been since the subjects of most accurate and fruitful research; and the Monograph now publishing by the Ray Society on the 'British Nudibranchiate Mollusca,' may be regarded as one of the most remarkable contributions made to the literature of natural history during the present century. This beautiful work contains the description of one hundred species; of these sixty have been added by Messrs. Alder and Hancock, and their forms and anatomy illustrated by a series of coloured plates from original drawings of the authors.

We need not enumerate the additions that have been made to this department of the European Fauna during the last half century; suffice it to say that of late years much attention has been paid to the *Nudibranchiata* by continental naturalists, and several new species have been described. Among the authors treating of the subject may be mentioned Risso, D'Orbigny, Cantraine, Quatrefages, Sars, Lovén, Delle Chiaje, Philippi, and Verany. No account however of the Nudibranchiate *Mollusca* of any one country has yet been published sufficiently complete to form the basis of a comparison with our own. The best are those of Lovén, ('Index Molluscorum Scandinaviae'), who gives thirty-seven species as members of the Scandinavian Fauna; and of Verany, whose Catalogue of the Mollusca inhabiting the Gulf of Genoa ('Catalogo degli Animali Invertebrati,' &c.), includes forty-eight species of *Nudibranchiata*. The Sicilian species described by Philippi are twenty-six ('Enumeratio Molluscorum Siciliae').

But it is not in a numerical point of view alone that our knowledge of this interesting tribe of animals has increased; their anatomy and physiology, their habits and alliances, have lately been studied with care and attention, and many curious facts concerning them have been ascertained. In 1841, the celebrated Norwegian naturalist, M. Sars, announced the discovery that these little creatures undergo a metamorphosis, having on their extrusion from the egg a very different form and character from those which they are afterwards destined to assume. In this first stage of their existence they have the appearance of small animalcules, swimming freely through the water by means of two ciliated lobes, and have their body covered by a nautiloid shell furnished with an operculum. Up to that time nothing approaching to a distinct metamorphosis had been known to exist in any of the true *Mollusca*; the announcement therefore did not fail to excite a considerable degree of interest. The investigation of this curious fact was pursued and extended by M. Lovén and other naturalists, the result of which showed that this peculiar mode of development was not confined to the Nudibranchs alone, but was common to many of the allied families; the metamorphosis however is most striking in those genera which, like the former, do not bear a shell in their adult state.

Professor Milne-Edwards was the first to describe ('Annales des Sciences Naturelles,' 2nd Series, vol. xviii., p. 330) a curious conformation of the digestive organs in the family of the *Eolididae*, the true significance and uses of which have since been the subject of

much controversy. Having observed in a small *Calliopaea*, found at Nice, a system of branched canals connected with the stomach, and extending to the papillae and other parts of the external surface, he thought he saw in this arrangement a blending of the functions of digestion with those of the vascular system, which he in consequence called gastro-vascular. This apparatus he compares to the system of vessels radiating from the stomach of the *Melusidae* on the one hand, and to the caeca connected with the digestive organs of the Nymphons among the *Crustacea* on the other.

During the same year (1842), M. Delle Chiaje had published a figure of his *Eolis cristata* (*Antipora cristata*, A. and H.), in which a similar apparatus of branching vessels connected with the stomach is represented, but without any letter-press description. This view was adopted by M. Quatrefages, who founded on it his theory of the degradation of certain forms of *Mollusca*, which he placed in an order by themselves, and which he called *Phleboterata*. The views of M. Quatrefages, although at first favourably regarded by the French Academy, have since met with much opposition; and in a report made by a Commission to the Biological Society in Paris, which was drawn up by Dr. Charles Robin, it is stated that the Commission regards the idea of Phleboterism as untenable. They consider the ramifications of the digestive system, which M. Quatrefages regarded as a gastro-vascular system, to be two biliary ducts in connection with a divided liver, and that they do not fulfil any other function than the usual one of that organ. They moreover consider that the circulatory system in these animals (*Eolis*, *Acteon*, &c.) is complete, the so-called lacunae being similar to the blood-sinuses known to exist in particular cases throughout all departments of the animal kingdom. They further express an opinion that the facts upon which is founded the doctrine, enunciated by M. Quatrefages, "that the form of the body and the internal organisation are independent of each other," are not real, and that that hypothesis cannot be any longer maintained.

Prior to the appearance of these reports, a series of very excellent papers had been published by M. Milne-Edwards, taking an extended review of the circulatory system in the *Mollusca*. He states his conviction, founded on extensive researches undertaken for the purpose, that the venous system is incomplete throughout the whole of this large division of the animal kingdom. In all instances he finds the true veins more or less imperfect, their place being supplied by a series of lacunae, and the blood in most cases also flowing into the abdominal cavity. The condition of the Nudibranchs he does not consider to be exceptional.

The difference of opinion amongst these distinguished naturalists with respect to the circulatory system, has resolved itself into a very subtle anatomical fact. Both parties admit the existence of large cavities into which the blood flows, but, on the one part, they are considered as mere expansions of the vessels into blood-sinuses, and hence the vascular system is uninterrupted; while, on the other, they are held to be lacunae or gaps in the continuity of the vessels, showing a yet imperfect state in the structure of these organs, and thus forming an intermediate stage in the development of the vascular system, between its first imperfect appearance in the lower animals, and the complete system of closed vessels, only to be found, according to M. Milne-Edwards, in the *Vertebrata*.

The *Nudibranchiata* exhibit a high state of organisation, not much inferior to that of any of the *Gastropoda*. They are all provided with a powerful muscular buccal apparatus, which has, in some instances, appended to it a gizzard, as in *Lamellidoris*, *Goniodoris*, *Idalia*, and others. The oral aperture is always guarded by fleshy lips, and the mouth itself is furnished with a tongue, bearing a spiny prehensile membrane, and occasionally with lateral corneous jaws.

The tongue is composed of a muscular apparatus bearing a stiffish membrane, furnished with small teeth or spines. These are divided into two kinds, central and lateral, distinguished by their position, and generally, when both are present, by a difference in form. The former have been called *Deutes* by Professor Lovén, the latter *Uncini*; and the portions of the tongue on which they are placed, are distinguished by that naturalist, under the names of *Rhachis* and *Pleuræ* respectively. The lingual membrane in the typical *Doridæ*, and in the *Tritoniadæ*, is very broad, and is supplied with numerous spines; it is narrow in *Lamellidoris* and *Acanthodoris*, there being very few spines in each transverse row—in some of the species as few as four. In such, the whole of the lingual spines do not amount to more than 112, while in *Doris tuberculata* there are no less than 6000, and in *Tritonia Hombergii* upwards of 36,000.

The oesophagus, stomach, and intestines are well marked; the former is generally short and passes from the upper surface of the buccal mass.

The stomach varies considerably in size and form; and in the *Dorididae* is frequently buried in the liver. In them, too, there is occasionally, besides a buccal gizzard, an anterior stomach or crop, formed by a dilatation of the oesophagus.

The intestine is always short.

The liver presents two great types of form. In the *Dorididae* and *Tritoniadæ* it is entire (excepting in *Scyllaea*, where it is broken up into six or seven globular masses), occupying its normal abdominal position; in the *Eolididae* it is more or less diffusel. In those genera with an entire liver it is very bulky, pouring the hepatic fluid into the

stomach by one or several large ducts. When the gastric organ is free, as in *R. tuberculata*, it receives only one duct; but in those species with the stomach buried in the liver, the bile enters through several large openings in its under surface.

All the Nudibranchs are hermaphrodites, each individual being furnished with male, female, and androgynous parts. These organs, taken together, are very bulky, and occupy the greater portion of the abdominal cavity. They communicate with a common vestibule, opening upon a nipple-like process on the right side of the body, and always below the mantle, when it is present.

The organs of circulation and respiration consist of central organs of propulsion,—a systemic and portal heart,—arteries, veins, and sinuses or lacunae; and of laminated, branched, or papillose branchim; arranged either on the median line, or along the sides of the back.

The systemic heart lies always immediately below the skin of the back, and consists of two chambers,—an auricle and a ventricle,—inclosed within a pericardium. A large aorta passes forwards, distributing branches to the various organs; and the blood is returned again to the heart in a partially aerated state, only a portion of it having passed through the branchim. The blood system is somewhat modified in each of the three families of the order.

The partial or hepatic circulation is probably provided with a complete system of capillaries, and has, in connection with it, a portal circulation, to which is appended a ventricle or portal heart, that lies under the pericardium, the latter being related to the former as an auricle. This portal heart propels venous blood into the renal and hepatic organs.

The flow of the blood is rapid; the pulsations of the heart varying, in the different species, from fifty to a hundred in the minute.

It is evident, from the state of the circulatory apparatus, that respiration is performed only in part by the branchim. In all the three families, the skin, which is covered with vibratile cilia, acts as an imperfect accessory breathing organ, and thus the blood is returned to the heart in a partially aerated condition.

The nervous system presents a high degree of concentration,—perhaps higher than in any other group of Molluscs,—and is divided into two very distinct portions;—one, the cephalic or excitomotor; the second, the splanchnic or sympathetic; these two portions intercommunicate at several points. The cephalic ganglia are situated at the origin of the œsophagus, and naturally divide themselves into two sets, which may be denominated respectively œsophageal and buccal, or supra- and infra-œsophageal. The latter are attached to the buccal mass; the former are more immediately related to the œsophagus, upon which they are always seated, and about which they, with their commissures, form one or more constricted collars. The two sets of ganglia are also interconnected.

The œsophageal set is composed essentially of three pairs of principal ganglia, however they may be fused or blended together, and of one or two accessory pairs. The principal ganglia are the cerebroid, the branchial, and the pedal; the accessory,—the olfactory and the optic. They are placed symmetrically with regard to the median line, there being one of each pair on either side. The cerebroids are invariably above the œsophagus; they hold a central position, and are united by a very short commissure across the median line, being usually in contact with each other, and, when distinct, are connected by commissures with the branchial and pedal: these two latter of the same side also intercommunicate. The branchials, as well as the cerebroids, are generally above the alimentary tube, and are frequently fused with them, so as to form a single mass on each side of the median line.

The œsophageal ganglia are united to the buccal by two long commissural cords, which pass from the under side of the cerebroids and embrace the gullet, forming a wide collar—the buccal—around that tube. A large sub-œsophageal commissure, passing between the œsophageal ganglia of either side, completes a second or great posterior œsophageal collar. This commissure varies in length, in accordance with the position of the ganglia: if they are all above the alimentary tube, it is long; if partly below, very short.

The cerebroid ganglia give nerves to the channel of the mouth, to the lips and oral tentacles, also to the veil, when it is formed by the fusion of these latter organs: they have likewise attached to them the two pairs of accessory ganglia—the olfactory and the optic.

The branchial ganglia distribute nerves to the mantle or dorsal skin, and to the branchial ganglia of the sympathetic system.

The pedal ganglia send all their nerves to the foot.

The buccal set of ganglia are generally two pairs: the buccal proper and the gastro-œsophageal.

The Sympathetic System is composed of numerous minute variably formed ganglia, connected together by open plexuses of nerves, spread out over the viscera. The principal of these plexuses are—the œsophageal, the gastro-hepatic, the pyloric, the intestinal, the branchial, and the genital. Similar ganglia and nerves have also been found in connection with the heart, arteries, buccal-mass, and skin. This system is connected with both sets of cephalic ganglia, with the œsophageal, through the visceral and branchial centres, and with the buccal by the par vagum, and gastro-œsophageal ganglia.

All the Nudibranchs are provided with auditory capsules, which contain numerous vibratile otoliths in all the genera, except *Embletonia* and a portion of *Eolis* (*Carolina* and *Tergipes*), where there is

only a single large spherical otolithe; the auditory organs thus, in these, retaining their embryonic condition. Eyes are also universally present, and are only a little inferior in organisation to those of the higher Gasteropoda. The dorsal tentacles are the organs of smell, and, judging from their great development, this sense must be more acute in most of the Nudibranchs than it is in any other mollusc, with the exception perhaps of *Nautilus*. Touch undoubtedly resides everywhere in the skin, but is specialised in the oral tentacles and parts about the mouth. The lips and channel of the mouth are probably the seat of taste.

The skin varies very much in thickness in the several groups. It appears to secrete the tenacious fluid that so abundantly exudes from these animals; though that which lubricates the foot is probably provided by a special gland.

As it is seldom possible to study these animals in their native haunts, the little that we know of their habits is mostly gathered from the observation of individuals kept in confinement, and consequently under influences more or less artificial.

Some of the species are nocturnal, but this is not the case with many of the littoral tribes. Such of these as are gregarious on small seaweeds, as *Polycera quadrilineata*, may be observed in a state of activity during the day time, in tide-pools left among the rocks, and apparently enjoying the warm rays of the sun. *Alderia modesta* has a similar habit in more shallow water, becoming almost amphibious: and *Doris bilamellata* is frequently found exposed on rocks left dry by the tide. But the greater number of the species avoid the light, concealing themselves under stones and shelving rocks. Most of the littoral tribes are found near to low-water mark; though some few kinds occur much higher up among the rocks, where they must remain several hours every tide deprived of water. *Doris pilosa*, *Eolis papillosa*, and *Eolis nana*, are generally met with in such situations; even the spawn of these species is frequently left dry by the receding tide.

The Nudibranchs partake largely of the sluggish character of the class to which they belong. Crawling is the usual mode of progression with these animals. This is effected in the manner of the snail, by a series of minute undulations of the under surface of the foot, arising from the alternate relaxation and contraction of the pedal muscles. None of our native species have the power of swimming freely through the water; and we are not aware of any means they have of reaching the surface but by crawling up any substance in contact with it. This they do frequently in confinement, by ascending the sides of the vessel, and then launching themselves, with outspread foot, on the surface of the water in an inverted position. Like most of the other aquatic Gasteropods, they are very fond of floating in this way, which they do without any apparent effort.

While floating in this manner the Nudibranchs occasionally drop suddenly down, suspending themselves from the surface by a thread of mucus, which is fixed to the tail or posterior extremity of the foot. In this way they will let themselves gradually down to the bottom, or remain some time pendent in the water without apparent support; for the thread of mucus is so transparent that it can scarcely be seen. On any of these occasions, either when floating or when suspended, if alarmed, the animal falls at once to the bottom. This is effected by the foot quitting its hold of the mucus, when the animal, being specifically heavier than the water, of course sinks; its specific gravity is, no doubt, increased by the collapse of the parts; but the Nudibranchs are never lighter than the water, even when fully expanded, though in this state many of them are nearly buoyant.

A species of *Pelidia* has been observed the Rev. R. T. Lowe to be phosphorescent.

The Nudibranchiate Mollusca are very sensitive to external influences, shrinking quickly from contact, and withdrawing their organs on the least sense of danger. When crawling on sea-weeds or corallines, they often detach themselves on being disturbed, and drop to the bottom of the water. The *Eolides*, when alarmed, or irritated, erect their papillæ, and sometimes agitate them in a convulsed manner, directing their apices to any source of annoyance; each papilla being endowed with a motion independent of the others. On such occasions urticating filaments are probably ejected from the tips of these organs. The papillæ of *Eolis*, *Doto*, *Antipora*, and some other allied genera, are very slightly attached to the back, and the animals appear to have the power of casting them off voluntarily, in the same manner as a crab throws off its claws, or a star-fish its arms. The organs thus cast off are quickly reproduced when the animal is in a healthy state; and what seems strange is, that in the meantime it does not appear to suffer any inconvenience from the loss of these, as might have been supposed, vital organs.

Their tenacity of life when kept in confinement varies much in the different species, but is greater than in many other marine animals. Any impurity in the water, or too great change of temperature, affects them very sensibly, so that it is difficult to keep them alive in warm weather, particularly those from deep water. The littoral species can sustain a greater change of temperature, and may be kept alive for a considerable time out of water in a moist saline atmosphere, but they die almost immediately when deprived of moisture. Several species have lived for months in the aquarium at the gardens of the Zoological Society, Regent's Park.

Though patient and long-suffering in the endurance of hunger, they are very voracious. The greater number of them are carnivorous; living principally upon zoophytes and sponges. The *Alcyonium digitatum* is a favourite food with the *Tritonia*: and the *Actinia* and *Lucernaria* often fall a prey to the attacks of the *Eolidæ*. These latter indeed do not scruple occasionally to devour the weaker among their own brethren.

Most of the species that are found between tide-marks make their appearance periodically, and the common kinds are generally found in considerable numbers for a time, extending from one to three months, after which they almost entirely disappear. This is their breeding season, and it is generally considered that these animals live mostly beyond low-water mark for a great part of the year and come into shallower water to spawn, as is the case with several tribes of marine animals. It is however more probable that the old ones die off before the young are old enough to be observed. It would thus appear that the duration of their existence is but short.

The following table of the British species, drawn up by Messrs. Alder and Hancock, will supply a list of the British species, and afford at the same time a view of their distribution in depth:—

DISTRIBUTION IN ZONES OF DEPTH.

1. Littoral Zone. 2. Coralline Zone. 3. Deep-Water or Coral Zone.

With the imperfect knowledge of foreign species that we yet possess, it is scarcely possible to arrive at any satisfactory conclusion concerning the general distribution of the *Nudibranchiata* in the different regions of the globe. So far as the observations of travellers go, they appear to be pretty generally diffused throughout all seas and in all climates. The tropical forms are, as usual, larger and more brilliantly coloured than those of colder climates, but the notices of extra-European species are so scanty that we cannot form any idea of their numerical preponderance; nor can we, for the same reason, point out, as may be done in many groups of animals and plants, any particular centres of distribution where they are more especially congregated. With the exception of a few oceanic wanderers, such as *Glaucus* and *Scyllaea*,

which have been met with by almost every voyager, nearly all the *Nudibranchs* that have been described by naturalists visiting the southern hemisphere belong to the *Dorididæ*; and these show a much greater variety of forms than are to be found in the same family with us. It may therefore be inferred that the members of this family are proportionally more numerous in warm climates than in the more northern and colder regions; but were we to take the number of species at present known as a ratio of their preponderance, we should certainly be very wide of the mark, for it cannot be doubted that a great deal of the apparent deficiency of other genera, in comparison with the *Dorididæ*, in foreign countries, arises from the want of proper examination, and from the little attention paid by collectors to the less conspicuous forms. It may therefore be expected that when naturalists visiting foreign countries shall have their attention directed more especially to this beautiful race of marine animals, they will not only collect those conspicuous species which, from their size and colour, obtrude themselves upon the eye, but will search out in their hidden retreats the smaller and often more interesting because more varied forms that belong to the other families.

From the previous table it will be seen that only three families of the *Nudibranchiata* are British. The following families are given in Woodward's 'Manual of Mollusca':—

Doridæ, Sea-Lemons.

Animal oblong; gills plume-like, placed in a circle in the middle of the back; tentacles two; eye-specks immersed, behind the tentacles, not always visible in the adult; lingual membrane with usually numerous lateral teeth; rachis often edentulous; stomach simple; liver compact; skin strengthened with spicula, more or less definitely arranged.

The genera belonging to this family are—*Doris*, *Goniadoris*, *Triopa*, *Egirus*, *Thecacera*, *Polycera*, *Idalia*, *Ancula*, *Ceratosoma*.

*Doris cornuta*.

a, seen from above; b, seen from below; c, side view.

*Doris lacera*.*Doris solen*.*Doris (Onchidoris) leachii*.

a, side view; b, seen from below.

stomach by one or several large ducts. When the gastric organ is free, as in *R. tuberculata*, it receives only one duct; but in those species with the stomach buried in the liver, the bile enters through several large openings in its under surface.

All the Nudibranchs are hermaphrodites, each individual being furnished with male, female, and androgynous parts. These organs, taken together, are very bulky, and occupy the greater portion of the abdominal cavity. They communicate with a common vestibule, opening upon a nipple-like process on the right side of the body, and always below the mantle, when it is present.

The organs of circulation and respiration consist of central organs of propulsion,—a systemic and portal heart,—arteries, veins, and sinuses or lacunae; and of laminated, branched, or papillose branchiæ; arranged either on the median line, or along the sides of the back.

The systemic heart lies always immediately below the skin of the back, and consists of two chambers,—an auricle and a ventricle,—inclosed within a pericardium. A large aorta passes forwards, distributing branches to the various organs; and the blood is returned again to the heart in a partially aerated state, only a portion of it having passed through the branchiæ. The blood system is somewhat modified in each of the three families of the order.

The partial or hepatic circulation is probably provided with a complete system of capillaries, and has, in connection with it, a portal circulation, to which is appended a ventricle or portal heart, that lies under the pericardium, the latter being related to the former as an auricle. This portal heart propels venous blood into the renal and hepatic organs.

The flow of the blood is rapid; the pulsations of the heart varying, in the different species, from fifty to a hundred in the minute.

It is evident, from the state of the circulatory apparatus, that respiration is performed only in part by the branchiæ. In all the three families, the skin, which is covered with vibratile cilia, acts as an imperfect accessory breathing organ, and thus the blood is returned to the heart in a partially aerated condition.

The nervous system presents a high degree of concentration,—perhaps higher than in any other group of Molluscs,—and is divided into two very distinct portions;—one, the cephalic or excitomotor; the second, the splanchnic or sympathetic; these two portions intercommunicate at several points. The cephalic ganglia are situated at the origin of the œsophagus, and naturally divide themselves into two sets, which may be denominated respectively œsophageal and buccal, or supra- and infra-œsophageal. The latter are attached to the buccal mass; the former are more immediately related to the œsophagus, upon which they are always seated, and about which they, with their commissures, form one or more constricted collars. The two sets of ganglia are also interconnected.

The œsophageal set is composed essentially of three pairs of principal ganglia, however they may be fused or blended together, and of one or two accessory pairs. The principal ganglia are the cerebroid, the branchial, and the pedal; the accessory,—the olfactory and the optic. They are placed symmetrically with regard to the median line, there being one of each pair on either side. The cerebroids are invariably above the œsophagus; they hold a central position, and are united by a very short commissure across the median line, being usually in contact with each other, and, when distinct, are connected by commissures with the branchial and pedal: these two latter of the same side also intercommunicate. The branchials, as well as the cerebroids, are generally above the alimentary tube, and are frequently fused with them, so as to form a single mass on each side of the median line.

The œsophageal ganglia are united to the buccal by two long commissural cords, which pass from the under side of the cerebroids and embrace the gullet, forming a wide collar—the buccal—around that tube. A large sub-œsophageal commissure, passing between the œsophageal ganglia of either side, completes a second or great posterior œsophageal collar. This commissure varies in length, in accordance with the position of the ganglia: if they are all above the alimentary tube, it is long; if partly below, very short.

The cerebroid ganglia give nerves to the channel of the mouth, to the lips and oral tentacles, also to the veil, when it is formed by the fusion of these latter organs: they have likewise attached to them the two pairs of accessory ganglia—the olfactory and the optic.

The branchial ganglia distribute nerves to the mantle or dorsal skin, and to the branchial ganglia of the sympathetic system.

The pedal ganglia send all their nerves to the foot.

The buccal set of ganglia are generally two pairs: the buccal proper and the gastro-œsophageal.

The Sympathetic System is composed of numerous minute variously formed ganglia, connected together by open plexuses of nerves, spread out over the viscera. The principal of these plexuses are—the œsophageal, the gastro-hepatic, the pyloric, the intestinal, the branchial, and the genital. Similar ganglia and nerves have also been found in connection with the heart, arteries, buccal-mass, and skin. This system is connected with both sets of cephalic ganglia, with the œsophageal, through the visceral and branchial centres, and with the buccal by the par vagum, and gastro-œsophageal ganglia.

All the Nudibranchs are provided with auditory capsules, which contain numerous vibratile otoliths in all the genera, except *Embletonia* and a portion of *Eolus* (*Carolina* and *Tergipes*), where there is

only a single large spherical otolithe; the auditory organs thus, in these, retaining their embryonic condition. Eyes are also universally present, and are only a little inferior in organisation to those of the higher Gasteropoda. The dorsal tentacles are the organs of smell, and, judging from their great development, this sense must be more acute in most of the Nudibranchs than it is in any other mollusc, with the exception perhaps of *Nautilus*. Touch undoubtedly resides everywhere in the skin, but is specialised in the oral tentacles and parts about the mouth. The lips and channel of the mouth are probably the seat of taste.

The skin varies very much in thickness in the several groups. It appears to secrete the tenacious fluid that so abundantly exudes from these animals; though that which lubricates the foot is probably provided by a special gland.

As it is seldom possible to study these animals in their native haunts, the little that we know of their habits is mostly gathered from the observation of individuals kept in confinement, and consequently under influences more or less artificial.

Some of the species are nocturnal, but this is not the case with many of the littoral tribes. Such of these as are gregarious on small seaweeds, as *Polycera quadrilineata*, may be observed in a state of activity during the day time, in tide-pools left among the rocks, and apparently enjoying the warm rays of the sun. *Alderia modesta* has a similar habit in more shallow water, becoming almost amphibious: and *Doris bilamellata* is frequently found exposed on rocks left dry by the tide. But the greater number of the species avoid the light, concealing themselves under stones and shelving rocks. Most of the littoral tribes are found near to low-water mark; though some few kinds occur much higher up among the rocks, where they must remain several hours every tide deprived of water. *Doris pilosa*, *Eolus papillosa*, and *Eolus nana*, are generally met with in such situations; even the spawn of these species is frequently left dry by the receding tide.

The Nudibranchs partake largely of the sluggish character of the class to which they belong. Crawling is the usual mode of progression with these animals. This is effected in the manner of the snail, by a series of minute undulations of the under surface of the foot, arising from the alternate relaxation and contraction of the pedal muscles. None of our native species have the power of swimming freely through the water; and we are not aware of any means they have of reaching the surface but by crawling up any substance in contact with it. This they do frequently in confinement, by ascending the sides of the vessel, and then launching themselves, with outspread foot, on the surface of the water in an inverted position. Like most of the other aquatic Gasteropods, they are very fond of floating in this way, which they do without any apparent effort.

While floating in this manner the Nudibranchs occasionally drop suddenly down, suspending themselves from the surface by a thread of mucus, which is fixed to the tail or posterior extremity of the foot. In this way they will let themselves gradually down to the bottom, or remain some time pendent in the water without apparent support; for the thread of mucus is so transparent that it can scarcely be seen. On any of these occasions, either when floating or when suspended, if alarmed, the animal falls at once to the bottom. This is effected by the foot quitting its hold of the mucus, when the animal, being specifically heavier than the water, of course sinks; its specific gravity is, no doubt, increased by the collapse of the parts; but the Nudibranchs are never lighter than the water, even when fully expanded, though in this state many of them are nearly buoyant.

A species of *Pelipidia* has been observed the Rev. R. T. Lowe to be phosphorescent.

The Nudibranchiate Mollusca are very sensitive to external influences, shrinking quickly from contact, and withdrawing their organs on the least sense of danger. When crawling on sea-weeds or corallines, they often detach themselves on being disturbed, and drop to the bottom of the water. The *Eolides*, when alarmed, or irritated, erect their papillæ, and sometimes agitate them in a convulsed manner, directing their apices to any source of annoyance; each papilla being endowed with a motion independent of the others. On such occasions urticating filaments are probably ejected from the tips of these organs. The papillæ of *Eolus*, *Doto*, *Antipora*, and some other allied genera, are very slightly attached to the back, and the animals appear to have the power of casting them off voluntarily, in the same manner as a crab throws off its claws, or a star-fish its arms. The organs thus cast off are quickly reproduced when the animal is in a healthy state; and what seems strange is, that in the meantime it does not appear to suffer any inconvenience from the loss of these, as might have been supposed, vital organs.

Their tenacity of life when kept in confinement varies much in the different species, but is greater than in many other marine animals. Any impurity in the water, or too great change of temperature, affects them very sensibly, so that it is difficult to keep them alive in warm weather, particularly those from deep water. The littoral species can sustain a greater change of temperature, and may be kept alive for a considerable time out of water in a moist saline atmosphere, but they die almost immediately when deprived of moisture. Several species have lived for months in the aquarium at the gardens of the Zoological Society, Regent's Park.

Though patient and long-suffering in the endurance of hunger, they are very voracious. The greater number of them are carnivorous; living principally upon zoophytes and sponges. The *Alcyonium digitatum* is a favourite food with the *Tritonia*: and the *Actinia* and *Lucernaria* often fall a prey to the attacks of the *Eolides*. These latter indeed do not scruple occasionally to devour the weaker among their own brethren.

Most of the species that are found between tide-marks make their appearance periodically, and the common kinds are generally found in considerable numbers for a time, extending from one to three months, after which they almost entirely disappear. This is their breeding season, and it is generally considered that these animals live mostly beyond low-water mark for a great part of the year and come into shallower water to spawn, as is the case with several tribes of marine animals. It is however more probable that the old ones die off before the young are old enough to be observed. It would thus appear that the duration of their existence is but short.

The following table of the British species, drawn up by Messrs. Alder and Hancock, will supply a list of the British species, and afford at the same time a view of their distribution in depth:—

DISTRIBUTION IN ZONES OF DEPTH.

1. Littoral Zone. 2. Coralline Zone. 3. Deep-Water or Coral Zone.

With the imperfect knowledge of foreign species that we yet possess, it is scarcely possible to arrive at any satisfactory conclusion concerning the general distribution of the *Nudibranchiata* in the different regions of the globe. So far as the observations of travellers go, they appear to be pretty generally diffused throughout all seas and in all climates. The tropical forms are, as usual, larger and more brilliantly coloured than those of colder climates, but the notices of extra-European species are so scanty that we cannot form any idea of their numerical preponderance; nor can we, for the same reason, point out, as may be done in many groups of animals and plants, any particular centres of distribution where they are more especially congregated. With the exception of a few oceanic wanderers, such as *Glaucus* and *Scyllaea*,

which have been met with by almost every voyager, nearly all the *Nudibranchs* that have been described by naturalists visiting the southern hemisphere belong to the *Dorididæ*; and these show a much greater variety of forms than are to be found in the same family with us. It may therefore be inferred that the members of this family are proportionally more numerous in warm climates than in the more northern and colder regions; but were we to take the number of species at present known as a ratio of their preponderance, we should certainly be very wide of the mark, for it cannot be doubted that a great deal of the apparent deficiency of other genera, in comparison with the *Dorididæ*, in foreign countries, arises from the want of proper examination, and from the little attention paid by collectors to the less conspicuous forms. It may therefore be expected that when naturalists visiting foreign countries shall have their attention directed more especially to this beautiful race of marine animals, they will not only collect those conspicuous species which, from their size and colour, obtrude themselves upon the eye, but will search out in their hidden retreats the smaller and often more interesting because more varied forms that belong to the other families.

From the previous table it will be seen that only three families of the *Nudibranchiata* are British. The following families are given in Woodward's 'Manual of Mollusca':—

Doridæ, Sea-Lemons.

Animal oblong; gills plume-like, placed in a circle in the middle of the back; tentacles two; eye-specks immersed, behind the tentacles, not always visible in the adult; lingual membrane with usually numerous lateral teeth; rachis often edentulous; stomach simple; liver compact; skin strengthened with spicula, more or less definitely arranged.

The genera belonging to this family are—*Doris*, *Goniadoris*, *Triopa*, *Egirus*, *Thecacera*, *Polycera*, *Idalia*, *Ancula*, *Ceratosoma*.

*Doris cornula*.

a, seen from above; b, seen from below; c, side view.

*Doris lacera*.*Doris sola*.*Doris (Onchidoris) Leachii*.

a, side view; b, seen from below.

Tritoniadae.

Animal with laminated, plumose, or papillose gills, arranged along the sides of the back; tentacles retractile into sheaths; lingual membrane with one central and numerous lateral teeth; orifices on the right side.

The genera included in this family are—*Tritonia*, *Scyllaea*, *Tethys*, *Purnella*, *Dendronotus*, *Dota*, *Melidea*, *Lomanotus*.

Tritonia Homborgii.

Scyllaea pelagica.

Tethys leporina.
a, seen from above; b, from below.

Melidea rosea.

b, veil which surrounds the mouth; c, tentacles; g, branchial club-like processes; h, orifices of the organs of generation; i, orifice of the anus; l, foot; a, caudal extremity.

Eolida, or Eolidae.

Animal with papillose gills, arranged along the sides of the back; tentacles obsoletous, non-retractile; lingual teeth 0.1.0; ramifications of the stomach and liver extending into the dorsal papillae; excretory orifices on the right side; skin smooth, without spicula; no distinct mantle.

The genera included in this family are—*Eolis*, *Glaucus*, *Piona*, *Embletonia*, *Prodomotus*, *Antiepa*, *Hermosa*, *Alderia*.

Eolis (Eolida) Cuvieri.

Eolis (Tergipes) lacinulatus.

Eolis (Cacolina) peregrina.

Glaucus (Lanigerus) Etfortii. De Blainville.
a, the mouth; b, the branchial cirri.

Phyllirhoidae.

Animal pelagic, footless (apodal), compressed, swimming freely, with a fin-like tail; tentacles two, dorsal; no branchiae; lingual teeth in a single series; stomach furnished with elongated coeca; orifices on the right side; sexes united.

This family has but one genus, *Phyllirhoe* (*Eurydia*, Esch.).

Elysiadae.

Animal shellless, limaciform, with no distinct mantle or breathing organ; respiration performed by the ciliated surface of the body; mouth armed with a single series of lingual teeth; stomach central; vent median, sub-central; hepatic organs branched, extending the length of the body, and opening into the sides of the stomach; sexes united; male and ovarian orifices below the right eye; female orifice in the middle of the right side; heart with an auricle behind, and traces of an arterial and venous system; eyes sessile on the sides of the head; tentacles simple or obsolete.

The genera of this family are—*Acteonia*, *Cenia*, *Limapontia*.

(We are indebted for the chief part of this article to the yet unpublished introduction to Messrs. Alder and Hancock's work on the 'British Nudibranchiata,' which the authors have kindly permitted us to use. Of this work Messrs. Forbes and Hanley, in the 'History of British Mollusca,' say that "it is one of the most beautiful and perfectly executed works of which zoological science can boast.")

NULLIPORA. [CORALLINACEAE.]

NUMB-FISH, a name for the *Torpedo*. [ELECTRICITY OF ORGANIC BEINGS.]

NUMENIUS. [ABOU-HANNEB.]

NUMIDA. [PAVONIDE.]

NUMMULITES. [FORAMINIFERA.]

NUPIAR, a genus of Plants belonging to the natural order *Nymphaeaceae*. It has a calyx composed of five or six petal-like sepals; the petals 10 to 18, much smaller than the sepals; the stamens indefinite, which, as well as the sepals and petals, are inserted into the base of the torus, so that the fruit appears as if it were superior. The stigmas are from 10 to 18, and radiated. Carpels 10 to 18, inclosed within the torus. The species, like those of the last genus, are elegant aquatic plants, and differ from them in appearance by their yellow flowers. There are several species growing in various parts of Europe and America. Of these the *N. lutea*, Yellow Water-Lily, is the most common. It has a calyx of 5 sepals; the stigmas are entire, 16- to 20-rayed, deeply umbilicated; the leaves ovato-cordate; the lobes approximate; the petioles triquetrous with acute angles. This plant is a native throughout Europe and in Siberia, and is also found in North America. The flowers have a strong smell, like that of brandy, and in many parts of the country the fruits are called Brandy-Bottles. There is a species very much resembling this in all points, except that it is about half the size; it is called *N. pumila*, Dwarf Yellow Water-Lily. It is a native of the North of Germany, Lapland, Norway, and Scotland. There are five or six other species, all of them natives of ponds and ditches of fresh water. There is a North American species, *N. advena*, which grows in salt water as well as fresh, and is very plentiful about Philadelphia and also in Canada.

NUSSIERITE, a Mineral which occurs in crystals almost lenticular. Primary form a rhomboid. It is generally found implanted in mammillary masses. Colour yellow, grayish, or greenish. Streak yellowish-white, grayish. Fracture somewhat conchoidal. Hardness 4.0. Lustre greasy, feeble. Specific gravity 5.0415. Found in the

mine of Nussière, near Beaujeu, department of the Rhône, France. The following is the analysis by Barruel :—

Phosphate of Lead	56.40
Phosphate of Lime	22.20
Chloride of Lead	7.65
Arsenate of Iron	6.50

NUTCRACKER. [NUCIFRAGA.]

NUTHATCH. [SITTA.]

NUTMEG. [MYRISTICA.]

NUTRITION. One of the chief differences between inorganic and organic bodies is, that the former retain their form and other characters by a passive resistance to change; the latter by a constant change of their particles, in which those that in the constant actions of life or by the influence of external agents have been destroyed, are replaced by others similar to themselves. This constant change is effected by the process of nutrition. Nutrition is the last step of the general process of assimilation, by which living bodies convert the materials which they derive from their food into substances like their own, and appropriate the materials thus changed to their own increase or repair. The several nutritive matters received into the living body are variously altered by digestion, absorption, respiration, and by all the other changes which the blood or other fluid undergoes in its passage to the several parts of the frame; these changes constitute the process of assimilation, at the end of which each part of the body abstracts from the general and homogeneous mass of nutritive fluid that which is required for its own growth or repair; muscle abstracting particles to form muscle, nerves from the same fluid abstracting particles to form nerve, and so on.

That a constant change of particles goes on in the majority of the tissues of the living body may be considered certain. It is evidently necessary from the nature of the case; for the living body is exposed to the same external agents as inorganic matter is, and all its own actions are so many more sources of waste to each tissue. Some constant power of repair must therefore be requisite to maintain living bodies in a state of integrity against these constant sources of waste; and that power is exerted in nutrition. Its influence is shown in the fact that the living body retains throughout life, or a great portion of it, its form and composition less altered than the most solid of inorganic matters exposed to similar influences. Within certain limits also, the greater the waste the greater the nutritive supply: thus, for example, by constant exercise the size of the muscles, so far from being decreased, is ultimately increased, the effect of nutrition being not only to replace that which was destroyed, but to supply a certain quantity more. We may clearly observe an application of the same law in the cuticle; that in the palm of the hand is more than twice as thick as that on the back of the arm, yet the former is subject to the most friction; and if the friction of the palm be greatly increased, the cuticle, notwithstanding the greater waste, increases in thickness in a yet greater proportion, so as to defend the subjacent skin from the greater source of injury to which it is exposed.

It is true that when the body does not change in any of its sensible qualities, we cannot be so well assured of any change of particles still going on; but we may reasonably assume that the two parts of nutrition, the removal of old and addition of new particles, which at other times we trace producing either an increase or decrease of the body, as one or the other of them predominates, are exactly balanced. If we examine, for example, the growth of any hollow organ of the body, as the heart, we find that in advancing years from childhood to manhood, it increases not only in its whole bulk, but also in the size of its cavities, and that, at every period of life, the size of the cavities and the thickness of their walls bear nearly the same proportion. Now, if only an addition were made to the exterior of the heart of a child, its whole bulk would be increased, but the size of its cavities would be disproportionately small. We must therefore assume that substance is removed from the interior of the heart, at the same time, though not in exactly the same quantity, that substance is added to its exterior. In like manner, when the heart diminishes in size, as it usually does in persons labouring under consumption, material must be at the same time abstracted from the exterior, and, in rather a less proportion, added to the interior. Whatever of this kind is true of the larger organs must be equally so of the small ones; so long as they preserve the same form and proportions, no change of size can take place without the concurrence of the two processes of nutritive deposition and absorption; when the former preponderates, the part will increase in size—when the latter preponderates, it will diminish; the former, when connected with disease is named Hypertrophy [HYPERTROPHY, in ARTS AND SC. DIV.], the latter Atrophy. [ATROPHY, in ARTS AND SC. DIV.]

The coincidence of these two processes, where any change of size takes place, being thus proved, and their continuance, when no such visible change occurs, being necessary, we may fairly assume that in the latter case, in the state of nutritive equilibrium, they still continue, though their opposite effects being exactly balanced, the ultimate result is not discernible. Popular belief, adopting this idea as one of whose truth there could be no possible doubt, has even assigned the periods of time in which one whole set of particles is

removed and replaced. There is no evidence whatever upon which any such calculation can be made; the period in which an entire change is completed probably varies greatly in different tissues and different external circumstances, and in the bones and teeth it is probable that the particles once deposited are never removed, so long as the animal's size and other characters remain unaltered.

The process of nutrition is concerned in the production of two apparently different results—that of development and that of growth. In development the added particles not merely increase the size of the part, but produce a change in its form or its substance. Thus, the whole body, with all its varieties of tissues, and through all its changes of form, is developed by nutrition, from a small part of a little sac [REPRODUCTION], which, to all appearance, is composed of homogeneous materials. In growth each part increases by the predominant deposition of particles within and around those of which it was previously composed, and similar to them. These two nutritive processes, though in the period of life previous to the adult age they are usually concurrent, may go on independently of each other. Thus the body may be deficient in development, some part of it being monstrous, that is, remaining of the same form as that which it had in the embryonic state [MONSTER], and yet with this defect in form it may increase in size, for monsters are commonly well grown; and, on the other hand, being perfect in development and form, the body, or some part of it, may be deficient in size. A dwarf is an example of a defect of growth; a hare-lip, a cleft palate, an anomalous unossified cartilage, are examples of defects of development: both are defects in the process of nutrition, but the failure is in each in a different direction.

One of the most important facts in regard to the process of nutrition, in both plants and animals, is that all tissues originate in cells. [CELL.] It is by the activity of these cells that all the processes of nutrition are carried on. In plants, they appropriate the inorganic or mineral matters and convert them into organic. In animals, they absorb the nutrient materials supplied by the chemistry of the plant-cell, and are the great agents by which these materials are first made subservient to life, and afterwards thrown off from the body. [ANIMAL KINGDOM; VEGETABLE KINGDOM.] In plants the materials of nutrition are brought to the cells by means of the sap, which consists of water holding other materials in solution. [SAP.] In the higher animals the blood is the great source of the materials from which the cells derive their constituents. [BLOOD.]

Thus the process of organic nutrition is widely different from that by which inorganic masses increase in size, as in crystallisation, which, as in it alone inorganic matter acquires definite forms as it increases, can alone be compared with organic growth. In crystallisation the addition of similar particles is entirely by external apposition, and the crystal has no power of attracting the particles of any matter different from its own. Organic particles (as cells), on the contrary, not only attract particles into their interior spaces, but alter them on their passage, decomposing them from their previous elementary composition, and recombining them into matter like their own.

In healthy nutrition each part appropriates particles similar to its own, or differing according to certain laws of development; in disease, parts frequently appropriate other substances than their own, and all the solid products of various diseases may be regarded as the effects of morbid processes of nutrition. Some of these are formed according to the laws of normal development, and are only morbid because out of place, as cicatrices, adhesions, and the other similar products of simple inflammation; others are produced by the deposition of substances different from any of those already existing in the body, as in the production of various tumours. The former are composed of a tissue similar to cellular tissue, but the injuries of parts are but partially repaired by it, because the new tissue, which is in all cases nearly the same, differs in many of its characters from that which it replaces.

The most complete exercise of the process of nutrition in repairing injuries, whether from accident or disease, is exhibited in the regeneration of parts, but in man and the higher animals there are but few examples of a perfect reproduction of the injured or destroyed tissue. The bones and the non-vascular tissues are probably the only instances in which a tissue destroyed by disease or internal injury is replaced by one similar to itself.

In all these cases of repair or regeneration of tissue, the same process of the effusion of nutritive matter and the several stages of formation and alteration of the cells is gone through which is observed in the first development of the tissues. But the process fails before the higher changes are accomplished, and the repairing tissue acquires only a low degree of development. As far also as they have been at present examined, the various morbid growths appear to be formed on a similar plan, and to proceed from a formation of primary cells.

NUTTAINIA, a genus of *Tribolites*, from the Silurian Strata of Tyrone. (Portlock.) It occurs also in England and Wales.

NUTTALITE, a Mineral which occurs crystallised. Primary form a square prism. Cleavage parallel to the lateral planes. Fracture uneven. Hardness 4.0 to 4.5. Colour gray. Lustre vitreous. Translucent. Specific gravity 2.7 to 2.8. It is found at Bolton in Massachusetts imbedded in calcareous spar. An analysis by Thomson gives :—

Silica	37.81
Alumina	26.10
Lime	16.33
Potash	7.30
Protoxide of Iron	7.89
Water	1.50
	— 97.93

NUT-WEEVIL. [BALANINUS.]

NUT-WEEVIL. [STYCHNOX.]

NYCTAGINACEÆ, *Nyctagins*, a small natural order of Hypogynous Exogenous Plants, belonging to Lindley's Chenopodal Alliance. They have a tubular often coloured calyx, which separates from its base, the latter becoming a hard spurious pericarp. The species are annuals or perennials often with fleshy roots, or shrubs or trees usually articulated at the tumid nodes. *Mirabilis dichotoma*, the Marvel of Peru of our gardens, may be taken as the type of the order. *M. Jalapa* was at one time supposed to be the plant yielding true jalap. This is however a mistake. [CONVOLVULACEÆ.] The roots of the plants of this order are generally purgative. They are natives of the warmer parts of the world in either hemisphere. They are tropical or subtropical. The order is related to *Polygonaceæ*, *Amarantaceæ*, and *Cannabaceæ*. It contains 14 genera and about 100 species. (Lindley, *Vegetable Kingdom*.)

NYCTERIBIA, a genus of Parasitic Insects of the order Diptera. They are closely allied to the Horse-Flies (*Hippoboscida*). They have neither wings nor balancers. Their intermediate legs are connected at the base by a pair of comb-like organs supposed to represent wings. They live on the bodies of bats.

NYCTERIS. [CHEIROPTERA.]

NYCTIARDEA. [NYCTICORAX.]

NYCTIBIUS, M. Vieillot's name for a genus of Birds, the type of which is the Great Ibis, the Grand Caperand Volant de Cayenne of Buffon, *Caprimulgus grandis* of Latham.

The bill is very much depressed and dilated, especially at the base, where it is furnished with bristles, narrowed and hooked at the point; upper mandible with an obtuse tooth on each edge, towards its origin, very much developed in the old bird; lower mandible larger, with the edges curved outwards; gape very wide, reaching to the eyes; anterior toes united at the origin by a small membrane; lateral toes unequal; hallux robust and flattened. First quill shorter than the fifth.

N. grandis, the Great Ibis, is about the size of a stout owl; total length of the bird rather more than twelve inches; of the bill, taken from the corners of the mouth, rather more than three inches; tail a little graduated, and exceeded by the wings when folded by a few

lines; plumage brown, speckled with black, fulvous, and white, principally upon the back, wings, and tail; breast of a deeper brown than the spots; head, neck, and lower part of the body striped transversely with the same colours. In some individuals the plumage is more brown than it is in others.

Its habits are solitary. The bird haunts hollow trees, and prefers those which are near the water. [CAPRIMULGIDÆ.]

NYCTICEBUS. [LEMURIDÆ.]

NYCTICORAX, Mr. Stephens's name for a genus of *Grallatores*, or Wading Birds, belonging to the family *Ardeæ* (Herons and Cranes). Mr. Swainson has changed the name to *Nyctiardea*; but besides the inconvenience arising from the change, the generic name *Nyctiardea* is a hybrid word derived from Greek and Latin roots, and therefore objectionable.

The genus has the bill very strong, rather longer than the head, compressed; upper mandible curved towards the point; maxilla sulcated for three-fourths of its length and emarginated; culmen rounded; tomia of both mandibles straight and sharp, that of the under mandible entering within the upper one. Nostrils basal, longitudinal, placed in the furrow of the maxilla, and covered above by a naked membrane; lores and orbits naked. Legs of mean length, slender. Toes three before and one behind; middle toe shorter than the tarsus, exterior toe connected by a membrane to the middle one as far as the first joint. Claws short, falcated, that of the middle toe pectinated. Tibia naked for a short space above the tarsal joint. (Gould.)

This form, of which several species are now known, is widely diffused. Species occur in Europe, Asia, Africa, and America; and have been found in Manila, New South Wales, and Tierra del Fuego.

N. Europæus, Stephens; *N. Gardeni*, Jard.; *Ardea Nycticorax*, Linn. In the old birds there is no difference in that stage of life between the sexes. Top of the head, back, and scapulars, black with bluish and greenish reflections; three white very narrow feathers, 6 or 7 inches in length, taking their origin at the back of the head just above the nape, and descending backwards; lower part of the back, wings, and tail, clear ash-colour; forehead, space above the eyes, throat, front of the neck, and lower parts, white; bill black, yellowish at the base of the lower mandible; iris red; feet yellowish-green; length rather more than 1 foot 8 inches.

In the young of the year the three long nuchal feathers are absent; top of the head, nape, back, and scapulars, of a muddy brown, with longitudinal bright-red dashes on the centre of each feather; throat white, with small brown spots; feathers of the front and sides of the neck yellowish, with wide brown borders; coverts of the wings and quills ashy-brown, marked with great yellowish-white spots at the extremity of each feather; lower parts clouded with brown, white, and ash-colour; middle of the belly whitish; arête and point of the bill brown, the rest greenish-yellow; iris brown; feet olive-brown.

In this stage it is the *Ardea maculata* and *A. Gardeni*, Gmel.; Le Pouarre and Le Pouarre de Cayenne, Buff.; Scarza Cenerino, Stor. degl. Ucc.; and Spotted and Gardenian Heron, Lath. Indeed ornithologists have described it as a distinct species in almost every progressive stage of plumage.

In the old state the bird is the Bihoureaux, Roupeau, and Heron Gris of the French; Scarza Nitticora of the Italians; Der Nacht-Reiher and Aschgräue Reiger mit 3-Nacken Federn of the Germans; Blaauw-wak of the Netherlands; Night-Heron and Lesser Ash-coloured Heron of the British.

Great Ibis (*Nyctibius grandis*).Common Night-Heron (*Nycticorax Europæus*).

Front figure, adult; back figure, young.

The Common Night-Heron appears to affect high situations by day, and in the evening resorts to the low lands, marsh, or river-side, for

its food, which consists of fish, for choice, and in their absence of frogs, mice, and even insects. The old French quatrain says:—

"Le Bihonreau, espece de Heron,
Es haults rochers et es collines hante.
Sa forme est peu au Heron differente.
Sus le rivage il vit, et environ."

The general truth of this picture of its habits is borne out by modern observation; and its fondness for perching on high situations is attested by Mr. Gould, who received a fine adult specimen which had been shot from a high tree in the gardeus at Frogmore, near Windsor. The nest is built of sticks on the topmost branches of trees, and the bird breeds, like the Common Heron, in society. Where there are no woods the nest has been found among reeds. The eggs, four in number, are pale greenish-hine.

The distribution of this bird is very wide. In these islands it is a rare visitor. In the last editions of Pennant, the specimen in the Leverian Museum, which was shot near London, is noticed, and the editor had heard of another having been killed in Suffolk; and Dr. Latham, in a note to the same work, records one that was killed at Cliefden in Buckinghamshire. He adds that it is common in Spain and about Gibraltar, and that it inhabits China and India; and falls into the general error, as it now seems to be considered, that the North American species is identical with it.

Montagu notices a specimen shot on the Ouse near Amphill, and another (a young bird, Gardenian Heron) was shot near Thame, in Oxfordshire, by Lord Kirkwall. Bewick took his figure from a specimen in the Wycliffe Museum. Two came under the observation of Mr. Selby:—one shot by the Earl of Home, at the Hirsell, near Coldstream, in 1823; and another, now in Sir W. Jardine's museum, killed about two years afterwards in the neighbourhood of Dnmfries. It appears in Mr. Thompson's Irish List. He saw a specimen in Dublin which, he was informed, was sent to the bird-preserver, in whose possession it was in a fresh state, from Letterkenny, early in 1834.

NYCTINOMUS. [CHEIROPTERA.]

NYCTIORNIS. [MEROPIDÆ.]

NYCTOPHILUS. [CHEIROPTERA.]

NYLGHAU. [ANTILOPEÆ.]

NYMPHÆACEÆ. [CONCHACEÆ; CONCHIFERA; MALACOLOGY.]

NYMPHÆA, a genus of Plants the type of the natural order *Nymphæaceæ*. It has a calyx of 4 sepals girding the base of the torus. The petals, 16 to 28, adnate to the torus, elevated about the ovary and covering the same, and therefore at first sight appearing inserted into it. The stamens are numerous, disposed in many series, and inserted in a similar way above the petals. There are upwards of 20 species of this genus described. They have all large floating leaves, with white, red, or blue flowers, which appear at the surface of the water.

N. carulea, Blue Water-Lily, has peltate nearly entire leaves without dots, glabrous on both surfaces, and 2-lobed at the base, the lobes free; the ather with an appendage at the apex; the stigmas 16-rayed. This plant is a native of Lower Egypt in rice-grounds and canals about Rosetta, Damietta, and Cairo. The flowers are very fragrant, and from its frequent representation in the sculptures of Egypt, it appears to have been regarded as a sacred plant by the ancient Egyptians.

N. edulis, the Eatable Water-Lily, has peltate broad oval entire leaves, with the under surface pubescent. This plant is a native of the East Indies, in wet fenny districts. Its flowers are small, and white or reddish. Like all the species, it has large pear-shaped roots, which contain an abundance of starch, and they are consequently used as articles of diet. The seeds also of a species nearly allied to this, the *N. rubra*, which has deep-red flowers, are also used as an article of diet. Its flowers also are held in superstitious veneration by the Hindoos in the districts of the East Indies in which it grows.

N. pubescens has peltate, sharply-toothed leaves, orbicularly reniform, with the under surface pubescent and spotted, and the lobes roundish. It is a native of the East Indies, Malabar, Moluccas, Tranquhar, Ceylon, Java, and has been also found at Waree and Acra on the western coast of Africa. This plant is called Lotos throughout India, and is held sacred by the Hindoos. Its flowers are of a beautiful white. They expand during the day and close at night, and exhale a strong vinous odour.

N. Lotus, the Egyptian Lotos, has peltate leaves, sharply serrated; the under surface is pilose at the nerves, and pubescent between them. This plant is a native of Egypt, and grows in slow-running streams, especially in the Nile near Rosetta and Damietta, and is found in rice-fields during the time they are under water. It has large white flowers, with the sepals red at the margins. The roots are large, tuberous, and eatable. The seeds dried were made into a bread by the ancient Egyptians, and the roots were employed in the same manner. This plant is regarded with superstitious veneration by the Egyptians. It resembles the Nelumbo of the Hindoos, a plant belonging to the same natural order, and called the True or East Indian Lotos. The latter has always been regarded as the emblem of fertility. Lotos is a name applied to various plants by the ancients. The Lotos of the *Lotophagi* was the *Zizyphus Lotos*; that of Homer and Dioscorides, a species of *Lotus*, or *Trifolium*. The Lotos of Hippocrates is the *Celtis Australis*; and the Italian Lotos is the *Diospyrus Lotos*.

N. alba, the Common White Water-Lily, has cordate quite entire

leaves; the stigmas 16-rayed, the rays ascending. This plant is native of ditches, ponds, and lakes throughout Europe, and is abundant in Great Britain. The flowers are white, and, according to Linnæus, open themselves in the morning at seven o'clock, and close them at four o'clock in the evening. This plant is very deservedly highly esteemed as the most beautiful of European plants. It is frequently accompanied with the yellow water-lily, and the two together give an exceedingly graceful appearance to the waters they occupy. The roots of the White Water-Lily contain an astringent principle, which renders them useful in dyeing. They also contain starch, and on this account are fed on them, although other animals reject them. The whole plant was at one time regarded as medicinal, but is now seldom employed by medical men, although it has a popular reputation as a remedy in many diseases. There is a variety of this plant occasionally met with, called *N. alba minor*, which has smaller flowers and leaves than the species.

N. odorata, Sweet-Scented Water-Lily, has cordate quite entire leaves, with the nerves and veins on the under surface very prominent; the stigmas 16 to 20-rayed; the rays erect, inflexed at the top. This plant is a native of North America from Canada to the Carolinas; it is found in deep ditches and slow-running rivers. This plant is often confounded with the European Lily, but it is quite distinct. Its flowers are white tinged with red, very fragrant; they open in the morning, and close at noon. The root is astringent, and much more powerful than the last species. It contains tannin and gallic acid, and a decoction of the root gives a black precipitate with sulphate of iron. The root is used by medical men in America as an astringent, and is employed by the people for making poultices.

NYMPHÆACEÆ, a natural order of Aquatic Plants, with floating leaves and solitary flowers, found in all the hot and temperate parts of the world. They usually have 4 sepals and many petals, which latter gradually contract into stamens, indefinite in number, and either hypogynous or adherent to the sides of the carpels. The ovary is superior, divided internally into numerous cells, to whose sides adhere many seeds, containing an abundance of albumen and a small embryo external to it: the stigmas radiate from the apex of the ovary. The order differs from *Ranunculaceæ* in the consolidation of its carpels, from *Papaveraceæ* in the placentation not being parietal, and from *Nelumbiaceæ* in the want of a large truncated disc containing monospermous achenia. The stems of these plants are fleshy rhizomata, rooting in the mud at the bottom of the waters in which they grow; and their woody tissue is so loosely disposed among the cellular, as to

White Water-Lily (*Nymphaea alba*).

1, the ovary, on which are seen the scars left by the petals and stamens removed from it; 2, a seed.

have given rise to a controversy concerning the real nature of the plan on which it is arranged, most writers considering, with us, that it is exogenous, while others refer it to the endogenous type. The species of this order are generally plants of great beauty, either the flowers or the leaves being of unusual size. The White Water-Lily (*Nymphaea alba*) [NYMPHÆA] and the Yellow (*Nymphaea luteum*) [NYMPHÆA] of our own rivers and ponds are among the finest specimens of floral development in these latitudes; in other countries both their size and colour are augmented, brilliant tints of blue and crimson being added to the pure white of our native species, and the most delicious odour being also emitted. In Demerara grows the *Victoria regia*, whose flowers have a diameter of 15 inches, while the leaves are as much as 6½ feet across. [VICTORIA.] In the East Indies the *Euryale ferox* emulates the *Victoria* in the size of the leaves, but its flowers are small and inconspicuous. [EURYALE.] In both these plants the farinaceous seeds are used for food. *Barclaya* is another genus belonging to this order. The five genera contain about 50 species.

NYMPHICUS. [PHTYALIDE.]

NYROCA. [DUCKA.]

NYSSONIDÆ, a family of Hymenopterous Insects belonging to the section *Pesores*. This family is thus characterised by Latreille:—Labiæ either entirely or for the most part hidden; the maxillæ and labium do not form a proboscis; mandibles without any internal notch; head moderately large; abdomen either conical or somewhat ovate, and with a short peduncle; antennæ filiform, with the first joint but slightly elongated.

The principal character which distinguishes this family from its congeners is the absence of a notch on the inner side of the mandibles. It contains the following genera:—*Astata*, *Nysson*, *Oxybelus*, *Nüela*, and *Pison*.

In the first of these genera, *Astata* of Latreille, the eyes are large and of an oval form, converging at the vertex, and in the male sex meeting; the mandibles are bifid at the apex; the anterior pair of wings have one narrow, short, and appendiculated marginal cell, and three submarginal cells, of which the first is narrow, longitudinal, divided obliquely near the middle by an obsolete nervure that runs from the base of the stigma to the middle of the first transverso-cubital; the second submarginal cell is triangular, and receives both the recur-

rent nervures; the third is very distant from the apex of the wing; the legs are moderately long and very spinous in the female.

Astata Boops (Sohrank) is about half an inch in length; the head, thorax, and legs are black, and the body is red, with a black tip and a small spot of black at the base. This species is found in various parts of England and on the Continent, but appears to be local. The female builds her nest in the ground, and is said to select the burrow formed by some other insect for the purpose. Mr. Shuckard, in his excellent work on the 'British Fossorial Hymenoptera,' states that the males are much more abundant than the females; and whenever he succeeded in capturing the latter with its prey, he always found it to consist of the larvae of *Pentatoma bidens*. Mr. Curtis has captured specimens laden with the larvae of *Pentatoma prasina*, and a little bee (*Epeolus variegatus*) is preyed upon by the *Astata* to feed her larvae.

In the genus *Nysson* (Latreille) the anterior wing has three submarginal cells; the second cell receives both recurrent nervures, and is petiolated; the first submarginal cell is considerably longer than the two others; the mandibles are terminated by a simple point; the eyes are oval and prominent. Five species of this genus are recorded as British.

The genus *Oxybelus* (Latreille) is distinguished by the eye being oval and slightly prominent; the antennæ short and arcuated; the anterior pair of wings have a narrow marginal cell slightly appendiculated, and one submarginal cell, which receives a single recurrent nervure; abdomen short. Eight species of this genus are described in Mr. Shuckard's work. The most common is the *O. uniglutinis*, an insect about a quarter of an inch in length; black, with a row of white spots on each side of the abdomen, and with the tibiae and tarsi red. It preys upon flies, which it carries by its hind legs to deposit in the burrow in which the young are reared.

The genus *Nüela* (Latreille) differs from the last in having the antennæ longer and nearly straight, and with the second and third joints of equal length. Like *Oxybelus*, it has but one submarginal cell; the mandibles are bifid at the apex; there are no protuberances on the thorax, nor spines on the legs.

In the genus *Pison* (Spinola) the eyes are emarginated; there are three submarginal cells to the anterior pair of wings; the second cell is very small, petiolated, and receives two recurrent nervures.

O

OAK. [QUERCUS.]

OAK-BEAUTY. [BUXON.]

OBSEIDIAN (called by the Romans Obsidianus Lapis; by the Greeks, *ὀψίδιον λίθος*), a Mineral, probably of volcanic origin, and so called, as stated by Pliny ('Hist. Nat.,' xxxvi. 26) from a person named Obsidius, who first found it in Ethiopia. This substance occurs in beds, in large and rolled masses, and in small grains. Its structure is compact. Fracture large, conchoidal. Hardness 6 to 7. Scratches glass. Brittle. Colour greenish, grayish, or brownish black. Lustre vitreous. Opaque. Translucent on the edges. Specific gravity 2.34 to 2.39.

Obsidian in the form of little grains of the size of peas, and of a pearly white colour, and consisting of very thin concentric layers, has been found at Marekan in the Gulf of Kamchatka. This variety has been called *Marekanite*.

Pliny says that gems and sometimes whole statues were made of obsidian; he also speaks of four elephants of obsidian which were dedicated by Augustus in the Temple of Concord. Statues were also made of it by the Egyptians.

Before the blow-pipe, it swells up strongly, and fuses into a transparent glass. It occurs in veins and beds traversing rocks, in many parts of Europe, Asia, and America, and in the neighbourhood of most volcanoes.

The analyses of different varieties of Obsidian differ considerably: the following analyses of Marekanite, and of Obsidian from Cerro de las Navajas, are by Klaproth and Vauquelin respectively:—

	Marekanite.	Obsidian.
Silica	77.50	78.0
Alumina	11.75	10.0
Soda	7.00	—
Potash	—	6.0
Oxide of Iron	1.25	3.6
Lime	0.50	1.0
Water	0.50	—
	—98.5	—98.6

OCEANIA. [ACALEPHÆ.]

OCEANUS. [NAUTILIDÆ.]

OCCELLARIA. [POLYPTARIA.]

OCELOT. [FELIDÆ.]

OCCHINACEÆ, a small natural order of Plants nearly allied to *Rutaceæ*, and remarkable for their fleshy carpels being elevated upon an enlarged succulent receptacle. They are shrubs, inhabiting the

tropics of either hemisphere, with shining evergreen leaves, showy yellow flowers, with 5 or 10 stamens, whose anthers open by pores at the point. They appear to be possessed of tonic and astringent qualities. The order contains 6 genera and 82 species. It is related to *Rosaceæ*, *Geraniaceæ*, *Simurabaceæ*, and *Xanthoxylaceæ*.

OCHRA, or OKRO, a Plant of which the fruit is used as a vegetable in the West Indies, the United States, and in South America, and which is remarkable for the similarity of its name to the vegetable called Ochra by the Greeks, but which has not been ascertained by botanists. The names by which the produce of the New World is distinguished in the works of Maregrave and Piso are Quingombo and Quigomhe, and in the later works by that of Gombo, and Gombaut, or Gombeau. It is possible therefore that a classical name, which was not otherwise engaged, may have been applied to a new vegetable, and, as has been the case in many instances, without any attempt being made to identify the plant named with that which had been described by classical authors. This plant is the *Hibiscus esculentus* of authors. [HIBISCUS.]

OCHRE, Hydrated Sesquioxide of Iron. [IRON.]

O'CREA. [STIPULES.]

OCTO'CERA, M. De Blainville's name for the first family of his order *Cryptodibranchiata*, containing the genus *Octopus*.

OCTODON. [HYSTRICIDÆ; MURIDÆ.]

OCTOLASMIS. [CIRRIPEDIA.]

OCTOMERIS. [CIRRIPEDIA.]

OCTOPODA, or OCTOPODIDÆ, a family of Cephalopodous Mollusca, to which the genera *Octopus*, *Eledone*, *Phidippus*, and *Argonauta* belong. It has the following characters:—Animal short, bursiform, ordinarily deprived of fins; head very distinct; 8 sessile arms, generally nearly equal, and furnished with simple suckers; naked or testaceous; no internal testaceous rudiment, but only two small cartilaginous pieces in some species.

Professor Owen, in common with other zoologists, divides the Octopods into two groups or families, the *Testacea* and the *Nuda*.

The *Testacea* consist of the genera *Argonauta* and *Bellerophon*. [BELLEROPHON; CEPHALOPODA.]

The *Nuda* comprise the genera *Eledone* and *Octopus*.

Argonauta (Linnaeus).—The best known species of this genus is called the Paper-Nautilus, or Paper-Sailor. It is the *Nautilos* or *Nautalos* of Aristotle. ('Hist. Anim.,' iv. l.) The *Argonauta* has the following characters:—Body oblong, rounded; mantle adhering posteriorly to the head; first or dorsal pair of arms dilated and

membranous at the extremity. Funnel without a valve, but articulated at its base by two ball-and-socket joints to the inner sides of the mantle. Branchial hearts with fleshy appendages. No internal horny or testaceous rudiments; but an external monothalameous symmetrical shell, containing, but not attached to, the body of the animal, which also deposits its eggs in the cavity of the shell. (Owen.)

Argonauta Argo has been from the earliest periods an object of great interest to zoologists, in consequence of the accounts of its sailor-like habits handed down to us from the ancients—we need only refer to the statements of Aristotle, Pliny, Ælian, Oppian, and others—and in consequence of the difference of opinion entertained with regard to the inhabitant of the shell by naturalists; some holding that the Cephalopod found in it was a mere parasite, or, even worse, a pirate that had destroyed the legitimate owner and possessed himself of the shell; and others, that the animal was the lawful possessor and original constructor of it.

Among those who supported the former opinion were Lamarck, De Montfort, Ranzani, Poli, and De Ferrussac, to say nothing of Cuvier, the inclination of whose mind evidently was that the shell belonged to the animal, though he only designates the opinion of those who held the contrary as extremely problematical. Professor Owen appears to have been early inclined to this view of the subject. Dr. Leach, M. Rafinesque, M. De Blainville, and Dr. Gray stand conspicuous among those who denied that the *Ocythoe* found in the shells of the genus *Argonauta* of Linnaeus was the constructor of the shell.

The reasoning of those who held that the Argonautic Cephalopod was the constructor of the shell appears to have been based upon the numbers found always fitting the shell, and, in the case of Poli and De Ferrussac, upon the supposed discovery of the animal and shell in the egg.

Those who opposed these views, or still doubted, were struck with the supposed anomaly which would be manifested if the cephalopod really were the natural inhabitant. Evidence that the animal was not affixed to the shell had been given over and over again, till it became largely cumulative, and had never been controverted. The animal had been seen to quit it when alive, and to fall out when dead by its own weight upon reversing the shell. How then was the shell to be secreted? Again, the specimens found in the greater majority of the shells were apparently females, and placed upon a great mass of eggs, which filled up at least all the spiral part of the shell; and on these the body of the animal rested. An *Octopus*, nearly allied to *Ocythoe*, was caught in the Madras Roads with its ventricose body firmly imbedded in a ghee-bowl; and *Octopus arnarius* had been found in a *Dolium*. These and other facts, with which we will not weary the reader, seemed very powerful; but if any credence is to be given to the carefully-conducted experiments of the lady whose valuable observations we shall now proceed to notice (and, after strict scrutiny, we see no reason to view them with the slightest suspicion), the question is now set at rest, though it was not by Poli, who must, if this lady's experiments were correctly made and accurately reported, have been in error when he supposed that he saw the animal and shell in the egg.

In 1836 Madame Jeannette Power laid before the academy at Catania her 'Osservazione Fisiche sopra il Polpo dell' Argonauta Argo,' in which, after a long and careful course of inquiry, she declared the following results:—1st, that the cephalopodous mollusc usually found therein is the constructor of the shell which it inhabits; 2nd, the clearing up of the doubts with regard to the first development of its eggs; 3rd, new facts respecting its habits.

In order to obtain the data from which Madame Power came to her important conclusions, she had cages constructed which were eight palms long and four palms broad, with a convenient interval (three or four lines) between the bars, which allowed the water to enter freely when placed in the sea, whilst the escape of the animal was prevented. Madame Power placed these cages on a shallow bottom in the sea near the citadel of Messina, where she could examine them undisturbed, and inclosed in them a number of living Argonauts, which she supplied every two or three days with food, consisting of naked and testaceous molluscs.

The following is this lady's description of the cephalopod of the Argonaut:—"It is furnished with eight arms, having on each two rows of suckers; the first two arms are more robust than the others, and should be so, because they serve as masts to support the sails, which, spread out, act before the wind as such. At the base they have on the inferior sides the double row of suckers, like the other six; but from the inferior row, at about an inch from the base in adults, a rather furrowed membrane begins to develop itself, which extends as far as the tip of the arm, and, holding it bent, it can no longer execute the office of a rowing arm, but is employed by the animal as a sail. These sails are so large that, when turned backwards and pressed against the shell, they can entirely cover and protect it. Thus, as far as I can conclude, the true office of these sails is exactly that of keeping themselves applied to the shell at all times, in reserve for the moment when the animal, coming to the surface of the water, removes them, and, spreading them, raises them as sails. In fact, the series of suckers of the sail-arms, when the membrane of the sails is wrapped about the shell, is placed exactly over the keel of it in such a manner that each sucker corresponds to each point in which the

ribs of the shell terminate, until they reach the two margins of the spiral."

Madame Power compares these sails with the two wing-like lobes of the mantle of *Cypræa* [CYPRÆIDÆ], not only from the manner in which they cover the shell, but because she has reason to believe that the formation of the shell is the result of a transudation from the membrane of the sails, the corrugations of which, in secreting the calcareous matter, may be the cause of the ribbed form of the shell.

This consideration, she remarks, may weigh in obviating the difficulties of those who cannot imagine how a shell containing a cephalopod should present no resemblance with the folds of the animal compressed within it. For if they would consider it the result of a calcareous deposition of the membrane of the sails, they would find not only the series of little points corresponding to the suckers, which adapt themselves to the keel of the spiral, but an explanation of the disposition of the ribs, and of the smooth and paper-like condition of the shell.

The sail, when spread out, presents, according to Madame Power, a silvery surface, speckled with concentric circles of spots, with a black spot in the middle, surrounded with a beautiful gold colour; this and the vicinity of the suckers along the keel and the spiral assume a purple colour so vivid that it approaches that of the *Janthina*. The mouth, the head, the bag, and the branchiæ, did not present Madame Power with any novelty beyond what had been already well described by naturalists, and which is common to the Cuttles and the Calamaries; but she makes two observations with regard to the funnel, which she believes to be new: that it fulfils the office of a pump or proboscis rather than that of a funnel, and that the animal employs it, when swimming with its arms on the surface of the water, as a helm, elongating it in front of the widest part of the shell, at the same time that the spiral serves as a prow.

"Reflecting," says Madame Power, "on the delicacy and fragility of the shells, and wishing to trace the cause of their being so rarely seen broken, I determined to touch one whilst its poulp, or animal, was within; and taking it dexterously between my fingers, to learn what degree of flexibility it would admit, I discovered that it was extremely pliant, so much so as to admit of the two extremities of the great curve being brought into contact without breaking; and indeed shells so fragile ought to possess this flexibility, in order that they might not be continually liable to be broken in pieces by the restless and uninterrupted movements of their poulps, as well as by the shocks which they would be likely to suffer in the depths during a stormy sea. In this case it would prove very unfortunate for them, as they are not capable of forming an entire new shell.

"Having ascertained the flexibility of the shell whilst the living animal was within, I immersed some empty ones which had been exposed to the air for some time in fresh water, and, at the end of three days, found them as pliant and flexible as at first.

"As regards the connection between the animal and the shell in which it is housed, I have not found any ligament or muscle which connects them; while the sac is simply held by the turning of the end of the spiral, from which it may be easily separated; and it appears that the tight adhesion of the sac against the internal surface of the ribs of the shell is sufficient to hold it attached. Moreover the external superposition of the sail-arms keeps the shell firmly upon the poulp."

Madame Power states that *Argonauta Argo* in its natural state is to be found in the neighbourhood of Messina, and even in the port, almost all the year through, in larger or smaller numbers. Their true season she considers to be autumnal, or in the months of September, October, and November. It may be, in her opinion, either because the current brings them at that time, or that food is more plentiful, or because it may be the season of their fecundation. They are seen in the most muddy parts of the port and where the anchored boats lie thickest. When the Argonauts are on the surface of the water, if they observe any person, they fold the sail-arms over the shell and stow the rowing-arms inside it: then they sink to the bottom. If they are beneath the surface, they eject ink, like other cephalopods, to make the water turbid, thus gaining time to hide themselves in the mud.

Those in the cage, when closely pursued, would, after ejecting their ink, squirt out water from the tube, and then shrink into the shell, which was covered with the sails. At first the appearance was silvery, but instantly afterwards a purple colour would spread along the suckers over the whole of the keel and spiral, and concentric circles of spots would show themselves upon the two surfaces.

During calms and when the water was quiet, they would, if not conscious of being observed, exhibit their many beauties, rowing along, their full sails tinged with elegant colours, resting the extremities of the sail-arms on the two sides of the shell or embracing the shell with them. Sometimes, when pressed by hunger, they would come almost to the surface of the water, and when Madame Power offered them food, they would snatch it out of her hands and greedily devour it.

With regard to the formation of the shell by the young Argonaut, Madame Power repeated the experiments of Poli in the company of Dr. Anastasio Cocco of Messina and other persons, but nothing more was found than a group of eggs in each individual, similar to millet-

ecoda, perfectly white and transparent, attached by filaments of a brilliant glue to a common stem of the same substance. Three days after the first observation, on visiting an Argonaut, little pouls were found in the shell of the parent, developed, but without shell, and resembling worms, having at the inferior extremity a spot of a brown colour, with some smaller spots disposed laterally. These, when examined by the microscope, were considered to be the viscera of the animal. After the three days the young pouls began to exhibit bud-like prominences, with two rows of obscure points, which were the rudiments of the arms and suckers. The other arms began to be distinguishable some days after the sailing-arms, and on the sixth day they had already formed the first lamina of the shell, which was exceedingly soft, yielding to the least pressure of the finger. The eggs are attached to the interior of the spire, and when excised remain between the roof of the spire and the mantle of the mother. From these observations Madame Power concludes that the newly-born pouls have no shell. The observations of Poli therefore do not correspond with the experiments made by Madame Power; and the lady adds, with characteristic modesty, "If I were not speaking of so celebrated a man, I should venture to say that the internal membrane of the egg was mistaken by him for the supposed rudiment of the shell."

Madame Power, wishing to discover whether the little pouls could, without extraneous aid, begin to work the structure of its shell, or whether the parent assisted in the original formation, cautiously cut off the spire of divers Argonauts at the time of their fecundation. In the direction of its axis she found in one a little new-born pouls rolled up near the apex. Upon attentive observation she perceived that between it and the bottom of the spire of the parent-shell there was a thin membrane, disposed in the same form as the curve of the spire, and fitted to the rolled-up little pouls, as if the gluten in which the whole infant mollusc was embedded, pressed between it and the end of the spire, became consolidated into a fine membrane in the same form as the spire, and embraced the young pouls.

In September, 1835, Madame Power inclosed in her cage some Argonauts at the time of their fecundation, taking care to examine them every fourth day carefully, for their irritability is such that they die if handled much. They were placed in a basin, and the observer was so posted that they could not see her.

On the 14th Madame Power found in one of the shells a little pouls 14 lines long. Other shells were searched; and in some, little pouls were found, in others none. On the 18th two parent pouls were dead. In the shell of that wherein she had first seen the little pouls she found that it had already passed into the spire. On the 24th, upon examination of this same shell, the little pouls was found already covered with its thin shell, which was $3\frac{1}{2}$ lines in length. This little animal appeared to be completely formed, and its shell had the form of the spire in which it had been framed.

All the experiments made by Madame Power had the same results; her inference is, that the young Argonaut, when excluded from the egg, is naked; that it is progressively developed in the end of the spire of the parent; and that after a certain period it goes on forming the shell.

As far as Madame Power has observed, not more than two or three eggs develop themselves at the same time; and when the young have grown to the length of nine lines, they successively inclose themselves in the spiral of the parent, where the other arms are thrown out in the manner of buds. The young one takes three days to arrive at the length of nine lines, and four in the spiral to develop itself. The parent retains the young one three more days under her, and then ejects it from the shell.

An attempt was made by Madame Power to produce the development of the eggs as far as the production of the young pouls, without the aid of the mother, by suspending them in a fine linen bag in seawater, which was changed thrice in the day. This attempt failed; the eggs swelled indeed, but it was the tumefaction of putrefaction.

Madame Power concludes from this experiment that the glutinous material in which the young are enveloped in the spire of the parent conduces to their development; and this material being evidently a parental secretion, it may be said that without her aid the eggs could not be developed, and the young shell could not have its foundation laid in the end of the spire.

We shall now let Madame Power speak for herself. "In spite of those successful experiments in favour of the shell being the property of the pouls of the Argonaut, I was anxious to be assured of the fact in a manner not hitherto attempted by others. 'If the Argonaut,' said I, 'constructs its own shell, it ought to be able to repair fracture.' Although Signor Ramazzini had said that it was not to be believed that these pouls of the Argonaut should be so ill provided with means necessary for the preservation of their existence, that if the first habitation should be broken or lost, they cannot construct another; still I thought, from his mode of expression, that he had never himself made experiments in proof of this. Moreover I, who had made experiments on a hundred of these molluscs, have found that, when they have lost their shell, they are incapable of constructing another, and die;"

* Aristotle speaks of the shell as being like a hollow pecten (*πτεν*), and not actually adherent to the polypus. He also states that it is freed very frequently near the land, so that it is thrown by the waves upon the sand, when the shell slipping from it, it is caught, and dies on land. ('Hist. Anim.,' iv. 1.)

but I broke in several places the shells of twenty-six individuals, and, to my great satisfaction, found, after thirteen days, the fractures healed in all the survivors, which were not more than three. The newly-secreted portion was stouter than the uninjured part of the shell, but not so white; it looked also a little rough and disturbed, neither did it present the usual rings, and, instead of ribs, it had some longitudinal furrows. Being desirous of observing in what manner the animal operated in repairing the broken shell, I took care the day after the first experiment, and found that the aperture was covered by a thin glutinous lamina, which, somewhat in the manner of a cobweb, unites the two margins of the broken shell. The next day the lamina was, to a certain degree, thickened and more opaque, till, at the expiration of ten or twelve days, the new piece had become quite calcareous. Whilst the Argonaut was in the act of mending the fractures in its shell, I am quite sure that it applied the sails to the shell and wrinkled them upon it, and by this movement I considered that the glutinous secretion which finally became calcareous was deposited."

So far Madame Power has shown that the Argonaut has the power of repairing fractures in the shell, like other Testacea, though not exactly by the same means; but she noticed another power, which she states that, as far as she knows, has not been observed in other testaceans. She found that whenever the animal which is going to repair its habitation can find pieces of other Argonaut shells, it takes, by means of its sail-arm, a fitting piece of broken shell and holds it in the fractured place, till it has secreted the material necessary for the firm attachment of the fragment, thus saving the expense and trouble of a secretion for supplying the whole area of the fractured aperture. "After such a series of experiments," says Madame Power, "it seems to be sufficiently proved that the pouls of the Argonaut is the constructor of the shell in which it lives, and out of which it cannot exist long."

Now, though there may appear in the account of these experiments evidence of their having been drawn up by one not deeply versed in zoology, there is an air of truth and sincerity about them that makes them to us as valuable at least as any that could have been the result of the inquiries of a more learned observer. Madame Power indeed has, in our opinion, come to a somewhat hasty conclusion that these animals are hermaphrodites, because all those that were examined by her (more than a hundred) were furnished with eggs; but this inference is evidently not deemed conclusive by her, for she states her intention of making careful anatomical researches on this subject, which she had not enjoyed the opportunity of making when she wrote.

In a second paper, with the title of 'Nuove Osservazioni sullo Uovo del Polpo dell' Argonauta Argo,' by the same lady, she makes the following observations on the progressive development of the young Argonaut. The egg was at first white and transparent; no structure was discernible in it. After fifteen days it presented spots of a beautiful red. In ten days more the pouls could be discerned through the epidermis of the egg. Then the pouls began to break through that involucre, and to the naked eye presented an elliptical form, with the eyes and mouth, and a very transparent membrane which forms the mantle. Towards the mouth some small and almost imperceptible filaments were observed, which Madame Power supposed to be the rudiments of the brachiae. The pouls were now naked, but in twelve days from that time, on visiting them again, some were found which had already formed their shell, and the parent retained them and nourished them with her gelatinous secretion, as Madame Power had already stated in her Memoir published in the 12th volume of the 'Transactions of the Giennan Academy.'

Captain Philip Parker King, R.N., during his well-known voyage, met with some specimens of *Argonauta* in a rather curious way; and though he expresses his opinion with much modesty, it is plain what the inclination of that opinion was.

"On our passage from Santos to St. Catherine's, in lat. 28° south, we caught," says Captain King, "a Dolphin (*Coryphæna*), the maw of which I found filled with shells of *Argonauta tuberculosa*," and all containing the *Octopus Ocythoe* that has been always found as its inhabitant. Most of the specimens were crushed by the narrow passage into the stomach, but the smaller ones were quite perfect, and had been so recently swallowed that I was enabled to preserve several of various sizes containing the animal. To some of them was attached a nidus of eggs, which was deposited between the animal and the spire. The shells varied in size from two-thirds of an inch to two and a half inches in length; each contained an *Octopus*, the bulk and shape of which were so completely adapted to that of the shell, that it seemed as if the shell increased with the animal's growth. When so many learned naturalists have differed so materially as to the character of the inhabitants of the *Argonauta*, it would be presumption in me to express an opinion; I therefore merely mention the fact, and state that in no specimen did there appear to be any connection between the animal and the shell." ('Voyages of the Adventure and Beagle,' vol. I. p. 106.) We had an opportunity of examining the specimens above alluded to soon after Captain King's return, and they bore out in every particular the description given by him.

M. D'Orbigny ('Voyage dans l'Amérique Méridionale') came to a

conclusion in favour of the animal being the constructor of the shell, and consequently against the parasitic theory, from observations made by him on *Argonauta hians*.

In 1837, M. Rang, on his return from Algiers, where he had been observing these animals, had an interview with M. De Blainville, who had then the observations which Madame Power had just made in his hands; and, in April of that year, M. De Blainville read his elaborate Report, and afterwards published it, with additional dissertations, in the form of a memoir or letter, in the third number of the 'Annales Françaises et Étrangères d'Anatomie et de Physiologie.' His arguments in favour of parasitism appear to be based on the following data:—1, That the same species of Cephalopod is not always found in the same species of shell. 2, That the natural position of the animal in the shell varies, the back of the animal being sometimes next the outer wall of the shell, sometimes next the involuted spire. 3, That the animal does not occupy the posterior part of the shell. 4, That the form of the animal and of its parts offers no concordance or analogy with the shell. 5, That the shell is too opaque to have permitted the influence of light in the development of the coloured pigment in the mantle of the cephalopod of the Argonaut. 6, That it is very far from being true that the argonaut-shell possesses the flexibility and elasticity requisite to harmonise with the locomotive and respiratory movements of the animal. 7, That the animal suffers no appearance of inconvenience when deprived of its shell. 8, That a cephalopod has been discovered in the Sicilian seas like that which inhabits the Argonaut, but without a shell. These data are designated by Professor Owen, to whose observations we shall presently advert, as false facts, with the exception of the third, which is only partially false, being true when stated with reference to the more mature animal only. The other arguments of M. De Blainville are noticed by Professor Owen as founded on undoubted or admissible facts; but the Professor denies the conclusion drawn by M. De Blainville.

M. Sander Rang in consequence of the appearance of M. De Blainville's memoir or letter, published in Guérin's 'Magasin de Zoologie' a very interesting paper under the title of 'Documents pour servir à l'Histoire Naturelle des Cephalopods Cryptodibranchés.' In this memoir M. Rang's observations are confirmatory—1, of Madame Power's statement that the siphon is applied to the part of the shell opposite the involuted spire; 2, of the accuracy of her description of the relative position of the so-called sails of the Argonaut with reference to the shell; 3, of her discovery of the faculty possessed by the animal of repairing the shell, and many other points.

No one will refuse to M. Rang the acknowledgment that he is not only a very accurate observer, but that he is well versed in the natural history and anatomy of the *Mollusca* generally; so that here at least no doubt can be thrown on the observations.

In February, 1839, a highly interesting and valuable series of specimens of the Paper Nautilus (*Argonauta Argo*) consisting of the animals and their shells of various sizes, of ova in various stages of development, and of fractured shells in different stages of reparation, were exhibited to the Zoological Society of London, and commented on by Professor Owen, to whom they had been transmitted for that purpose by Madame Power, who had formed the collection in Sicily, in 1838. In the course of his comments the Professor went at large into the subject, and in addition to the observations above alluded to with regard to the alleged false facts and admissible facts whereon M. De Blainville had founded his reasoning, combated at great length, and, in our opinion, with signal success, the arguments of those who adhered to what may be termed the parasitic opinion; and recapitulated as follows the evidence which, independently of any preconceived theory or statement, could be deduced from the specimens then on the table.

1. The cephalopod of the Argonaut constantly maintains the same relative position in its shell.

2. The young cephalopod manifests the same concordance between the form of its body and that of the shell, and the same perfect adaptation of the one to the other as do the young of other testaceous molluscs.

3. The young cephalopod entirely fills the cavity of its shell; the fundus of the sac begins to be withdrawn from the apex of the shell only when the ovarium begins to enlarge under the sexual stimulus.

4. The shell of the Argonaut corresponds in size with that of its inhabitant, whatever be the differences of the latter in that respect. (The observations of Poli, of Prevost, of King, and of Owen, are to the same effect.)

5. The shell of the Argonaut possesses all the requisite flexibility and elasticity which the mechanism of respiration and locomotion in the inhabitant requires; it is also permeable to light.

6. The cephalopod inhabiting the Argonaut repairs the fractures of its shell with a material having the same chemical composition as the original shell, and differing in mechanical properties only in being a little more opaque.

7. The repairing material is laid on from without the shell, as it should be according to the theory of the function of the membranous arms as calcifying organs.

8. When the embryo of the Argonaut has reached an advanced stage of development in ovo, neither the membranous arms nor shell are developed.

9. The shell of the Argonaut does not present any defined nucleus.

Professor Owen concluded a most elaborate commentary by stating that he regarded the facts already ascertained to be decisive in proof that the cephalopod was the true fabricator of the shell; and thus, in our opinion, is set at rest—principally by the experiments of Madame Power—a question which had divided the opinions of zoologists from the time of Aristotle, who left the subject with the following acknowledgment:—"But as touching the generation and growth of the shell nothing is as yet exactly determined."*

M. Rang's account of the locomotion of *Argonauta Argo* is most interesting. When the animal was at rest, and contracted within its shell, it exhibited the appearance figured below.

Argonauta Argo contracted within its shell, and the membrane of the sails partly covering it: The eggs were never seen by M. Rang in the place where they are represented, but much more within the opening. (Rang.)

"To return to the description of our poulp," says M. Rang, "which we left contracted within the argonaut-shell, and watching with an attentive eye what took place around it, we saw it extending itself from out its shell, and protruding six of its arms; then it threw itself into violent motion, and travelled over the basin in all directions, often dashing itself against the sides. In these different movements the body leant a little towards the anterior part of the shell; and the long slender arms, very much extended and collected into a close bundle were carried before it, as well as the tube, which showed itself open and protruded. The locomotion was effected in the ordinary manner of poulps, the movement being backwards by means of the contraction of the sac and the expulsion of water through the siphon. The disposition of the animal and shell is the most favourable for accelerating the motion of the creature. The lightness of the shell; its narrow and keeled form; its width, which is smallest at the part presented first for cleaving the water; the membrane smoothing over all inequalities of the shell; the bundle of arms extending behind so as to offer the least possible resistance; the two arms stretched like a bridge over the cavity where the eggs are, as if to throw off the water from that cavity;—all these adaptations concur to facilitate the gliding of the animal through the medium in which it is to move."

M. Rang thought that he perceived in the movements of the animal, when in open water, that it had its back uppermost, and consequently the tube below, but he did not constantly see it so; he observed it however with more certainty in specimens of poulps whose arms had been deprived of their membranes.

The animal which they had been watching, as above described, fatigued by its efforts in a confined space, and perhaps injured by the shocks which it had sustained in coming in contact with the side of the basin, allowed itself to sink to the bottom, and half contracted itself in order to take repose; soon after which it exhibited another and unexpected spectacle. Fixing some of the acetabula of its fore arms upon the bottom of the basin, it erected itself upon its head, spreading out its disc, and carrying the shell straight above it in the normal position of the shells of gastropods; then, beginning to crawl, it presented the appearance of a pectinibranchiate mollusc, as M. Rang had remarked in the note to the Academy of Sciences. Half drawn back into its shell, the animal appeared to crawl upon its disc, the palmatures of which were a little raised to follow the movements of its arms. The body was hidden in the shell; the siphon, placed in the anterior part of it, was turned forwards; the arms which were at liberty were very much protruded and twisting round, two before and two on each side; the base of the two large arms seemed to prolong backwards the locomotive surface, and then rising along the keel they again covered it with their large membranes, as when the poulp was swimming in deep water. "Thus," continues M. Rang, "this mollusc, at once pelagic and littoral, presents a most singular anomaly; when it swims at the surface of the water having its ventral part lowermost

* 'Hist. Anim.' ix. 37; where a detailed account of the locomotion of the Nautilus, its sailing, &c., is given.

and when it crawls along the bottom having it, on the contrary, uppermost; two things which are completely contrary to what we see

Disposition of the shell and animal when moving through the water in the direction of the arrow. (Rang.)

Argonauta Argo, moving on its head at the bottom. (Rang.)

among the pelagic molluscs on the one hand, and the littoral molluscs on the other."

The progress of the animal when moving as last represented was slow, and it worked itself onwards like the gastropodous molluscs. M. Rang remarks that the reptation was only apparent, for the suckers really caused the motion.

When the poulp was at the point of death it drew in by slow degrees its large arms and their membranes, and contracted them upon themselves and all the other arms, so as to obstruct the opening of the shell. At this moment the shell was moved, and the poulp separated itself from it, not voluntarily but accidentally, for it no longer held it in any way. It appeared at first to become a little reanimated, made some movements in the basin upon its head, then fell from weakness, and soon died. All this passed in less than ten minutes.

A beautiful series of preparations of this animal exists in the museum of the Royal College of Surgeons.

Shells of *Argonauta Argo*. a, young.

Shells of *Argonauta tuberculosa*. a, a, young.

Several species are already known; and the specific characters rest in great measure upon the tuberculosities and rib-like elevations on

the outside of the shell and on the breadth of the keel. The absence or presence of projecting pointed processes at the sides of the aperture near the spiral part cannot safely be relied on as a specific character: we possessed both broad-keeled and narrow-keeled specimens (now in the British Museum), in which the projecting process was present on one side of the shell and absent on the other. They are inhabitants of the seas of warm latitudes, both littoral and pelagic.

Eledone (Aristotle; Leach).—Arms provided with a single series of sessile acetabula.

E. ventricosa (*Octopus ventricosus*, Grant). Body short, round, the eight arms connected at their base by a membrane.

Eledone ventricosa. a, Sucker of *Eledone*.

Our cut was taken from a beautiful specimen captured at St. Just, Cornwall, in 1822, and preserved in the Museum of the College of Surgeons, among the preparations illustrative of natural history in spirit, No. 164 A. "Its arms are compressed, and connected at their roots by a thick web, and in the contraction preceding death they have become spirally convoluted in a very elegant manner; the three upper or dorsal pairs describing four gyrations, the ventral pair five; the surface of the integument is slightly wrinkled and granulate; it is of a mottled lilac or livid colour behind, but is smooth and approaches to white on the opposite aspect of the arms." ('Catalogue,' part iv., fasc. 1.)

Octopus (Lam., Πολύπους, Antiq.; and Leach).—Arms provided with a double alternate series of sessile acetabula.

O. vulgaris (*Sepia octopodia*, Linn.; *Sepia octopus*, Gmel. Body short and ovoid, the eight arms connected at their base by a wide membrane.

It is found in the European seas, and has been taken in Great Britain.

This is the Eight-Armed Cuttle of Pennant; the Poulp, or Preke, of the English. Professor Owen has given a very good figure of this species, representing it in the act of creeping on the shore, its body being carried vertically in the reverse position with the head downwards, and its back being turned towards the spectator, upon whom it is supposed to be advancing. ('Cyclopædia of Anatomy and Physiology,' vol. i. f. 210.) This is the cephalopod which is said to be luminous in the dark. Linnæus quotes Bartholinus for the statement that one gave out so much light, when the candle was taken away, "ut totum palatium ardere videretur." It has also been alleged that the application of its suckers upon any part of the human body occasions inflammation and subsequent pain.

Three specimens of *Octopus vulgaris* are preserved in spirit. (Mus. Coll. Surg., Nos. 162, 163, 164.)

It was probably a species of *Octopus* that Mr. Beale encountered while searching for shells upon the rocks of the Bonin Islands. He was much astonished at seeing at his feet a most extraordinary looking animal crawling towards the surf, which it had only just left. It was creeping on its eight legs, which, from their soft and flexible nature,

being considerably under the weight of its body; so that it was lifted by the efforts of its tentacula only a small distance from the rocks. It appeared much alarmed at seeing him, and made every effort to escape. Mr. Beale endeavoured to stop it by pressing on one of its legs with his foot; but although he used considerable force for that purpose, its strength was so great that it several times liberated its member, in spite of all the efforts he could employ on the wet and slippery rocks. He then laid hold of one of the tentacles with his hand, and held it firmly, so that the limb appeared as if it would be torn asunder by the united efforts of himself and the creature. He then gave it a powerful jerk, wishing to disengage it from the rocks to which it clung so forcibly by its suckers. This effort it effectually resisted; but the moment after, the apparently enraged animal lifted its head with its large projecting eyes, and, loosing its hold of the rocks, suddenly sprang upon Mr. Beale's arm, which he had previously bared to the shoulder for the purpose of thrusting it into holes in the rocks after shells, and clung with its suckers to it with great power, endeavouring to get its beak, which Mr. Beale could now see, between the roots of its arms in a position to bite. Mr. Beale declares that a sensation of horror pervaded his whole frame when he found that this monstrous animal had fixed itself so firmly on his arm. He describes its cold slimy grasp as extremely sickening, and he loudly called to the captain, who was also searching for shells at some distance, to come and release him from his disgusting assailant. The captain quickly came, and taking Mr. Beale down to the boat, during which time the latter was employed in keeping the head of the Cuttle away from his hand, quickly released him by destroying his tormentor with the boat-knife, when he disengaged it by portions at a time. Mr. Beale states that this cephalopod must have measured across its expanded arms about four feet, whilst its body was not bigger than a large clenched hand. It was the species called by the whalers Rock-Squid ('Natural History and Fishery of the Sperm Whale.')

Eight-Armed Cuttle (*Octopus vulgaris*).

"The males of some species of *Octopus* and *Eledone* are similar to the females, but are comparatively scarce. Only the females of many others are known, and every specimen of the Argonaut hitherto examined (amounting to many hundreds) has been of that sex. Dr. Albert Kölliker has suggested that the real males of the Argonaut, and also of *Octopus granulatus*, and *Tremoctopus violaceus*, are the *Hectocotyles*, previously mistaken for Parasitic Worms. The *Hectocotyle* of *Octopus granulatus* was described by Cuvier, who obtained several specimens from Octopods captured in the Mediterranean. It is 5 inches in length, and resembles a detached arm of the *Octopus*; its under surface being bordered with 40 or 50 pairs of alternate suckers.

"The *Hectocotyle* of *Tremoctopus* was discovered by Dr. Kölliker at Messina in 1842 adhering to the interior of the gill chamber and funnel of the poulp; the body is worm-like, with two rows of suckers on the ventral surface, and an oval appendage at the posterior end. The anterior part of the back is fringed with a double series of branchial filaments. Between the branchie are two rows of brown or violet spots, like the pigment cells of the *Tremoctopus*. The suckers closely resemble those of the *Tremoctopus* in miniature. Between the suckers are four or five series of pores, the openings of minute canals passing into the abdominal cavity. The mouth is at the anterior extremity, and is minute and simple; the alimentary canal runs straight through the body nearly filling it. The heart is in the middle of the back, between the branchie; it consists of an auricle and a ventricle, and gives origin to two large vessels. There is also an artery and vein on each side, giving branches to the branchial filaments. A nerve extends along the intestine, and one ganglion has

been observed. The oval sac incloses a small but very long convoluted tube, ending in a muscular *vas deferens*; it contains innumerable *Spermatozoa*. The *Hectocystyle* of the Argonaut was discovered by Chiale, who considered it a Parasitic Worm, and described it under the name of *Trichoccephalus octubularis*; it was again described by Costa, who regarded it as a "Spermatophore of singular shape," and lastly by Dr. Kolliker.

"It is similar in form to the others, but is only 7 lines in length, and has a filiform appendage in front 6 lines long. It has two rows of alternate suckers, 45 on each side, but no branchiæ. The skin contains numerous changeable spots of red or violet, like that of the Argonaut." (Woodward, *Manual of Mollusca*.)

OCTOPUS. {OCYPODIDÆ.}

OCULINA. {MADREPHYLLIDÆ.}

O'CYMIUM, a genus of Labiate Plants, remarkable for the fragrance of their leaves, which are used as an ingredient in savoury dishes, on which account some of the species have from time immemorial been objects of very general cultivation. In English gardens they are called *Basils*, a corruption of *Basiliaca*, the name given to comon Basil by the monkish writers upon plants, in allusion to its regal qualities.

O. Basilicum, Linn., Common Basil, has many varieties, differing in their size, in the form and colour of their leaves, and in minor particulars: in their qualities they are nearly alike. This species is found wild in the hotter parts of the East Indies, where it is a perennial, with a woody root; but in our gardens it is treated as a tender annual, being raised in the spring in a hot-bed, and turned into a warm border when the summer is so far advanced that there is no longer any danger from frost, which is instantly fatal to such plants. Besides this Mr. Bentham enumerates 43 other species ('*Labiatarum Genera et Species*'), one of which, the *O. viride*, is used as a febrifuge in Sierra Leone. The genus is readily known by its calyx being bent downwards when the fruit is ripe, and then appearing covered as it were by a very large ovate dorsal lobe, and by the stamens being declinate.

OCYPODIDÆ, or OCYPODIANS (Milne-Edwards), a tribe of Brachyurous Crustacea, placed by M. Milne-Edwards between his Pinnotherians and Gonoplacians.

The tribe has the following characters:—Carapace rhomboidal or trapezoidal, very much elevated anteriorly and depressed posteriorly; the frontal border occupying the whole width, and the front, which is lamellar and bent down to the epistome, extremely narrow; its width does not equal a third of the

length of the eyes, nor the half of the width of the buccal frame, which itself is very narrow. The eyes are very long, and the cornea in general is very large. The basiliary joint of the internal antennæ is oval, rather large, and placed vertically in the anterior angle of the orbit; the moveable stem of these appendages is extremely small and hidden under the front; the two terminating filaments are very short, large, and hardly annulated, a disposition which is not observed in any of the Crustaceans previously treated of in the system of M. Milne-Edwards, except in the *Doto*. The external antennæ are rudimentary, and situated, as they ordinarily are, in an opening of the internal angle of the orbit; their first joint is less than the second, and the third only reaches to the edge of the anterior border of the basiliary joint of the internal antennæ. The epistome is continuous with the lower border of the orbit, and the buccal frame is remarkably more narrow anteriorly than it is posteriorly. The external jaw-feet close the mouth completely; the interior border of their lamellar portion is straight; their third joint is very much elongated, and their fourth inserted at the external angle of the preceding. The sternal plastron has a trapezoidal form, the base of which is directed backwards; it is strongly curved in its longitudinal direction, and gives passage to the male organs at a considerable distance from its external border. The anterior feet are generally compressed and of very unequal size; the rest are very long and exhibit so great differences between themselves; the terminating joint is often depressed, but has never the form of a natatory oar. The abdomen, composed ordinarily of seven distinct segments in both sexes, is very narrow. In general it does not cover more than a third of the posterior portion of the sternal plastron of the male, and even in the female leaves that part of the plastron which approaches the base of the feet exposed. In the greater part of the cases, if not always, there are only seven branchiæ on each side of the thorax, five of which only are coched under the vault of the sides, and two reduced to the state of vestiges only, and fixed to the jaw-feet.

The Ocypodians, as their name implies, are very swift runners, living nearly always on the strand, where they dig holes for themselves.

M. Milne-Edwards, who remarks that this small and very natural group is closely allied to the genera *Doto* and *Mycteria* among the Pinnotherians, thus divides the tribe:—

Tribe of Ocypodians.	Cornea transparent, very large, oval, occupying at least the half of the length of the ocular peduncle, and commencing very near the base of those stems.	Ocypoda.
	Cornea transparent, very small, rounded, not occupying the fourth part of the length of the ocular peduncle, and only commencing close to its extremity.	

Ocypoda (Fabricius).—Carapace rhomboidal or even nearly square, as large behind as before. The front is much longer than it is wide; it does not cover the articulation of the ocular peduncles, and only equals in width the half of the epistome, to the anterior border of which it unites itself. The orbits are very large, not deep; the upper border is much less advanced than the lower. The form of the eyes is very remarkable; the cornea is oval, very large, and extends below within a very small distance of the base of the peduncle; but in general this last is prolonged beyond its extremity, so that the eyes terminate with a kind of horn, the length of which seems to increase with age. The internal antennæ are disposed as stated in the character of the group; the external antennæ are rudimentary; their third joint is not half so long as the second, and their terminal stemlet is scarcely longer than their peduncle. The epistome is very small and presents at its median part a small quadrilateral prolongation which is soldered to the front. The third joint of the external jaw-feet is quadrilateral and much smaller than the preceding. The anterior feet are in general shorter than the rest, and the band which terminates them is much compressed and very large in comparison with the arm; the difference between the hands of each side is often very great, especially in the male. The succeeding feet are also much compressed, and increase in length up to the fourth pair inclusively. The abdomen is much narrower at its base than the posterior part of the thorax, and in both sexes leaves a considerable portion of the last segments of this part of the body exposed.

The branchia which ordinarily exists on the antepenultimate joint of the sides is wanting in the *Ocypoda*; the others are directed very obliquely backwards, and the branchial cavity is elevated so as to leave above a great void space which is lined by a membrane more or less spougy. (M. Milne-Edwards.)

So rapid are the *Ocypoda* in their motions that those who have observed these animals in their native haunts declare that they run so fast that a man can hardly overtake them. They hollow out holes for themselves in the sand of the sea-bank, and remain shut up in their burrows throughout the winter.

They are found in warm climates of both hemispheres.

M. Milne-Edwards records seven recent species, which he separates into two divisions:—

A. Species whose transparent cornea occupies the extremity of the ocular peduncle, and is not overpassed by a styliform prolongation or a terminal tubercle.

O. arenaria, the Sand-Crab of Catesby. Length about two inches; colour yellowish. It is found on the coasts of North America and the Antilles.

It lives in holes three or four feet deep, which it hollows out in the sand immediately above the level of the wash of the sea. Its general time of quitting the burrow to seek its food is the night, and when pursued it runs with great swiftness, elevating at the same time its claws in a menacing manner. This is their summer life; but towards the end of October they retire inland to hibernate in the earth. When they have found a place proper for their purpose they dig a hole like that which they had occupied on the edge of the sea; and after entering therein stop up the entrance so cleverly that no trace of its existence is left. Then they retire to the bottom, and there remain till the warm weather brings them forth, when they again repair to their marine residences.

B. Species whose eyes carry at their extremity an appendage, in the form of a tubercle, cylinder, or stylet, which overpasses the transparent cornea.

O. hippea. Terminal appendage of the eyes large, short, conical,

Ocypoda arenaria. a, under side of the head. Milne-Edwards.

and furnished at its extremity with a pencil of long hairs. Length 2 inches, French.

It is found in Syria, Egypt, Cape de Verd, &c.

Ocypoda hippea.

a, pincers; b, under side of male in detail. (Milne-Edwards.)

Gelasimus.—Carapace much wider than that of *Ocypoda*, more convex, and much narrower backwards. Stomachal region very small, and genital region generally very large. Disposition of the front and of the internal antennæ nearly the same as in the preceding genus: ocular peduncles, on the contrary, very narrow, and the cornea which terminates them not occupying more than its fifth part; upper border of the orbits much less projecting than the lower; not divided into two portions as in the *Ocypoda*, and convex nearly throughout its length; external extremity of those cavities largely open, and communicating with a furrow which is obliquely directed behind and downwards. External antennæ much more developed than in the preceding genus. The external jaw-feet have the same form as the *Ocypoda*. The anterior feet, in general, very small in the female; but, in the male, one of them acquires enormous dimensions. Sometimes it is the right, sometimes the left claw which grows to this great size, being, in certain instances, twice as large as the body. The claws of the smaller anterior foot are enlarged and lamellar towards the end and a little contorted; those of the great anterior foot are arched, elevated, and slightly dentated on the edges.

Gelasimus annulipes. (Indian Seas.) Milne-Edwards.

a, under side of head; b, abdomen; c, antennæ.

M. Milne-Edwards, who gives the above character, states that Mr. Thomas Bell had informed him that some *Gelasimi* have at a certain age, if not always, a stylet at the extremity of the ocular peduncle, on the side of the great claw, whilst the eye of the opposite side always retains the ordinary form. It inhabits the warm countries in both hemispheres.

The *Gelasimi* live in holes near the edge of the sea, in pairs, and the great claw of the male is used to stop the entrance of the hole. The species are numerous.

G. Marionis. Length about 8 lines; width about an inch, French. It is a native of Manilla.

Gelasimus Marionis.

Fossil Ocypodians.—The fossil species which most resembles *Gelasimus Marañoni* seems to be *G. nitidus*, figured by M. Desmarest in his 'Histoire Naturelle des Crustacés Fossiles,' but the lateral edges of the carapace in the fossil are quite smooth, and the front is terminated by a very short sharp point. Neither the geological nor geographical locality appears to be known. The specimen is in the Paris museum.

OCYPTERUS. [LANIADÆ.]

OCYROË. [ACALEPHÆ.]

ODATRIA. [MONITORIDÆ.]

ODERIT, a Mineral. It is probably Black Mica; for, like that substance, it may be split into thin leaves. [MICA.] It is opaque, black, and has very little lustre. Its colour is, probably owing to some foreign substance, which may cause the difference between its appearance and that of common mica. It occurs in Sweden.

ODONTIS. [MONODONTA; TROCHIDÆ.]

ODONTOPTERIS. [COAL PLANTS.]

ODOSTOMIA, Fleming's name for a genus established from several small species of land shells—*Turbo plicatus*, *T. spiralis*, *T. unidentatus*, &c. of Montagu. It has the following characters:—Shell conical; aperture ovate; peristome incomplete retrally, and furnished with a tooth on the pillar. Operculum ovate-acute, subspiral, corneous, transversely striated, placed on a simple lobe. Forbes and Hanley in their 'History of British Mollusca,' describe upwards of 20 species as British. The species are difficult to distinguish.

CEDE'MERA, a genus of Beetles belonging to the third family of Heteromorous Coleoptera, the *Stenelytra*. *C. cærulea* is a very common British Insect.

CEDES. [CULICIDÆ.]

CECINEMUS. [CHARADRIADÆ.]

GENANTHE, a genus of Plants belonging to the natural order Umbellifera. One of the species, *G. pimpinelloides*, appears to have been the *Οἰνάρη* of Theophrastus and Dioscorides. The species of this genus are readily known, independently of other characters, by their fruits being, by the contraction of the rigid pedicels, strongly compacted into heads, the upper side of which is muricated by the stiff straight long styles. The fruits have on each face five convex obtuse ridges, of which the marginal ones are a little the largest.

The species are all inhabitants of damp meadows or watery places, and are common in Europe. The most important is *G. crocata*, an inhabitant of ditches, banks of rivers, and similar situations. This plant, which Dr. Christison reckons the most energetic of the narcotico-acrid poisonous plants of its class, has a root of many fleshy fingers, looking exactly like a dahlia-root in miniature, but abounding in an orange-coloured fetid juice, which is also plentiful in other parts of the plant, and in which the deleterious qualities reside. The stem grows from two to five feet high, is much branched, round, and hollow; the leaves are of a dark shining green, doubly pinnate, with wedge-shaped leaflets variously and deeply cut; the umbels are large and convex, of many general and a still greater number of partial rays; the bracts of the involucre are variable in number and size; the flowers are white, tinged with purple. Cases of accidental poisoning with this plant, in consequence of its roots being mistaken for ground-nuts,

paranips, &c., by ignorant people, are common. In general death takes place within three hours and a half of the poison having been administered, and often within the first hour.

Eranthis crocata.

The other British species are—*E. fistulosa*, *E. Lachenalii*, *E. salvi-folia*, *E. Phellandrium*, *E. Auriatilis*.

ENOTHERA, a genus of Plants belonging to the natural order Onagraceae, or Onagraceae. It has a 4-cleft calyx; 4 petals; a filiform style, with a clavate or cruciform stigma; linear capsules of 4 cells, with 4 valves; and numerous seeds.

E. biennis, Evening Primrose, has ovate-lanceolate flat-toothed leaves; a rough hairy stem; petals longer than the stamens, and about half as long as the tube of the calyx; the flowers are large, numerous, and of a bright yellow-colour. It abounds on the Lencashire coast, and covers several acres of ground near Woodbridge, Suffolk. The roots are eatable, and were formerly taken after dinner to flavour wine, as olives now are; therefore the generic name was changed from *Onagra*, the Ash-Food, to *Enothra*, the Wine-Trap. This plant was once cultivated for the sake of its tubers, which might in some measure have stood instead of the potato, had they not been superseded by the introduction of the latter. This is the only British species of the genus.

There are 85 species enumerated by Don, growing chiefly in North America. They are handsome border-flowers, and deserve to be cultivated, but are not valuable on account of any properties they possess.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Barnett, *Outlines of Botany*.)

ERSTEDTITE, a Mineral, occurring crystallised. Primary form a right square prism. Colour brown. Lustre splendid. Hardness 6.5. Specific gravity 3.623. It is found at Arendal, Norway. The following is its analysis:—

Titanate of Zirconia	63.065
Silica	19.708
Lime	2.612
Magnesia	2.047
Protoxide of Iron	1.136
Water	5.332

—90.8

ESOPHAGUS, or Gullet, is the canal leading from the pharynx, the short cavity at the back of the mouth, to the stomach. In man it is composed of two layers of muscular fibres, an external longitudinal layer, and an internal, composed of circular fibres, by which the food

is propelled towards the stomach, and which are lined by a layer of soft mucous membrane and a moderately thick cuticle continued from that of the lips and mouth. In many animals its interior is beset with numerous firm pointed processes, directed towards the stomach, to prevent any food that has passed through it from returning into the mouth; in the ruminants, on the other hand, it is one of the chief means by which the partially-digested food is brought again to the mouth for the chewing of the cud.

ESTRIDÆ, a family of Dipterous Insects of the section *Athericera*, distinguished by the proboscis being either in a rudimentary state or wanting; the palpi are sometimes distinct and occasionally wanting; the antennæ are short, inclosed in a cavity in the fore part of the head; the third joint is usually globular, and the stylet is usually dorsal; the abdomen is generally large; the wings have generally three posterior cells, of which the first is often closed.

It will be seen from the above definition that the *Estri* of the moderns cannot be the same as the *Cetrus* (*Oiarpus*) of the ancient Greeks, a fly, which, we learn from Aristotle ('Hist. Anim.' iv. 4, &c.), Virgil ('Georgica,' iii. 148), Ælian, and others, is armed with a strong tongue (proboscis), pierces the hides and sucks the blood of quadrupeds, and makes a peculiar kind of harsh humming noise. Mr. Bracy Clark states that the *Cetrus Beris* makes no noise whilst flying, and Mr. W. S. M'Leay says, "the *Cetrus Equi* is also silent in flying, as I have repeatedly myself observed." The absence in some and the rudimentary state of the proboscis in others of the modern *Estri*, proves that they are not blood-suckers; and this fact is otherwise at variance with the description given by the ancients, their *Estri* having a strong proboscis, a circumstance which, connected with the blood-sucking habits of the *Tabanidæ*, another family of Dipterous Insects, induces Mr. M'Leay to imagine that the *Cetrus* of the ancients belongs to that group. An ingenious paper on this subject, by the gentleman last mentioned, will be found in the fourteenth volume of the 'Linnean Transactions.' [Bors.]

In Macquart's 'Histoire Naturelle des Insectes Diptères,' seven genera are enumerated as belonging to the family *Estridæ*:—*Cuterebra*, *Hypoderma*, *Edemagena*, *Cephenemyia*, *Cephalemyia*, *Colax* and *Cetrus*.

ESTRUS. [Bors.]

ETHRA (Leach), a genus of Brachyurous Crustacea, placed by M. Milne-Edwards as the representative of his first division (Cancericns Cryptopodes) of his tribe Cancerians; and indeed his Cryptopod Cancerians are composed of this genus solely. Latreille made *Ethra* and *Calappa* [CALAPPA] form the family *Cryptopoda*; but M. Milne-Edwards is of opinion that the only character which they have in common with the latter is the existence of lamellar prolongations on the sides of the carapace, dispositional which are also found in certain Leucosians, whilst all the rest of their organisation approaches that of the Crabs.

M. Milne-Edwards is of opinion that this form has great affinity with the genus *Cryptopodia* belonging to the family of Oxyrhynchs, and that it establishes the passage between those Crustaceans and the other Cancerians, at the same time that it approaches *Calappa*, whose natural place is in the family of Oxyatomes. It is found in the East Indian and African Seas.

E. scruposa may be taken as an example. Its length is 2 to 3 inches. Colour grayish. It is found near the Island of Mauritius, and in the Indian Archipelago.

Ethra scruposa.

α, the right pincer, external view.

OIDEZIA. [Ducks.]

OIDIUM, a genus of Plants belonging to the order of *Fungi*, some of the species of which are found upon the human body and others attack plants. It is known by possessing a simple or branched mycelium, which is very minute and pellucid, aggregated into flocculent masses slightly interwoven and articulated. The sporidia are simple and pellucid, and arise from the joint of the mycelium.

O. albicans, the Thrush-Fungus, is found in the mucous membrane of the mouth, fauces, and œsophagus of sucking children, and also occasionally in grown-up persons in a state of extreme exhaustion. The ulcerations, amidst the discharge of which this fungus is found, are usually called thrush. Although constantly present in this disease the fungus does not appear to produce the disease but to be the result of the changes produced in the mucous membrane. It has been observed that the mucous membrane in this state constantly affords an acid reaction, and this acidity seems necessary to the growth of the fungus. The best account of this fungus will be found in Robin's 'Histoire des Végétaux Parasites.' Several other species of *Oidium* have been described. The fungus found in connection with the recent grape-vine disease is an *Oidium*. [ENTOPHYTA; FUNGI.]

OIL-PALM. [ELÆIS.]

OIL-TREE. [BASSIA.]

OILS are substances of organic origin, and are found in both the animal and vegetable kingdoms. They are divided into Fixed and Volatile. The latter are principally products of the vegetable kingdom. The Fixed Oils are composed of carbon, hydrogen, and oxygen. Their general formula is $C_{11}H_{10}O$. They are liquid or solid according to the manner in which their elements are disposed. Most of them are composed of two compounds, a liquid called Olein, and a solid called Margarin, or another called Stearin. According as those solid substances abound in oils, they are liquid or solid at the ordinary temperatures of our atmosphere. Fixed Oil is found in the fat or adipose tissue of animals. [ADIPOSE TISSUE; FAT.]

Fixed Oil is found amongst plants principally in their seeds. In some cases as in the Olive [OLEA] it is yielded by the fruit.

Some families of plants especially abound in oil. Thus among the *Cruciferae* we have Mustard, Rape, and Colza seed oil, with other species cultivated in Europe, India, and Japan, of which some have of late years been imported into this country. Several of the family of *Compositae* secrete oil in quantities large enough to render it desirable to cultivate them for this purpose alone, as the sunflower and Jerusalem artichoke, also some species of *Carthamus*, or Bastard Saffron, and also the *Verbesina sativa* of India, now known to be identical with the Abyssinian *Guizotia oleifera*, and of which the oil is known in commerce by the name of Hutayellow oil. So *Madia sativa* yields Madi oil, and its seeds are said to be more abundant in oil than any plant introduced into Europe. Most of the *Cucurbitaceae* also, as the Melon, Gourd, Cucumber, and the numerous varieties, cultivated especially in India, contain a large proportion of oil, which is expressed in the East, as it formerly was in Europe. The *Rosaceae* also store up a large proportion of oil in the kernels of their fruit, as in the Almond, which is particularly valued; so also that of the Apricot, as well as that of the Briançon Apricot, and other species of *Prunus*. In the Himalayas, oil is also expressed from the Apricot kernel, and has been sent to this country of a fine quality.

Among the *Amentaceae* we have also several species which yield oil of good quality, and in sufficient quantity to repay the expense of expression, as Nut oil, obtained from the Hazel; Beech-Nut oil, from *Fagus sylvatica*; with these may be mentioned Walnut oil, from *Juglans regia*. Besides these, Poppy oil, Ben-Nut oil (*Hyperanthra*), Ground-Nut oil (*Arachis*), Physic-Nut oil (*Jatropha*), are well known. So the cotton-seed yields oil, which is also the case with the seeds of the tea-plant, especially of the species called *Thea oleifera*, and some of the *Camellias*.

Two species of *Bassia*, *B. longifolia* and *B. latifolia*, both yield oil; another species, *B. butyracea*, yields a vegetable butter, and is commonly known as the Ghee, or Butter-Tree of Almora. [BASSIA]. The native name of this tree is Choonee, and Mr. Traill describes it as not being found in Kemaon, but in the adjoining Goorkh province of Dotee. [COCOS; CROTON; MYRISTICA; THEOBROMA; OLEA; PAPAVER; BRASSICA; ELÆIS; RICINUS; AMYGDALUS.]

The volatile oils are very numerous in the vegetable kingdom. They are called volatile on account of the ready manner in which they may be volatilised under the influence of heat. The facility with which they are diffused in the atmosphere renders them easy of detection, and it is to this class of substances that plants owe their peculiar odours. Many of them are employed in perfumery, others are used as stimulants in medicine, and some are poisons. Their composition is much more varied than that of the fixed oils, and to the chemist they offer an exceedingly interesting field of research. Many of them have a constitution analogous to the compounds obtained by chemists from the compound radicals. [COMPOUND RADICALS, in ARTS and SC. DIV.] They are divided by chemists into three groups:—1, those containing only carbon and hydrogen, as oil of turpentine; 2, those containing also oxygen, as oil of cloves; 3, those containing sulphur, as oil of garlic. Many natural orders are characterised by yielding volatile oils. Thus the *Lamiaceae*, *Myrtaceae*, and others, embrace species all of which contain volatile oil in their leaves. Many of the *Umbelliferae* yield a volatile oil in their fruits.

The petals are often the seat of these secretions, and especially those most prized as the Rose, the Jasmine, the Heliotrope, and many others.

OKENITE is a Mineral, a variety of *Dysclasite*. It occurs in fibrous masses, having a radiated structure; also imperfectly fibrous, or composed of minute crystals. Its hardness is 4.5 to 5. Colour white. Specific gravity 2.28. It exhibits double refraction. It is found at Disco Island, Greenland. Its analysis by Kobell afforded—

Silica	56.99
Lime	26.35
Water	16.65

—99.99

OLACA'CEÆ, a small natural order of Exogenous Plants, chiefly found within the tropics. Its most important characters are—a small inferior calyx, often becoming enlarged around the ripe fruit, a polypetalous valvate corolla, a small number of hypogynous stamens, partly fertile and partly barren; a 1-celled ovary, with pendulous ovules, indehiscent fruit, and a small embryo amongst a large quantity of albumen. Its affinities are little understood, but are supposed to be greatest with *Pittosporaceae*, on the one hand, and *Aurantiaceae*, on the other. The plants are of little importance for useful qualities; one species, *Heisteria coccinea*, is erroneously supposed to yield the Partridge-Wood of cabinet-makers. The fruit of some species is eatable when ripe, though not very pleasant. There are 21 genera and 48 species in this order.

OLD RED-SANDSTONE. By this title English geologists have almost universally designated the variable series of rocks which separate the youngest slates (Transition Rocks) from the mountain-limestone and coal. Messrs. Conybeare and Phillips ('Geology of England and Wales') ranked the Old Red-Sandstone in their Medial Order along with the coal and mountain-limestone; and this classification has been unreservedly followed till within a short period. Sir Roderick Murchison, in his work on the 'Silurian System,' has preferred to separate the Old Red-Sandstone from the superincumbent strata, and to constitute for it an additional system. Since the publication of that work, the same author, in conjunction with Professor Sedgwick, believing that the limestones and slaty and conglomerate rocks of South Devon belong to the same geological period as the true Old Red-Sandstone of Herefordshire, and desirous of improving the nomenclature, has proposed for these variable strata the title of the Devonian System.

The following table and account of this formation is given by Professor Ansted in his 'Elementary Geology':—

Old Red-Sandstone Series.		
Herefordshire.		Scotland.
Old Red Conglomerate		{ Quartzose Yellow Sandstone. Impure Limestone. Gritty Red-Sandstone.
Cornstone		Gray Fissile Sandstone.
Cornstone and Marl		{ Red and Variegated Sandstone. Bituminous Schist. Coarse Gritty Sandstone. Great Conglomerate.
Devonian Series.		
Devonshire.		Belgium.
Calcareous Grit and Impure Limestone		{ Indurated Shale and Psammite. Calcareous Shale.
Red Flagstone		Lower Limestone of Belgium.
Calcareous Slat and Plymouth Limestone		Hard Siliceous Beds and Conglomerates.

The fossils of this period include many species of corals, Encrinures, and shells. There are also a number of remains of fishes, some of very great interest from the remarkable peculiarities of form and structure which they present. Many of these are small, but others of gigantic proportions. [FISH.]

The Old Red-Sandstone of England and Wales consists of various strata of limestone, marl, and sandstone, alternating with great thicknesses of conglomerate, which often pass upwards into overlying sandstones; and the series is expanded over a considerable portion of our island, rising into lofty mountains, occupying extensive plains, and developed to an enormous thickness.

In North Wales, although the Old Red-Sandstone retains its general character, we find it inferior in thickness and importance to its development in Herefordshire and South Wales. It again increases however as we advance still farther northward into Westmoreland and Cumberland, where it appears as an irregular conglomerate. In this part of England its largest development is near the foot of Ullswater, and it rises into a succession of round-topped hills several hundred feet high, the beds being of great thickness. No true passage is there discernible into the overlying limestones.

The loftiest points occupied by this deposit are the Vans of Caermarthen and Brecon, the former 2590 and the latter 2500 feet above the level of the sea. These hills are made up of a conglomerate composed of white quartz pebbles embedded in a red matrix; and it is this quartzose conglomerate which gives its name to the uppermost group of the formation.

The highest beds of the series do not however always consist of conglomerates, but are more frequently composed of beds of sandstone, hard and finely grained, and alternating with a few imperfectly-exhibited mottled marls. The lower portion capping the escarpment of the Cornstone in Herefordshire furnishes thick beds of valuable building material, and is occasionally quarried for tiles. The upper beds are for the most part less compact, and commencing as a fine conglomerate they afterward become coarser, and alternate with bands of red and green argillaceous marl. Fine examples of the conglomerate beds (attaining near Abergavenny a thickness of 200 feet) may be seen on the banks of the Wye between Ross and Monmouth, and again on the right bank of that beautiful river to the north of Tintern Abbey.

The Cornstone consists of a number of argillaceous marly beds, sometimes alternating with sandstone and sometimes with impure limestone, affording by decomposition the soil of the richest tracts of Herefordshire and Monmouthshire. The lower part of this rock very often contains flaggy beds, some of which are extensively quarried near Downton Hall, the stone being of a greenish colour and highly micaceous, and usually more or less intermixed with party-coloured marls or soft argillaceous sandstones, not so compact as the rock which incloses them. The surface of the sandstone is frequently worn into irregular holes and patches.

But the subdivisions of the sandstones are too entirely local to allow of any lithological character being given which can apply to more than a very limited district. Generally speaking, the impure concretionary limestone, which is more especially denominated Cornstone, appears at intervals in irregular lenticular masses throughout the district, contracting and expanding in the most capricious manner; and sometimes replaced by finer and more crystalline limestone, and sometimes alternating with hard flaggy sandstones. Nearly the whole of the central and northern parts of Herefordshire, and the contiguous parts of Shropshire and Worcestershire, are occupied by this formation; and its vast thickness is well displayed in the hills crossed by the new road from Leominster to Hereford. In the northern portion of the range, and near the mouth of the Towey in Caernarthenshire, the limestones are most fully developed, becoming much thicker and also more crystalline than in other parts.

In Scotland the uppermost beds are highly arenaceous, and often consist of sandstone conglomerates. The intermediate calcareous band is barren of fossils, and is of somewhat singular composition, yielding unequally to the weather, and exhibiting a brecciated aspect. It contains masses of chert exceedingly hard, and these, from the manner in which they are incorporated with the rock, appear to have been of contemporaneous origin. The bed is several yards in thickness, and is very persistent, being found both in Moray and in Fife, localities 120 miles apart.

The middle group of the Old Red-Sandstone of Scotland, corresponding to the Cornstone of England, is developed in Forfarshire, in Morayshire, and in the Gray-Sandstone of Balrnrdery, where the lower beds are absent. It is represented as consisting, for the most part, of rocks of a bluish-gray colour, sometimes, as at Balrnrdery, resembling the silurian mudstones, at others forming a hard fissile flagstone exported as a paving-stone, and occasionally appearing in beds of friable stratified clay, easily washed away by the sea. The colour however throughout is gray, and in this respect differs essentially from the English contemporaneous beds, which are chiefly red and green marls.

The base of the whole system is represented by Mr. Miller as consisting of an extensive and thick conglomerate rising into a lofty mountain-chain in the county of Caithness, and attaining an elevation of 3300 feet in the hill called Morrhain, but a great thickness of arenaceous strata, containing conglomerates of various magnitude, intervene between these and the middle beds.

The Devonian Beds present a series so distinct that no relations of mineral or mechanical condition can be traced between them and the Old Red-Sandstones. The upper beds on which the culms of Devonshire repose, consist of coarse red flags and slates, sometimes alternating with or overlaid by other slates and limestones, while the lower beds are to be sought for among the calcareous slates of Cornwall and South Devon. The calcareous slates are occasionally fossiliferous, and are based upon an impure limestone. The Plymouth Limestone in the south, and a group of coarse arenaceous beds in the north of Devon, together with the general series of Cornish rocks, are all included among these calcareous slates. Throughout the whole series fossils occur, but they are very unequally distributed, being locally abundant, although owing to the metamorphic character of many of the beds they are sometimes much altered, and frequently obliterated. (Aborted.)

The Old Red-Sandstone is largely developed in Ireland, and is particularly interesting as presenting all those parts of the series which are found in different parts of England.

This formation is well represented in Belgium by a series of beds consisting of 1500 feet of strata. They are principally composed of a yellowish-sandstone alternating with shale and calcareous beds.

The Devonian or Old Red-Sandstones of Russia occupy a tract nearly as large as the whole of the British Islands. They rest conformably upon low plateaux of silurian rocks, and attain a height of from 500 to 900 feet above the sea level.

This formation is repeated with nearly the same mineral characters and organic remains in America. It is found in both North and South America.

The following are the genera of the Invertebrate Fossils found in the Devonian Group, as given by Mr. Tennant in his 'Stratigraphical List of British Fossils':—

Amorphozoa.

Manon cribrosum, Goldf.

Scyphia turbinata, Goldf.

Zoophyta.

Aplexus tortuosus, Phil.

Gorgonia ripisteria, Goldf.

Astrea, Blainv., 3 species.

Hemitrypa oculata, Phil.

Aulopora conglomerata, Goldf.

Millepora gracilis, Phil.

Cannopora ramosa, Phil.

Millepora similis, Phil.

Coscinopora placenta, Goldf.

Petraia, 4 species.

Cyathophyllum, 2 species.

Porites pyriformis, Ehrenh.

Cyathiphyllum, 2 species.

Stromatopora, 2 species.

Favosites, 4 species.

Strombodes, 2 species.

Pencatella, 5 species.

Syringopora catenata, Mart.

Glaucanome bipinnata, Phil.

Echinodermata.

Adelocrinus hystriz, Phil.

Platycrinus, 2 species.

Cyathocrinus, 8 species.

Tazocrinus macrodactylus, Phil.

Pentatremitis ovalis, Goldf.

Crustacea.

Brontes flabellifer, Goldf.

Olenus punctatus, Stein.

Calymene Sternbergii, Munst.

Phacops, 3 species.

Harpes macrocephalus, Goldf.

Conchifera Dimyaria.

Corbula Hennahii, Sow.

Mytilus Damnoniensis, Phil.

Cucullaea, 7 species.

Nucula, 3 species.

Cypriocardia, 2 species.

Pleurorhynchus, 2 species.

Megalodon, 2 species.

Pullastra, 3 species.

Modiola, 3 species.

Sanguinolaria, 3 species.

Conchifera Monomyaria.

Avicula, 9 species.

Posidonomya, 2 species.

Pecten, 8 species.

Pterinea, 3 species.

Brachiopoda.

Atrypa, 19 species.

Productus, 6 species.

Calceola sandalina, Lam.

Spirifer, 33 species.

Chonetes, 3 species.

Strigocephalus, 3 species.

Leptaena, 7 species.

Terebratulina, 31 species.

Orthis, 16 species.

Gastropoda.

Acroculia sigmoidalis, Phil.

Naica, 2 species.

Buccinum, 4 species.

Nerita, 2 species.

Euomphalus, 3 species.

Platyceras vetustum, Sow.

Lxonema, 8 species.

Pleurotomaria, 8 species.

Macrocheilus, 3 species.

Schizostoma, 2 species.

Murchisonia, 6 species.

Trochus Bouei, Stein.

Murex haryula, Sow.

Turbo, 3 species.

Heteropoda.

Bellerophon, 8 species.

Porcellia Woodwardii, Sow.

Pteropoda.

Crescis dimidiatum (*Orthoceras*, sp. Sow.).

Cephalopoda.

Clymenia, 7 species.

Nautilus, 2 species.

Cyrtoceras, 12 species.

Orthoceras, 12 species.

Goniatites, 11 species.

OLEA, a genus of Plants, the type of the natural order *Oleaceae*. It has a 4-cleft corolla, a berry with two brittle 1-seeded cells, one of them generally abortive. The leaves undivided. Flowers greenish, clustered, axillary.

O. Europaea has lanceolate quite entire 2-coloured leaves, with axillary racemes. It grows wild in rocky places in Italy. It differs from most trees, except the Sweet Bay (*Laurus nobilis*), some species of *Cornus*, and a very few others, in yielding a fixed oil from the pericarp; the seed being the source of fixed oils in most plants. The oil which is expressed from the ripe fruit immediately after being collected is most esteemed, and called Virgin Oil, Oleum Provinciale. That which is most highly prized comes from Nice and Genoa. When the oil is extracted by a stronger pressure, or by the aid of heat, or after the olives, having been collected into heaps, have remained till a kind of fermentation has occurred, it is the common Olive Oil, the properties of which vary in proportion as the fermentation has been of long or short duration. An oil of still inferior quality is obtained, when the husk of the olive, after the former treatment, is boiled in water. This kind is employed solely for the preparation of soap.

Virgin Oil is of a very pale-yellow or yellowish-green colour, more limpid when fine than any other fixed oil; inodorous; when fresh, but emitting a very peculiar odour when old; taste purely oily but

by age becoming slightly rancid. Common olive-oil is of a deep-greenish or brownish-yellow colour, and an odour and taste more or less subrancid. Its specific gravity is greater than the other. The unripe fruit of the olive is preserved in brine, and eaten frequently at dessert.

The olive flourishes only in warm and comparatively dry parts of the world, as the south of France and Spain, in Italy, Sicily, Syria, and the north of Africa. Humboldt has stated that "the olive flourishes between 36° and 44° N. lat.; wherever the mean annual temperature is from 62°6' to 58°1', where the mean temperature of the coldest month is not below from 41° to 42°8', and that of the whole summer from 71°6' to 73°4'." Great cold is injurious to it, as that of 1709 was to the olive-trees of France; and as M. Bové states that the olive thrives in Egypt, and Delile that it contributes to the riches of the Fayoum, which is nearly in the latitude of Cairo, it is evident that it is capable of bearing a greater degree of heat, as is probable indeed from its being a native of Asia, having been cultivated in early times in Syria and Palestine by the ancient Hebrews, and known to them by the name of Zait, and to the Arabs by that of Zaitoon. It is said to have been introduced by the Phœceans into Marseille.

OLEACEÆ, Olive-works, a natural order of Monopetalous Exogenous Plants, with a superior 2-celled ovary, a subvalvate corolla, two stamens, and a fruit with pendulous albuminous seeds. In the artificial collocations of natural orders to be found in books, these plants are usually stationed next *Jasminaceæ*, with which they have been even combined. It is however probable that they have really as much affinity with some of the monopetalous dicarpous orders. Lindley, in his 'Vegetable Kingdom,' arranges them in the Solanum Alliance, and gives their further affinities as with *Aceraceæ*, *Jasminaceæ*, and *Solanaceæ*.

The species of the order best known in this country are, the Olive, or *Olea Europæa* [OLEA]; the Lilac; or *Syringa vulgaris*; the Evergreen Phillyrea of many forms; the Privet, or *Ligustrum*; and the Fringe-Tree, or *Chionanthus*; all corresponding in habit and in sensible properties, which latter are very generally bitter and febrifugal. The bark of the Olive has been extensively used by the French instead of *Cinchona*, and the young fruits of the Common Lilac form an infusion scarcely inferior to gentian.

Olive (*Olea Europæa*).

1, a flower; 2, an ovary divided vertically; 3, a ripe fruit cut in half; 4, a stone divided longitudinally.

The most anomalous genus of the order is the Ash, which, in its most genuine form, has no petals, and in the division called *Ornus* has the petals present, but separate to the base. It is however, in all essential circumstances, the same in structure as the more regular genera; and its relation to the order has been ingeniously proved by the fact that the Olive and the Lilac will both live when grafted upon it. It is from the *Ornus*, or Flowering-Ash, that the bitter-sweet purgative called manna is secreted. [FRAXINUS.]

The order has 24 genera and 130 species.

OLEANDER. [NERIUM.]

OLEGON SPAR, a Mineral consisting of Carbonate of Iron and Manganese. Its primary form is an obtuse rhomboid. Cleavage on the faces of the primary. Its colour is yellow, reddish-brown. Lustre

vitreous. Hardness 4·0. Specific gravity 3·745. It is found at Ehrenfriedensdorf. Its analysis by Magnus gives—

Carbonate of Iron	59·99
Carbonate of Manganese	40·66
	—100·65

OLEIN. [ADIPOSE TISSUE; FAT.]

OLIBANUM. [BOSWELLIA.]

OLIGISTE. [IRON.]

OLIGOCLASE, a Mineral occurring crystallised. Its primary form is an oblique rhombic prism. Colour white, yellowish, and greenish-white. Fracture conchoidal, uneven. Hardness 6·0. Transparent, sub-translucent. Specific gravity 2·64 to 2·67. It is found at Danvikszoll near Stockholm, Arendal in Norway, &c. Its analysis by Berzelius gives—

Silica	63·70
Alumina	23·95
Lime	2·05
Magnesia	0·65
Soda	8·11
Potash	1·20
Peroxide of Iron	0·50
	—100·16

OLIGODON (Boîé), a genus of Snakes.

OLIVA. [VOLUTIDE.]

OLIVE-OIL. [OLEA.]

OLIVE-TREE. [OLEA.]

OLIVELLA, Mr. Swainson's name for a genus, or rather a sub-genus, separated by him from *Oliva*; and characterised as having two plaits on the columella.

OLIVENITE. [COPPER.]

OLIVINE. [CHRYSLITE.]

OLYGYRA. [HELICIDE.]

OMALAXIS. [TROCHIDE.]

OMALISUS. [LAMPYRIDE.]

OMENTUM is a broad band of membrane connecting two or more of the abdominal viscera. The chief of these membranes is the great omentum, or caul, which forms a large fold connecting the stomach with the transverse arch of the colon; others of less size and importance connect the stomach and liver, and the stomach and spleen. The great omentum always contains some fat surrounding its blood-vessels, so that it looks like a network of fatty tissue, and it is one of the chief seats of the accumulation of fat in corpulent persons, in whom it contributes largely to the peculiar prominence of the abdomen.

OMMASTREPHES, a genus of Cuttle-Fishes belonging to the family *Teuthidæ*. Body fleshy, firm, cylindrical, elongated, flanked near its posterior extremity by two triangular fins. Locomotive apparatus formed of "conical perpendicular pits, each communicating by a narrowed groove with a small horizontal pit, surrounded by a prominent margin, the whole describing a rather prominent triangle, placed at the base of the locomotive tube; and, besides, of a tubercle prolonged into its upper part into a decreasing nose-shaped crest; and lastly, of little horizontal inferior crests placed on the inner margin of the body." Eyes very large, opening widely exteriorly, and provided with a lachrymal sinus; arms 10, like those of *Loligo*; pen corneous, flexible, elongated, as long as the body, terminating at its lower extremity in a hollow simple cup.

The Cuttle-Fishes of this genus closely resemble those belonging to *Loligo*. Besides the character just given, they may generally be distinguished by the short rhomboidal termination of the body, formed by the fins, combined with the hinder extremity.

The species are mostly pelagic, and some of them are gregarious. They seem to be distributed all over the world. They are called Flying Squids by fishermen. (Forbes and Hanley.)

The following species have been taken on the British coasts:—

O. sagittatus (*Sepia Loligo*, Linnaeus), with an elongated body; peduncles of tentacular arms without suckers; extremities of their clubs covered with closely-set rows of numerous minute suckers. This species is very rare on the British coast, but Messrs. Forbes and Hanley record two instances of its recent capture. M. D'Orbigny regards the *Loligo Piscatorum*, *L. Harpago*, *L. illecebrosa*, and *L. Coidetii* as founded on this species.

O. todarus (*Loligo sagittata*, Lam.), Delle Chiaje. It has an elongated body, and the peduncles of the tentacula provided with suckers throughout their length. This squid is often called in British catalogues *Loligo sagittata*. It is frequently found on the coasts of Great Britain. It has been made the subject of an elaborate memoir on the anatomy of its nervous system by Mr. Albany Hancock.

O. Eblana (Ball), has a short body; suckers confined to the clubs of the tentacles, minute, and 4-ranked at their extremities. It has been found in Dublin Bay, and was first described by Dr. R. Ball of Dublin.

(Forbes and Hanley, *History of British Mollusca*.)

OMPHALEA, a genus of Plants belonging to the natural order *Euphorbiaceæ*. The seeds of one of the species are said to be eatable when the embryo is extracted, but if this is not done, they are too cathartic for food. On the authority of Mr. W. McLeay, Dr. Lindley

says this nut is most delicious and wholesome, and that it is known by the name of Cob-Nut or Hog-Nut in Jamaica. Other euphorbiaceous seeds have the same properties.

O. triandra is a Guyana plant with a white juice, which turns black on drying, and is then used as ink.

(Lindley, *Vegetable Kingdom*.)

ONAGER. [EQUIDE.]

ONAG'IA. [EQUIDE.]

ONAGRA. [EQUOTHERA.]

ONAGRACEÆ, *Onagraceæ*, a natural order of Polypetalous Exogenous Plants, which, in their more complete condition, are certainly known by their inferior ovary, and by all the parts of the flower being four, or a constant multiple of that number. Thus in the plant now figured (*Jussiaea grandiflora*) there are four sepals, four petals, twice four stamens, four stigmas, four cells to the ovary, and the fruit when ripe bursts into four valves. The species characterised by this peculiarity are chiefly herbaceous plants, inhabiting the more temperate parts of the world, and have white, yellow, or red flowers, such, for example, as the great genus of *Enotheras*, or Evening Primroses, and the *Epilobiums*, which are so common as wild plants. It is only in the *Fuchsia*, which has a succulent fruit, and forms an approach to *Myrtaceæ*, that a woody structure is met with. [FUCHSIA.]

Jussiaea grandiflora.

1, a fruit nearly ripe, and surmounted by its four sepals; 2, a transverse section of the same, to show the four cells.

But although genuine *Onagraceæ* are thus plainly limited, botanists admit into the order other plants which do not possess the character proper to the order, and which are regarded as imperfect states of it. Thus *Hippuris*, which has only one stamen, no petals, and a 1-celled ovary, is regarded as a case of degradation from the *Onagraceous* type; and *Lopesia*, with only one perfect stamen, one imperfect stamen, and two petals, is considered another but less degraded condition of the order. [HALORAGACEÆ.]

A large proportion of *Onagraceous* plants are ornamental, and consist of common garden flowers, especially the species (*Enothera*, *Gedelia*, *Epilobium*, and *Fuchsia*; but they possess no useful qualities. [CICUTA; ENUOTERA; EPILONIUM.]

The order contains 28 genera and 450 species.

ONCIDIUM is a very large genus of tropical and subtropical (*brechidaceæ*), found in the western hemisphere, where the species are common, especially in Mexico and some of the West Indian Islands, Brazil, and Peru. They have usually yellow flowers spotted with a rich reddish brown; sometimes the blossoms are purple, and more rarely white. They belong to the Vandeous section of their order (*ORCHIDACEÆ*), and are known by their labellum being broad, more or less lobed, distinct from the column, and furnished at the base with a tuberculated disc, which usually presents some grotesque appearance. Their sepals and petals are spreading, their column has a membranous ear on each side, and they have two pollen masses attached to a long caudicula. The most remarkable species is the Butterfly-Plant, so called in consequence of the supposed resemblance of its flowers to some insect upon the wing. This is found in Trinidad, growing on the branches of trees, and bears a long, jointed, compressed, spotted scape, from the apex of which swings lightly a large yellow and brown flower, whose labellum is compared to the body of an insect, the column to its head, a pair of processes arising from the column to short antennæ, and the long narrow sepals and petals to legs. It is now common in hot-houses.

Butterfly-Plant (*Oncidium Papilio*).

ONDATRA (Lacépède), a genus of Mammalian Animals belonging to the family *Castoridae*. *Ondatra* is the native name of the Musquash, which has been adopted as its generic designation. The only species of this genus is the Musquash of America. Of this animal Sir John Richardson gives the following synonyms:—

Rat-Musqué of Sagard Theodat; *Castor Zibethicus* of Linnæus; *Ondatra* of Buffon; Musk-Rat of Lawson; Musk-Beaver of Pennant; *Mus Zibethicus* of Linnæus and Gmelin; *Fiber Zibethicus* of Sabine and Harlan; Musk-Rat of Godman; Musquash, Watuss, or Wachusk, also Peesquaw-Tukeyew (the animal that sits on the ice in a round form), of the Cree Indians.

In a tract which has for its title, 'A Perfect Description of Virginia,' 1649, we find among the "Beasts great and small . . . a Musko-Rat, so called for his great sweetness and shape."

Dental Formula:—Incisors, $\frac{2}{2}$; Molars, $\frac{3-3}{3-3} = 16$.

Teeth of Musquash. F. Cuvier.

The head is short. Body thick and rather flat; legs very short; hind feet large, not webbed. Dark amber-brown above; sides, anterior part of belly, middle of breast, lateral part of neck and cheeks, shining yellowish-brown; chin, throat, sides of the chest, and posterior part of the abdomen, ash-gray; tail compressed, convex on the sides, with its acute edges in a vertical plane, covered with a thin sleek coat of short hairs, which allow a number of small roundish scales, well separated from each other, and which as well as the hair are dusky-brown, to appear through them; acute margins of the tail (which is rather thicker in the middle than at the root, and tapers gradually from its middle to its extremity, which is not acute) covered with a close line of longer hairs dark-brown on the upper edge and soiled white on the under one. Length of head and body 14 inches; of the tail, 8 inches 6 lines.

The fur, which much resembles that of the beaver, but is shorter,

resists the water during the life of the animal, but is easily wetted immediately after death.

Musquash (*Castor Zibethicus*).

Charlevoix states that the Musk-Rat takes the field in March, at which time its food consists of bits of wood, which it peels before it eats them. After the dissolving of the snows he says that it lives upon the roots of nettles, and afterwards on the stalks and leaves of that plant. In summer it feeds on strawberries, &c., to which succeed the autumnal fruits. During this time he states that the male and female are rarely seen asunder. According to the same author they separate in winter, when each takes up its lodgings apart in some hole or in the hollow of a tree, without any provision; and the Indians declared that not the least morsel of anything is eaten by them whilst the cold continues. "They likewise," adds Charlevoix, "build cabins nearly in the form of those of the heavers, but far from being so well executed. As to their place of abode, it is always by the water-side, so that they have no need to build causeways. . . . The flesh is tolerably good eating, except in the time of rut, at which season it is impossible to cure it of a relish of musk, which is far from being as agreeable to the taste as it is to the scent."

The habitations of the Musquashes, and the mode of hunting them, are thus described by Sir John Richardson:—"In the autumn, before the shallow lakes and swamps freeze over, the Musquash builds its house of mud, giving it a conical form, and a sufficient base to raise the chamber above the water. The chosen spot is generally amongst long grass, which is incorporated with the walls of the house, from the mud being deposited amongst it; but the animal does not appear to make any kind of composition or mortar by tempering the mud and grass together. There is however a dry bed of grass deposited in the chamber. The entrance is under water. When ice forms over the surface of the swamp the Musquash makes breathing holes through it, and protects them from the frost by a covering of mud. In severe winters however these holes freeze up in spite of their coverings, and many of the animals die. It is to be remarked that the small grassy lakes selected by the Musquash for its residence are never so firmly frozen nor covered with such thick ice as deeper and clearer water. The Indians kill these animals by spearing them through the walls of their houses, making their approach with great caution, for the Musquashes take to the water when alarmed by a sound on the ice. An experienced hunter is so well acquainted with the direction of the chamber and the position in which its inmates lie, that he can transfix four or five at a time. As soon as, from the motion of the spear, it is evident that the animal is struck, the house is broken down, and it is taken out. The principal seasons for taking the Musquash are—the autumn before the snow falls, and the spring after it has disappeared, but while the ice is still entire. In the winter time the depth of snow prevents the houses and breathing-holes from being seen. One of the first operations of the hunter is to stop all the holes with the exception of one, at which he stations himself to spear the animals that have escaped being struck in their houses, and come hither to breathe. In the summer the Musquash hurrows in the banks of the lakes, making branched canals many yards in extent, and forming its nest in a chamber at the extremity, in which the young are brought forth. When its house is attacked in the autumn it retreats to these passages, but in the spring they are frozen up. The Musquash is a watchful but not a very shy animal. It will come very near to a boat or canoe, but dives instantly on perceiving the flash of a gun. It may be frequently seen sitting on the shores of small muddy islands in a rounded form, and not easily to be distinguished from a piece of earth, until on the approach of danger it suddenly plunges into the water. In the act of diving, when surprised, it gives a smart blow to the water with its tail."

Sir John Richardson records three varieties besides that above described:—

1. The Black Musquash, rare.
2. The Pied Musquash, with dark blackish-brown patches on a white ground.
3. The White Musquash (*Fiber Zibethicus-albus*, Sabine). This albino is not unfrequent.

According to Hearne, the Musquash is easily tamed, soon becomes attached, and is cleanly and playful.

The fur is used in hat-making, and upwards of one million of skins are imported into this country every year.

ONION. [ALLIUM.]

ONISCIA. [ENTOMOSTOMATA.]

ONISCODA. [ISOPODA.]

ONISCUS. [ISOPODA.]

ONOBRYCHIS (from *ὄνος*, an ass, and *βρύχω*, to gnash the teeth), a genus of Plants belonging to the natural order *Leguminosae*. It has a calyx with 5 nearly equal subulate teeth; the keel obliquely truncate, longer than the wings; the pod 1-celled, compressed, indehiscent, 1-seeded, upper suture straight, lower curved, toothed, winged or crested. The species of this genus are natives of Europe or Asia, with unequally pinnate leaves, and axillary elongated pedicels having spikes of flowers red or white at their tops. The most common, as well as only British species is *O. sativa*, Common Sainfoin. [SAINFOIN, in ARTS AND SC. DIV.] About forty other species have been described, but none of them possess useful properties. Many are showy plants when in bloom, and are adapted for flower-borders or rockwork. They may be propagated by seeds. (Babington, *Manual of British Botany*.)

ONONIS (from *ὄνος*, an ass, and *ὄνημι*, to delight, some of the species being said to be grateful to asses), a genus of Plants belonging to the natural order *Leguminosae*. It has a 5-cleft campanulate calyx, narrow segments, the lower ones longer. The keel is beaked, the style filiform and ascending, the stigma terminal and subcapitate.

O. arvensis, Trailing Rest-Harrow, has a procumbent uniformly hairy stem, axillary stalked solitary flowers, broadly oblong leaflets, ovate pods shorter than the calyx. It is usually without spines. The stems root at their base, and the seeds are tubercular and scabrous.

O. antiquorum has an erect or ascending stem, bigariously hairy; axillary solitary stalked flowers, oblong leaflets, and ovate erect pods longer than the calyx. It is doubted by many botanists as to this being the true *O. antiquorum*. Koch and Reichenbach both describe quite a different plant, with smooth seeds.

O. reclinata has a viscid pubescent stem, axillary flowers with one-flowered pedicels shorter than the leaf-flower, a pod without bracts, the corolla about equal to the calyx, obovate cuneate leaflets serrated at the lip, ovate stipules, and cylindrical reflexed pods. It is found in sandy places in Galloway and the Channel Isles, and in the south of France by the sea coast.

There are 107 species of this genus described, but none of them are used in medicine or the arts. They are chiefly natives of Europe; about twelve species are found in Africa, and a few on the coast of Asia.

(Babington, *Manual of British Botany*.)

ONOPORDUM, a genus of Plants belonging to the natural order *Compositae*. It has a honeycombed receptacle, a 4-ribbed fruit, and an imbricated involucre, with simple spinous pointed scales.

O. Acanthium, Cotton-Thistle, has an erect many-headed stem, elliptic oblong leaves, woolly on both sides; serrate, spinous, and decurrent; the outer involucre scales lanceolate, subulate, recurved, and spreading. The stem is from 4 to 5 feet high; woolly, with broad spinous wings; the involucre nearly globose, large, and somewhat cottony; the scales fringed with spinous teeth; the florots are purple. This plant is found on waste ground in Great Britain and Spain. Another name for the same species is Wild Artichoke, or Alcachofa of the Spaniards, on account of the fleshy receptacle being once cultivated as an esculent vegetable. The expressed juice of this plant is said by Eller to be a serviceable application to cancer of the breast, and to cleanse foul ulcers; and a decoction of the root, which is astringent, has been used to restrain discharges from the mucous membranes. The seeds are oleiferous; and M. Durand reports, as the result of experiments, that 22 lbs. of onopordum heads will yield 12 lbs. of seeds, from which 3 lbs. of oil fit for burning may be extracted by heat.

(Babington, *Manual of British Botany*; Burnett, *Outlines of Botany*.)

ONOSMA (from *ὄνος*, an ass, and *ὄσμη*, smell; grateful to the ass), a genus of Plants belonging to the natural order *Boraginaceae*. It has a 5-parted calyx, a tubularly campanulate corolla, and a naked throat. The anthers are sagittate, and connected together by the bases of the lobes. The nuts are ovate, strong, and fixed to the bottom of the calyx, unperforated at the base. The species are small scabrous caespitose plants, with crowded lanceolate or linear leaves, and terminal racemes of large yellow second and usually drooping flowers.

O. Emodi has lanceolate triple-nerved leaves, less hairy beneath, terminal solitary racemes, linear bracts, not half so long as the flowers; the calyx is 5-cornered with ovate segments, a ventricose 5-keeled corolla contracted towards the mouth, and the anthers longer than the filaments. It is a native of Nepal, in Gosaingthan, where it is called by the natives Maharanga. The root is branched, of a dark purple colour, and is used in dyeing.

O. cochineum is a hispid plant, covered with white pungent hairs. It has terminal racemes and pedicellate flowers. The corolla is yellow, a little longer than the calyx, tubularly campanulate with reflexed teeth.

O. tinctorium is a native of Tauria, in the vicinity of the Bosphorus. The root is simple, blackish, and covered with a red pigment, which stains paper a violet colour.

All the species of this genus, which exceed thirty in number, are extremely handsome when in blossom, but are not valuable on account of any peculiar properties. Most of them are natives of rocks and sandy places in Europe and Asia, and answer well to grow in rock-work or wall tops. They are short-lived, and apt to rot. They do well however in pots among other alpine plants.

(Don, *Dichlamydeous Plants*.)

ONYCHOTHERIUM. [MEGATHERIIDÆ.]

ONYX. [AGATE.]

OOLITE, the characteristic rock of one of the great systems of secondary strata. [GEOLOGY.] One of the purest examples of Oolite is the fine yellow freestone of Kotton in Northamptonshire, which is wholly composed of round grains of concretionary structure, adherent by their contiguous surfaces, so as to form a stone easily wrought with the chisel, and of a durable quality. The Bath free stone is another example, where the grains (often hollow) are connected by interposed calcareous matter; the Portland stone resembles the former, but contains disseminated or aggregated silex; and not to extend the catalogue, much of the Lincolnshire freestone is Oolite, of which the round grains are firmly compacted in a general basis of crystallised carbonate of lime. The resemblance of the grains to small ova, or the roe of fishes, has given origin to the English term Oolite (from the Greek *ὄωρ*, an egg), and the German Rogenstein, or roestone.

Limestones possessing the oolitic character occur in different parts of the series of strata, but nowhere very abundantly except between the lias and the greensands. Specimens may be found in the mountain-limestone at Clifton, Kirkby Lonsdale, &c., and in the magnesian limestone of Yorkshire and Derbyshire; and in this latter case the grains, large and distinct, show obviously the concentric lamination which belongs to certain oolites called Pisolites, and which may be detected in nearly all with the aid of the microscope.

At one time it was supposed that the little round masses which are so characteristic of this formation were portions of limestone which had gathered round various forms of minute fossil animals. It was suggested that these organisms were probably *Foraminifera*. Recent microscopic investigations have however shown that these little round bodies are purely inorganic, and that they are formed in the same manner as the larger nodules of the magnesian limestone. [MAGNESIAN LIMESTONE.]

The oolitic deposits are divided naturally in England into three parts, the Upper Oolite resting on the Kimmeridge Clay, the Middle Oolite representing the Oxford Clay covered by the Coral Rag, while the Lower Oolite is more varied, being composed of numerous bands of clay, sand, and limestone.

The *Upper Oolite*, called on the continent the Portlandian Group, are, so far as the British Islands are concerned, almost entirely confined in their development to the south of England, only that stratum of clay which usually forms the base of the group being exhibited in Yorkshire, in the vale of Pickering.

The group of strata containing the Portland stone, and exhibited in Portland Island, includes several layers of coarse earthy limestone, which rest on a bed of siliceous sand, mixed with green particles. This is called the Portland Sand, and sometimes attains a thickness of as much as 80 feet in the west of the island, and forms a complete passage into the underlying clay.

Above the coarse limestones of the lower part, which usually consist of alternate hard and soft layers to a thickness of 50 or 60 feet, there are three beds of serviceable stone, interstratified with clayey or siliceous bands. Fossils occur in all these strata; but they are rare in those beds of the stone which are worked to advantage for economical purposes.

In the upper part of the Portland series there occurs a very interesting bed, about a foot in thickness, of a dark-brown substance, containing much earthy lignite. This bed, called the Dirt-Bed, seems to be made up of black loam, which at some distant period nourished the roots of trees, fragments of whose stems are now found fossilised around it. Whenever the dirt-bed is laid open to extract the subjacent building-stone these remains of trees occur, and they are placed at such distances from one another as trees growing in a modern forest.

It results from the circumstances of this deposit, that the surface of the Portland stone, at the termination of the Oolitic period, must have been for some time dry land, and covered with a forest; and we have a kind of measure even of the duration of this period in the thickness of the dirt-bed, which has accumulated more than a foot of black earth, loaded with the wreck of its former vegetation. "The regular and uniform preservation also of this thin bed over a distance of so many miles, shows that the change from dry land to the state of a fresh water lake or estuary (which the nature of the overlying rock proves to have succeeded the period of dry land) was not accompanied

by any violent denudation or rush of water, since the loose earth, together with the trees which lay prostrate on its surface, must inevitably have been swept away had any such violent catastrophe then taken place."

The *Kimmeridge Clay* is of a blue, slaty, or grayish-yellow colour. It frequently contains a considerable quantity of silenite, or crystallised sulphate of lime. It usually effervesces with acids, and exhibits in tolerable abundance both vegetable and animal impressions, although its fossils are rarely in such good condition as to be preservable in a collection. It is a bed of great thickness; horizontal, or nearly so, in its stratification; extremely persistent in its peculiar mineral and fossil characters, but not very extensively developed either in England or on the continent. The name, Kimmeridge Clay, has been applied to it because it is well exhibited at Kimmeridge Bay, and near the village bearing the same name in the Isle of Purbeck.

At this spot there are also found, alternating with the clay, certain beds of highly bituminous shale, occasionally used for fuel, and locally known as the Kimmeridge Coal. There are many beds of lignite found in the Oolites, but these are perhaps the most remarkable, next to those of the lowest Oolitic deposits of Yorkshire and North America.

Among the foreign rocks of this part of the oolitic period are—1st, the Calcaire de Blangy, on the coast of Normandy; 2nd, the upper beds of the Jura, in Switzerland; and 3rd, the Soleuhofen beds.

On the banks of the Donetz, in southern Russia, there are beds of Oolitic Limestone of light-yellow colour, which appear to belong to this division of the secondary series.

The *Middle Oolites* consist for the most part of a thick bed of clay, called the *Orford Clay*, widely expanded throughout England, and met with also in the same form on the Continent, and a series of overlying limestones, chiefly remarkable for the abundant remains of coral found in them.

The upper beds of the Middle Oolitic Series are partly calcareous and partly sandy, the former consisting chiefly of a very interesting group of corals known under the name of Coral-Rag, and the latter, the sandy beds, or calcareous grits, often more or less intermixed with calcareous matter, and containing thin laminae of clay sometimes passing into irregular bands of hard and tough marly rock. This calcareous matter seems entirely due to the presence of crushed and decomposed organic remains.

It is chiefly in Wiltshire, near the towns of Calne and Steeple Ashton, and in the surrounding neighbourhood, that the corals of the Coral-Rag are found in greater abundance and perfection; and this part of our island, at the time of the deposit, has clearly existed in the condition of a coral island in an open sea. The thickness of the bed is about 40 feet; large portions of it are frequently made up of the remains of a single species, and an earthy calcareous freestone, sometimes used as a building-stone, and full of fragments of shells, rests immediately upon it, and is surmounted by a fine-grained ferruginous sandstone, slightly oolitic in structure, and containing a few fossils, marking the close of the Middle Oolitic period.

In the north of England the contemporaneous bed is a calcareous deposit, also containing corals, but (as at Malton, in Yorkshire) including a considerable proportion of the fossil remains of shells, both bivalves and univalves. The bed never loses its coralline character, and may perhaps represent an imperfect coral reef, once extending from the south-west of England to what is now the right bank of the Humber.

The *Orford Clay* is a very important member of the oolitic series, attaining a thickness of not less than 500 feet, and spreading over a great part of England—more especially occupying the fen-districts in the counties of Cambridge and Lincoln, which appear to be partly caused by the union of this bed with the Kimmeridge Clay, producing a wide expanse of flat and undrained country. The same deposits are well seen at Weymouth; and they cover an important part of the East Riding of Yorkshire. The stratification throughout is nearly horizontal and undisturbed, being conformable with that of the formations immediately above and below it.

The appearance of the Oxford Clay is that of a stiff pale-blue argillaceous bed, containing a large proportion of calcareous matter, and a more or less abundant mixture of iron pyrites. Numerous organic remains are found in it, which are sometimes preserved in the clay itself, but more frequently form a nucleus, about which iron pyrites have aggregated. Those preserved in the clay have been generally found in a very rotten condition.

The *Lower Oolites* admit of considerable subdivision in the British Islands, but the details seem to be rather of local than general interest; and though partially extending to Normandy, are by no means universal in other parts of Europe. [GEOLOGY.]

1. The Cornbrash (the uppermost bed) consists of a variable thickness of clays and sandstones, which ultimately pass into a thin rubbly stone, tough and occasionally crystalline.

2. The Forest Marble, which consists of carbonate of lime.

3. The Great Oolite, consisting of a variable series of coarse shelly limestones.

4. The Bradford Clay, consisting of a pale-greenish clay, containing a small proportion of calcareous matter and inclosing thin slabs of tough brownish limestone.

5. The Great Oolite is separated from the next bed, containing amongst them the clay used in the manufacture of cloth under the name of Fuller's Earth, and also a thin calcareous flag-stone known as the Stonesfield Slate. The latter is remarkable for containing the remains of Marsupiate Animals. [MARSUPIATA.]

6. The Inferior Oolite is the last of the series of oolitic limestones. It is employed to a great extent as a building material. Its representative in France is the Caen Limestone.

The oolitic system embraces also the formation called Lias. In England it consists of a series of strata in which an argillaceous character predominates throughout; it also contains limestone mixed with clay. It seems to form four principal members, which are thus described by Professor Ansted.

"The Upper Lias, or Alum-Shale, is best seen at Whitby, and on the Yorkshire coast, and it attains there a considerable thickness. It consists of three distinct parts: the lower division including soft shales, extremely fossiliferous, which are separated from the uppermost series, also composed of incoherent slaty beds, by an intermediate stratum of hard shale, about 30 feet thick, containing a quantity of the mineral called jet, and also occasionally large fragments of the bituminized wood of coniferous trees. The jet itself is but a peculiar form of carbon, and there can be little doubt that it is of organic origin. It is in the upper shales of the lias, both on the coast of Yorkshire and at Lyme Regis, that there have been found the most remarkable and interesting of those fossil remains of extinct animals, for which the formation is so celebrated. The presence of alternate bands of tolerably hard limestone and soft shale is usually characteristic of the lias in the different parts of England where it is most developed. The dark bluish-gray colour, united with the singular riband-like structure, is more particularly remarkable in the upper beds of the formation, and is well seen at Lyme Regis, Whitby, and Barrow-upon-Soar, in Leicestershire.

"The principal locality of the middle beds of the lias is the neighbourhood of Cheltenham, where the marlstone of Dumbleton Hill is crowded with interesting organic remains. It is made up of alternating layers of coloured clays and sands, which are occasionally calcareous, and of beds of impure limestone.

"This part of the series is also represented in the north of England, where it has an average thickness of about 130 feet, and consists of sandy shales, of which the upper portions are distinguished by the presence of several bands of argillaceous iron nodules.

"Lower Lias Shale.—The great mass of the lower division of the Lias is found in the middle of England, and consists of thick beds of dark coloured and finely laminated shale, in which are calcareous bands and concretions. These form the base of the series, and graduate downwards into a whitish sandstone, belonging to the uppermost beds of the New Red-Sandstone system. The transition is different again in the south of England; and at Lyme Regis marls of a light-bluish colour represent the upper beds of the New Red-Sandstone and pass into the Lias Limestone by a succession of dark slaty marls, which are overlaid by a number of gray calcareous beds, and these again by other slaty marls of the upper series. The Marlstone and Upper Lias Shales are not present in this part of the deposit in their ordinary form.

"The lowest portion of the Liassic System occasionally consists of a very thin bed, in some places entirely made up of the fragments of fossil bodies (chiefly the remains of fish), but sometimes passing into a white micaceous sandstone, still recognisable as the same bed. This bed was first observed underlying a small patch of Lias, near the town of Aust (situated on the left bank of the Severn, nearly opposite the mouth of the Wye); but it has since been recognised at Axmouth, in Devonshire, and in other parts of England farther north, having a total range of upwards of 100 miles. It is rarely more than 2 or 3 inches in thickness, but invariably occupies the same geological position, and is for the most part so exclusively composed of organic remains, that a long period must have been required for its formation. In some parts of the country, and especially in Gloucestershire and Worcestershire, the passage of the Lias into the underlying beds of New Red-Sandstone is marked by the presence of calcareous flagstones, called Lower Lias Limestones; and these usually alternate with laminated shales, the whole in that case forming together the lowest deposits of Lias.

"On the Continent the Lias is frequently found, and the upper beds resemble those developed in England; the middle however are usually more calcareous, and the lower more sandy, and these latter sometimes, as in Belgium, pass insensibly into the upper New Red-Sandstone. The town of Luxemburg is built upon a hard sandstone of this kind, and these beds pass into the rock called Arkose, a peculiar and often metalliferous metamorphosed deposit, occurring where the Lias sands come in contact with crystalline rocks. Fossils have been found in South America, and also in Northern India, attributed to the period we are now considering.

"The Lias is a formation exceedingly rich in fossils; and amongst them are representatives of all the principal natural groups. Corals however are exceedingly rare, and of small size. Ecnrinites are numerous and abundant, especially the Pentacrinite, which attached itself to floating wood. Radiated animals of other kinds characterise parts of the deposits, and of these the *Diadema* is an example.

Insects and Crustaceans have been frequently found. Star-Fishes are common in the marlstone.

"Both univalve and bivalve shells of various kinds are characteristic either of the whole deposit or of different beds. The *Spirifer* is one of the later species of a genus represented far more abundantly in more ancient deposits, while the *Plicatula* and *Plagiostoma* are among the ancient representatives of more recent forms. The *Pecten* is an example of a similar kind; and the *Ammonite* and *Belemnite* are eminently characteristic cephalopodous shells, infinitely abundant during the Lias, and scarcely less so for a great part of the oolitic period. Above 170 species of *Mollusca* have been described from the British localities only, of which as many as 70 are *Ammonites*.

"Fishes' remains are common in some parts of the Lias, and as many as 60 species in all have been described; of these many resemble the shark, but none seem to have attained very gigantic proportions. This however was not the case with the Reptiles, which during the period in question, were equally remarkable for their large size, voracious habits, and incredible abundance. Many species belonging to natural orders of these animals long since lost, were then widely dispersed; and many other species existed of genera now common in distant parts of the world. The Flying Reptile [*PTERODACTYL*] is a striking instance of anomalous structure. The swimming and indeed strictly marine monsters named *Ichthyosaurus* and *Plesiosaurus*, are other examples." [ICHTHYOSAURUS; PLESIOSAURUS.]

The following is a list of the Fossil Genera found in the Oolitic Beds:—

Planifera.

<i>Alethopteris</i> , 2 species.	<i>Peuce</i> , 2 species.
<i>Araneurites peregrinus</i> , Presl.	<i>Phleboteris</i> , 2 species.
<i>Bensonia ovata</i> , Buck.	<i>Polypodites</i> , 2 species.
<i>Brachyphyllum mammillare</i> , Liudl.	<i>Polystichites Murrayana</i> , Presl.
<i>Bucklandia squamosa</i> , Brong.	<i>Pterophyllum</i> , 4 species.
<i>Carpolithes</i> , 3 species.	<i>Salicites longifolius</i> , Buckm.
<i>Cyclopteris</i> , 2 species.	<i>Solenites</i> , 2 species.
<i>Dictyophyllum rugosum</i> , Lindl.	<i>Sphæredia paradoxa</i> , Lindl.
<i>Equisetites</i> , 2 species.	<i>Sphenopteris</i> , 6 species.
<i>Lilia lanceolata</i> , Buckm.	<i>Sphærococcites</i> , 2 species.
<i>Lycopodites</i> , 2 species.	<i>Stricklandia acuminata</i> , Buckm.
<i>Naiadea</i> , 2 species.	<i>Strobilites elongata</i> , Liudl.
<i>Neuropteris recentior</i> , Lindl.	<i>Terniopteris</i> , 3 species.
<i>Olopteris</i> , 2 species.	<i>Thuytes</i> , 4 species.
<i>Pachypteris</i> , 2 species.	<i>Tympanophora</i> , 2 species.
<i>Pecopteris</i> , 11 species.	<i>Zamites</i> , 6 species.

Amorphozoa.

Spongia, 7 species.

Zoophyta.

<i>Alecto dichotoma</i> , Lamx.	<i>Heteropora</i> , 2 species.
<i>Aspendesia cristata</i> , Lamx.	<i>Idmonea triquetra</i> , Lamx.
<i>Agaricia lobata</i> , Goldf.	<i>Intricaria Bajocensis</i> , Bronu.
<i>Astrea</i> , 5 species.	<i>Lithodendron elegans</i> , Goldf.
<i>Caryophyllia</i> , 2 species.	<i>Madrepora limbata</i> , Goldf.
<i>Cerriopora clavata</i> , Goldf.	<i>Meandrina Soemmeringii</i> , Goldf.
<i>Chrysaora</i> , 2 species.	<i>Millepora</i> , 2 species.
<i>Cricopora</i> , 2 species.	<i>Monticallia caryophyllata</i> , Lam.
<i>Diatopora</i> , 3 species.	<i>Terebellaria ramosissima</i> , Lamx.
<i>Eunomia radiata</i> , Lamx.	<i>Theonoe clathrata</i> , Lamx.
<i>Fungia orbulites</i> , Lamx.	<i>Turbinolia dispar</i> , Phil.

Echinodermata. [ECHINODERMATA.]

<i>Serpula</i> , 17 species.	<i>Annelida.</i>
<i>Vermilia sulcata</i> , Sow.	<i>Vermicularia</i> , 5 species.

<i>Pollicipes</i> , 3 species.	<i>Cirripedia.</i>
--------------------------------	--------------------

Insecta. [INSECTA.]

Crustacea.

Astacus, 4 species.

Conchifera Monomyaria.

<i>Amphidesma</i> , 3 species.	<i>Lutaria</i> , 5 species.
<i>Anatina undulata</i> , Sow. sp.	<i>Lysianassa</i> , 4 species.
<i>Arca</i> , 9 species.	<i>Mactromya Cardiodes</i> , Phil. sp.
<i>Astarte</i> , 16 species.	<i>Modiola</i> , 17 species.
<i>Cardiniu</i> , 12 species.	<i>Mya</i> , 3 species.
<i>Cardium</i> , 12 species.	<i>Myocncha crassa</i> , Sow.
<i>Corbis</i> , 3 species.	<i>Mytilus</i> , 4 species.
<i>Corbula</i> , 4 species.	<i>Nucula</i> , 11 species.
<i>Cucullea</i> , 14 species.	<i>Opis</i> , 2 species.
<i>Cypriocardia solida</i> , Lycett.	<i>Panopæa</i> , 3 species.
<i>Cythereu</i> , 2 species.	<i>Pectunculus</i> , 2 species.
<i>Gastrochaena tortuosa</i> , Sow.	<i>Pholadomya</i> , 19 species.
<i>Gresslya Anglica</i> , Ag.	<i>Pholas</i> , 2 species.
<i>Hippopodium ponderosum</i> , Sow.	<i>Pinna</i> , 8 species.
<i>Isocardia</i> , 11 species.	<i>Psammobia levigata</i> , Phil.
<i>Lucina</i> , 4 species.	<i>Pullastra</i> (?), 4 species.

Conchifera Monomyaria.

Sphæra Madridi (Cardium), Arch. *Thracia depressa*, Sow. sp.
Sanguinalaria, 8 species. *Trigonia*, 13 species.
Tellina ampliata, Phil. *Unio distortus*, Bean.
Thais varicosus (Læus), Sow. *Venus Nuculaformis*, Roemer.

Monomyaria.

Asomia, 2 species. *Monotis decussata*, Munn.
Aracula, 16 species. *Ostrea*, 19 species.
Crenatula, 2 species. *Pecten*, 31 species.
Gavillia, 10 species. *Perna*, 2 species.
Gryphæa, 14 species. *Plagiostoma*, 16 species.
Laoceramus, 3 species. *Plicatula*, 3 species.
Lima, 6 species. *Spondylus comptus*, Goldf.
Limea duplicata, Goldf.

Brachiopoda.

Crania antiquior, Jelly. *Spirifer*, 6 species.
Lingula Beani, Phil. *Terebratula*, 43 species.
Orbicula, 4 species.

Gastropoda.

Actæon, 2 species. *Phasianella cincta*, Phil.
Buccinum, 4 species. *Pileolus*, 2 species.
Nulla (1), 3 species. *Pleurotomaria*, 11 species.
Cirrus, 5 species. *Rimula clathrata*, Sow. sp.
Dentalium, 3 species. *Rissoa*, 4 species.
Helphinula coronata, Fiem. *Routellaria*, 3 species.
Emarginula, 2 species. *Rotella*, 4 species.
Littorina, 4 species. *Solarium calyx*, Phil.
Murex Haccanensis, Phil. *Terebra*, 8 species.
Natica, 10 species. *Trochotoma sulcata*, Lycett.
Neritina, 6 species. *Trochus*, 10 species.
Nerita, 6 species. *Turbo*, 4 species.
Patella, 5 species. *Turritella*, 2 species.

Cephalopoda. [CEPHALOPODA.]*Pisces.* [FISH.]

(Ansted, *Elementary Geology*; Tennant, *Stratigraphical List of British Fossils*).

OOLITIC SYSTEM. [OOLITE.]

OPAL. Of this mineral, which is essentially a hydrate of silica, there are mentioned by Mr. Brooke, in the 'Encyclopædia Metropolitana,' eleven varieties, and nearly as many are described by Phillips.

Precious Opal, or *Noble Opal*.—This mineral is white, bluish, or yellowish-white, and exhibits a beautiful variety or play of colours, as blue, green, yellow, and red, several of which appear together. Fracture conchoidal, with a vitreous or resinous lustre; it is easily broken, but scratches glass. Specific gravity 2.06 to 2.09. Infusible by the blow-pipe, but becomes opaque and loses water. The most beautiful specimens occur in Hungary, but it has also been found in Saxony, South America, &c. Analysis of the Hungarian opal by Klaproth:—

Silica	90
Water	10
	—100

Fire-Opal.—In this the internal reflection is bright red. It occurs with the Precious Opal in Hungary, and has also been found in Cornwall.

Hydrophane.—It is usually opaque, but is rendered transparent, and exhibits the iridescent colours of the Precious Opal by immersion in water. According to Klaproth it contains a little alumina in addition to silica and water.

Common Opal.—This is of various shades of colour, as white, green, yellow, and red; but is entirely destitute of the play of colours exhibited by the Noble Opal. In other properties they greatly resemble each other. It is stated to contain a little oxide of iron mixed with the silica and water. It is found chiefly in Hungary and Saxony, but specimens have also been produced in Cornwall.

Semi-Opal.—This is more opaque than the Common Opal, and is dull. It occurs either white, gray, yellow, brown, or green. It is found in the same places as the foregoing.

Wood-Opal, so called from its showing the woody structure. It occurs of several tints of white, gray, brown, and black. It is generally harder than the Semi-Opal, but does not materially differ from it in other properties. It occurs in Hungary and in Transylvania.

Jackstone is white opaque opal; harder than the Common Opal; dull; brittle; fracture flat conchoidal. Specific gravity 2.2. Infusible before the blow-pipe. It is found on the banks of the river Cech in Bucharia, in loose masses. It occurs also in the Faroe Islands, Greenland, and Iceland.

Opal Jasper, *Ferruginous Opal*.—Opaque, or but feebly transparent on the edges. Colour generally deep shades of red, yellow, and gray. Fracture flat conchoidal. It appears to be a silicate of iron with water. It occurs in Hungary, Siberia, &c. Klaproth's analysis of a variety from Tekubanya gave—

Silica	43.5
Oxide of Iron	47.0
Water	7.5
	—98.0

Menilite.—It occurs in irregular or reniform masses. Colour usually smoke-brown. Opaque, or slightly translucent. It occurs at Menil-Montant, and St. Ouen near Paris, in beds of adhesive slate. According to Klaproth it consists of—

Silica	85.5
Alumina	1.0
Water, Inflammable Matter, and traces of }	11.0
Lime and Iron	
	—97.5

Hyalite, *Muller's Glass*.—It occurs in small globular and botryoidal forms. Lustre vitreous. Brittle, but scratches glass. Specific gravity about 2.4. Infusible by the blow-pipe. It occurs in amygdaloid, near Frankfort-on-the-Maine, in Hungary, &c. According to Bucholz it consists of—

Silica, with a trace of Alumina	92.0
Water	6.3
	—98.3

Geyserite, *Siliceous Sinter*.—This mineral is white, or yellowish or grayish-white. Brittle. Specific gravity about 1.907. Infusible per se by the blow-pipe. It is deposited by the hot-springs of Iceland and elsewhere. According to Klaproth it consists of—

Silica	98.0
Alumina	1.5
Iron5
	—100

OPEN-BEAK. [HANS.]

OPERCULIFERA, one of the families of *Polyparia Membranacea* of De Blainville, also called *Eschariæ*.

OPERCULUM (Malacology), the plates or pieces which protect the apertures or exposed parts of certain Mollusca. In many of the Testaceous Gastropods it becomes a cover or door, which fits the aperture of the shell more or less accurately when the animal has retired within it. Opercula of this kind vary much in structure and shape. Thus they are sometimes horny, as in *Trochus* and *Murex*; sometimes shelly, nay almost stony, as in *Turbo*; and in construction they are for the most part either spiral, concentric, or unguiculated.

In Botany this term is chiefly used for the cap which forms the upper extremity of the theca, or sporangium, of a moss, covering over the peristome, and usually falling off when the spores are ready for dispersal. It has also been applied to the lid which covers in the Pitcher of *Nepenthes*, where it is the lobe of a modified leaf.

OPHIDIA, an order of Reptiles without feet, and consequently, as Cuvier observes, more deserving the name of Reptiles than any other order.

According to Cuvier, the order *Ophidia* consists of the genus *Anguis* [BLINDWORM], of True Serpents, and Naked Serpents. Cuvier's second family, or that of the True Serpents, comprehends the genera which have no sternum nor any vestige of a shoulder-blade, but whose ribs still embrace a great part of the circumference of the trunk, and the body of whose vertebrae are also articulated by means of a convex surface which is received into a socket or concavity of that vertebra which succeeds it. They want the third eyelid and the tympanum; but the ossiculum auditus exists under the skin, and its shaft or handle (so to speak) passes behind the tympanic bone. Many have vestiges of a posterior member under the skin, and the extremity of this rudiment of a limb shows itself externally in the form of a small hook. [BOIDE.]

Those serpents to which the names of Doubles Marchours, or *Amphisbænæ* [AMPHIBÆNA; TYRMOLOS], have been given, have the lower jaw carried, as in the Tortoises [CHELONIA] and Lizards [SAURIA], by a tympanic bone which is articulated directly with the cranium, the two branches of that jaw soldered anteriorly, and those of the upper jaw fixed to the cranium and the intermaxillary bone, so that their mouth cannot be dilated, as in Cuvier's next tribe (the Serpents properly so called), and their head is of uniform size with their body; a form and structure which enable them to make progress equally well in both directions, head or tail foremost. The bony frame of the orbit is incomplete backwards, and their eye is very small. Their body is covered with scales, the anus very near its extremity, the trachea long, and the heart placed very far backwards. Of this tribe no venomous species are known.

The Serpents, properly so called, have the tympanic bone, or pedicle of the lower jaw, moveable, and nearly always suspended to another bone analogous to the mastoidian, attached to the cranium by muscles and ligaments which permit its mobility: the branches of this jaw are not united to each other except by ligaments, nor are those of the upper jaw united to the intermaxillary bone in any other manner, so that they can be more or less separated; a conformation which gives these animals the power of dilating their mouth to such an extent as to enable them to swallow bodies larger than themselves. Their palatine arches participate in this mobility, and are armed with pointed teeth curved backwards—the most marked and constant character of this tribe. Their trachea is very long; their heart situated very far

backwards; and the greater number have only one very long lung, with the vestige of a second. These serpents, says Cuvier, in continuation, are divided into venomous and non-venomous; and the former are subdivided into venomous with many maxillary teeth, and venomous with isolated fangs. In the non-venomous, the branches of the upper jaws are furnished throughout their length, as well as those of the lower jaw and of the palatine branches, with fixed teeth which are not pierced: there are therefore four nearly equal rows of these teeth in the upper part of the mouth, and two in the lower. [BOIDEÆ.] Those which have the mastoidian bones comprised in the cranium, the orbit incomplete backwards, and the tongue thick and short, much resemble the *Amphisbænide* in the cylindrical form of their head and body, and have, Cuvier observes, been united to the Orvets [ORVET], in consequence of the smallness of their scales.

The Venomous Serpents with isolated fangs present a very peculiar structure in their organs of mastication. Their superior maxillary bones are very small, carried on a long pedicle analogous to the external pterygoid apophysis of the sphenoid bone, and very moveable: here is fixed a pointed tooth, pierced with a small canal which gives issue to a liquor secreted by a considerable gland situated under the eye. It is this liquor which, when shed into the wound made by the bite of the serpent, carries havoc into the body of the wounded animal, and produces effects more or less fatal according to the species which has inflicted the wound. This fang is concealed in a fold of the gum when the serpent does not wish to use it; and there are behind it many germs destined to fix themselves in their turn, in order to replace it if it should be broken in the wound it makes. Naturalists, Cuvier remarks, have named these teeth crochets mobiles, or moveable fangs; but it is, properly speaking, the maxillary bone that moves: that bone carries no other teeth, so that, in the Venomous Serpents, only two rows of palatine teeth are seen in the roof of the mouth. All the venomous species bring forth their young alive, in consequence of the egg being hatched internally before it is laid, whence their general name of Vipers, a contraction of *Vivipares*.

These deadly serpents with isolated fangs, though they present external characters of the same nature as the preceding group, have, the greater number of them at least, very dilatable jaws and a very extensible tongue. Their head, wide behind, has generally a ferocious aspect, which announces in some degree their malevolent nature. [VIPERIDÆ.]

A third tribe has the jaws organised and armed nearly as in the Non-Venomous Serpents, but the species have the first of their maxillary teeth greater than the others, and pierced so as to conduct the venom in the same manner as is effected in the Venomous Serpents with isolated fangs. Such are the *Bungari* and *Hydri*. [HYDRIDÆ; PELAMYS.]

The serpents, with one exception (*Deirodon*, to which we shall presently more particularly call attention), subsist on living prey; and, whether non-venomous or venomous, have their teeth, as might be expected, admirably constructed and arranged for the purpose of securing their prey and assisting in deglutition.

Professor Owen, in his valuable and copiously-illustrated 'Odontography,' observes that the order *Ophidia*, as it is characterised in the system of Cuvier, requires to be divided into two sections according to the nature of the food and the consequent modification of the jaws and teeth. Certain species, he observes, which subsist on worms, insects, and other small invertebrate animals, have the tympanic pedicle of the lower jaw immediately and immovably articulated to the walls of the cranium; the lateral branches of the lower jaw are fixed together at the symphysis, and are opposed by the usual vertical movement to a similarly complete maxillary arch above: these, as we have above seen, belong to the genera *Amphisbæna* and *Anguis*, Linn. The rest of the Ophidians, observes the Professor, which form the typical members, and by far the greatest proportion of the order, prey upon living animals, frequently of much greater diameter than their own; and the maxillary apparatus is, as we have also above seen, conformably and peculiarly modified to permit of the requisite distension of the soft parts surrounding the mouth, and the transmission of the prey to the digestive cavity.

But the mechanism by means of which this distension is accomplished, and which is in fact a dislocation of adapted parts which return to their original positions when the act of deglutition is accomplished, requires, to be well understood, a more particular description than the general account above given, and we proceed to that presented by Professor Owen, as the best and clearest known to us.

The two superior maxillary bones have, he observes, their anterior extremities joined by an elastic and yielding fibrous tissue with the small and single intermaxillary bone: the symphyseal extremities of the lower maxillary ramus are connected together by a similar tissue, allowing of a still wider lateral separation. The opposite or posterior extremity of each ramus is articulated to a long and moveable vertical pedicle formed by the tympanic or quadrate bone, which is itself attached to the extremity of a horizontal pedicle formed by the mastoid bone, so connected as also to allow of a certain yielding movement upon the cranium. The palatine and pterygoid bones have similarly loose and moveable articulations, and concur with the other dentigerous bones of the mouth in yielding to the pressure of large bodies with which the teeth may have grappled.

Professor Owen first describes the dental peculiarities of the true serpents, which, as he remarks, swallow their food whole, whether they prey on living animals, as is the case in almost every species, or feed on the eggs of birds, as does *Deirodon scaber*, Owen (*Coluber scaber*, Linn.) With the exception of this and some congeneric species, in which the teeth of the ordinary bones of the mouth are so minute as to have been deemed wanting, the maxillary and premandibular bones in all true Ophidians are, he observes, formidably armed with sharp pointed teeth; there is on each side of the palate a row of similar teeth supported by the palatine and pterygoid bones: in the great Pythons and some species of *Boa*, he adds, the intermaxillary bone also supports teeth. But whatever be their position, all the teeth, according to the Professor, present a simple conical form, the cone being long, slender, and terminated by an acute apex, and the tooth is either straight, or more commonly bent a little beyond the base, or simply recurved, or with a slight sigmoid inflection. Thus the teeth are adapted for piercing, tearing, and holding, not for dividing or bruising. Certain teeth in some species are traversed by a longitudinal groove, as above noticed, for conveying an acrid saliva into the wounds which they inflict; in others, two or more teeth are longitudinally perforated for transmitting venom. These poison-fangs, he remarks, are always confined to the superior maxillaries, as we have already stated, and are generally placed near the anterior extremity of those bones.

Professor Owen notices in the first instance the serpents whose teeth are all simple and solid, where the pulp which occupies the nasal cavity is calcified.

After this the teeth of the poisonous serpents are described, and Professor Owen calls attention to the fact that in certain genera of non-venomous serpents, as in *Dryophis*, *Dipsas*, and *Bucephalus*, in which the superior maxillary teeth increase in size towards the posterior part of the bone, the large terminal teeth of the series are traversed along their anterior and convex side by a longitudinal groove. In the *Bucephalus Capensis* the two or three posterior maxillary teeth present this structure, and are much larger than the anterior teeth or those of the palatine or premandibular series; they add materially therefore, he observes, to the power of retaining the prey, and may conduct into the wounds which they inflict an acrid saliva, but they are not in connection with the duct of an express poison-gland. The long grooved fangs are either firmly fixed to the maxillary bones, or are slightly moveable, according to their period of growth; they are concealed by a sheath of thick and soft gum, and their points are directed backwards. The sheath also contains loose recumbent grooved teeth, ready to succeed those in place.

In most of the Colubers each maxillary and premandibular bone includes from 20 to 25 teeth: they are less numerous in the genera *Tortrix* and *Homalopsis*, and are reduced to a still smaller number in the poisonous serpents, in the typical genera of which the short maxillary bone supports only a single perforated fang.

The transition to the poisonous serpents, which was begun in the *Bucephali* and allied genera with grooved maxillary teeth, is, according to Professor Owen, completed by the poisonous serpents of the genera *Pelamys*, *Hydrophis*, *Elaps*, *Bungarus*, and *Hamadryas*, which latter genus, as its cervical integument can be expanded into a hood, constitutes an immediate link between the *Bungarus* and *Naja*.

The structure of the venom-fangs of serpents, and the machinery by which their deadly agency is brought to bear against those who are so unfortunate as to be the objects of their attacks, are so interesting, that we subjoin the following remarks in the author's own words:—

"The superior maxillary bone diminishes in length with the decreasing number of teeth which it supports. The transverse or external pterygoid bone elongates in the same ratio, so as to retain its position as an abutment against the shortened maxillary, and the muscles implanted into this external pterygoid style communicate through it to the maxillary bone the hinge-like movements backwards and forwards upon the ginglymoid articulations, connecting that bone with the anterior frontal and palatine bones. As the fully-developed poison-fangs are attached by the same firm basal anchylosis to shallow maxillary sockets, which forms the characteristic mode of attachment of the simple or solid teeth, they necessarily follow all the movements of the superior maxillary bone; when the external pterygoid is retracted, the superior maxillary rotates backwards, and the poison-fang is concealed in the lax mucous gum, with its point turned backwards: when the muscles draw forward the external pterygoid, the superior maxillary bone is pushed forwards, and the recumbent fang withdrawn from its concealment and erected.

"In this power of changing the direction of a large tooth, so that it may not impede the passage of food through the mouth, we may perceive an analogy between the Viper and the Lophius; but in the fish the movement is confined to the tooth alone, and is dependent on the mere physical property of the elastic medium of attachment. In the serpent the tooth has no independent motion, but rotates with the jaw, whose movements are governed by muscular actions. In the fish the great teeth are erect, except when pressed down by some extraneous force; in the serpent the habitual position of the fang is the recumbent one, and its erection takes place only when the envenomed hew is to be struck.

"The peculiar structure of the poison-fang was first described by

Fontana, as it exists in the Viper, and subsequently received additional elucidation by Mr. Smith's careful examinations of the fangs of the *Hydrus*, *Naja*, and *Crotalus*, and by Mr. Clift's illustrative drawings appended to Mr. Smith's paper. A true idea of the structure of a poison-fang will be formed by supposing the crown of a simple tooth, as that of a *Ilex*, to be pressed flat, and its edges to be then bent towards each other, and soldered together so as to form a hollow cylinder open at both ends. The flattening of the fang, and its inflection around the poison-duct, commence immediately above the base, and the suture of the inflected margins runs along the anterior and convex side of the recurved fang; the poison-canal is thus in front of the pulp-cavity. The basal aperture of the poison-canal is oblique, and its opposite outlet is still more so, presenting the form of a narrow elliptical longitudinal fissure, terminating at a short distance from the apex of the fang.

"The character most commonly adduced from the dental system, as distinguishing the venomous from the non-venomous serpents, is, that the former have two, the latter four, rows of teeth in the upper jaw; the two outer or maxillary rows being wanting in the venomous species, and their place being supplied by the single poison-fang. The exceptions to this rule are however too numerous for its value as a distinguishing character in a question of such practical moment as the venomous or non-venomous properties of a serpent. In all the family of Marine Serpents the poison-fang is only the foremost of a row of fixed maxillary teeth. In the *Hydrophis striatus* there are four teeth, and in *Hydrophis schistosa* five teeth, behind the venom-fang, of rather smaller size than it; the Two-Coloured Sea-Snake (*Pelamys bicolor*) has also five maxillary teeth in addition to the perforated one. The poison-fang in this genus is relatively smaller than in the venomous serpents of the land, but presents the same peculiar structure. The poison-gland presents a correspondingly small development; it is pyriform, and its structure, according to Dr. Cantor ('Zool. Trans.' vol. ii. p. 304), is minutely cellular; it is covered by the aponeurotic expansion of the articulo-maxillaris, and transmits a straight duct horizontally to the basal opening of the venom-fang. It is a curious fact that the smaller non-venomous teeth of the poisonous serpents all present a trace of the structure of the functional venom-fang, being more or less deeply grooved along the convex anterior side; and in the *Hydrus* this groove commences by a depression analogous to the oblique basal aperture of the poison-canal in the true fang.

"The colubiform poisonous serpents of the land have comparatively short venom-fangs, but they are larger than those of the pelagic serpents; and behind the venom-fangs there are likewise some smaller grooved teeth in the maxillary bones; there are three such teeth in the *Bungarus Pama*, and five in the *Bungarus annulatus*. In the *Hamadryas*, or Great Hooded Poisonous Tree-Snake of India, the venom-fang is relatively as large as in typical poisonous serpents, but three or four smaller grooved teeth are implanted behind it on the maxillary bone.

"In the most deadly venom-snakes, as the Viper (*Berus*), the Puff-Adder (*Vipera*), the Asps or Hooded Snakes (*Naja*), the Rattle-Snakes (*Crotalus*), and the Cophias and Fer-de-Lance (*Trigonocephalus*), the poison-fangs acquire their largest size, and are associated only with their successors. These are clustered in greater or less number behind them, presenting the same structure, but of a size proportionate to their degree of development, and further differing in being loosely imbedded in the thick and wide mucous gum, which likewise conceals the fixed and functional fang in its ordinary position of retraction and repose. This fang is more strongly curved backwards than the ordinary teeth, but its acute and slender apex is frequently bent slightly in the contrary direction, as in the Rattle-Snake.

"The mechanism by which the short maxillary bone and the poison-fang are rotated backwards and forwards upon the ginglymoid joint that connects the maxillary with the prefrontal and palatine bones has already been noticed; and as some description of the secreting apparatus to which the peculiar modification of the venom-fang is subservient might here be expected, I have selected for its illustration the accurate figure which Professor Müller has given of the salivary and poison-glands in the *Trigonocephalus lanceolatus*, in his great work on the glandular system. ('De Glandularum Scernentium Structura Penitiori,' fol. tab. vi. fig. 1, p. 55.)

"The poison-glands occupy the sides of the posterior half of the head; each consists of a number of elongated narrow lobes, extending from the main duct which runs along the lower border of the gland upwards and slightly backwards. Each lobe gives off lobules throughout its extent, thus presenting a pinnatifid structure; and each lobule is subdivided into smaller secreting areas, which constitute the ultimate structure of the gland. The whole gland is surrounded by a double aponeurotic capsule, of which the outermost and strongest layer is in connection with the muscles by whose contraction the several areas and lobes of the gland are compressed and emptied of their secretion. This is then conveyed by the duct to the basal aperture of the poison-canal of the fang. We may suppose, that as the analogous lachrymal and salivary glands in other animals are most active during particular emotions, so the rage which stimulates the venom-snake to use its deadly weapon must be accompanied with an increased secretion and great distension of the poison-glands; and as the action of the compressing muscles is contemporaneous with the

blow by which the serpent inflicts its wound, the poison is at the same moment injected with force into the wound from the apical outlet of the perforated fang.

"The duct which conveys the poison, although it runs through the centre of a great part of the tooth, is nevertheless, as we have seen, really on the outside of the tooth, the canal in which it is lodged and protected being formed by a longitudinal inflection of the parietes of the pulp-cavity or true internal canal of the tooth. This inflection commences a little beyond the base of the tooth, where its nature is readily appreciated, as the poison-duct there rests in a slight groove or longitudinal indentation on the convex side of the fang; as it proceeds it sinks deeper into the substance of the tooth, and the sides of the groove meet and seem to coalesce, so that the trace of the inflected fold ceases in some species to be perceptible to the naked eye; and the fang appears, as it is commonly described, to be perforated by the duct of the poison-fang.

"From the real nature of the poison-canal, it follows that the transverse section of the tooth varies in form in different parts of the tooth; at the base it is oblong, with a large pulp-cavity of a corresponding form, with an entering notch at the anterior surface; farther on, the transverse section presents the form of a horse-shoe, and the pulp-cavity that of a crescent, the horns of which extend into the sides of the deep cavity of the poison-fang. A little beyond this part the section of the tooth itself is crescentic, with the horns obtuse and in contact, so as to circumscribe the poison-canal; and along the whole of the middle four-sixths of the tooth the section shows the dentine of the fang inclosing the poison-cavity, and having its own centre or pulp-canal, in the form of a crescentic fissure situated close to the concave border of the inflected surface of the tooth. The pulp-cavity disappears, and the poison-canal again assumes the form of a groove near the apex of the fang, and terminates on the anterior surface in an elongated fissure.

"If the end of each inflected fold of cement in the tooth of the *Labyrinthodon* were dilated sufficiently to contain a tube, that tooth might convey the ducts of fifty poison-glands deeply imbedded in its substance, and yet all of them actually on the outside of the tooth itself; it is the existence of a single fold of the same kind, but more simple, inasmuch as it is straight instead of wavy, which forms the complication of the viper's fang subservient to the completion of its peculiar offensive weapon.

"The venom-fangs of the Viper, Rattle-Snake, and Fer-de-Lance are coated only with a thin layer of a subtransparent and minutely cellular cement. The disposition of the calcigerous tubes is obedient to the general law of verticality to the external surface of the tooth. Since the inflected surface of the tooth can be exposed to no other pressure than that of the turgescient duct with which it is in contact, the tubes which proceed to that surface, while maintaining their usual relation of the right angle to it, are extremely short, and the layer of dentine separating the poison-tube from the pulp-cavity is proportionally thin. The calcigerous tubes that radiate from the opposite side of the pulp-cavity to the exposed surface of the tooth are disproportionately long.

"The pulp-cavity, following the form of the tooth itself, presents in a transverse section of this part the form of a fissure describing four-fifths of a circle; the fissure is widest at the middle and at the two extremities; the exterior calcigerous tubes, in quitting the pulp-cavity, form a graceful curve, the convexity being turned towards the nearest horn of the crescent; at the middle of the pulp-fissure the tubes proceed straight to the opposite surface; and at the two extremities of the crescent the central tubes are nearly straight, while the lateral ones radiate in graceful curves which become bolder as they diverge from the central and straighter tubes. Throughout the greater part of the tooth the calcigerous tubes describe their various inflections in a plane transverse to the axis of the tooth; but towards the apex they begin gradually to rise from that plane; and as the pulp-cavity reassumes, with the tooth itself, the simple conical form beyond the termination of the poison-canal, the calcigerous tubes extend to equal distances from the linear remnant of the pulp-cavity, which has again passed to the centre of the tooth, and those tubes which are continued from its extremity pass to the apex of the fang in a line parallel with the axis of the tooth. The calcigerous tubes present secondary curvatures of a slightly wavy character, which become more marked and irregular near their termination. In whatever part of the section an entire tube could be clearly traced to its termination, it formed an anastomotic loop at the periphery of the dentine with an adjoining tube. The calcigerous tubes present a diameter of the 1-18,000th of an inch, and they are separated by interspaces equal to four of their own diameters. Each calcigerous tube gives off many primary branches in its course, but is rarely seen to divide dichotomously until it begins to form its irregular sinuosities near the periphery of the tooth. In the transverse section, the primary branches are sent off from the concave side of the tube, at an acute angle with the trunk; the secondary smaller and more numerous branches proceed from the same side of the main tube or of its primary branches, at a less acute angle, into the clear uniting substance; they are remarkably parallel with each other and straight. In old poison-fangs the pulp-cavity or fissure is obliterated by ossification of the remains of the pulp.

"The external layer of cement is very thin where it covers the crown of the tooth; it is best seen at the line of union of the co-adapted margins of the inflected tooth. At this part the cement is more abundant in the viper's tooth, and its transparency permits a bristle inserted into the poison-canal to be seen through it. The layer which coats the inflected surface of the fang is thinner than the outer one, which, from its transparency, has been regarded as enamel. There is however no trace of true enamel upon the teeth of the poisonous serpents, any more than upon those of the innocuous species. The cells of the cement are more minute and inconspicuous in the poison-fang than in the simple teeth of the Python and Boa.

"The teeth of all Ophidians are developed and completed in the original seat of the tooth-germs in all animals, namely, the mucous membrane or gum covering the alveolar border of the dentigerous bones. This gum presents the same lax tissue and is as abundantly developed as in the Pike, Lophius, and many other fishes, in which it likewise serves as the nidus and locality for the complete development of the teeth.

"The primitive dental papilla in the common harmless snake very soon sinks into the substance of the gum and becomes inclosed by a capsule. As soon as the deposition of the calcareous salts commences in the apex of the papilla, the capsule covering that part becomes ossified and adherent to the dentine, and the tooth begins to pierce and emerge from the gum, before its mould, the pulp, is half completed. Fresh layers of cells are successively added to the base of the pulp, and converted by their confluence and calcification into the tubular dentine, until the full size of the tooth is attained, when its situation in the gum is gradually changed, and its base becomes ankylosed to the shallow cavity of the alveolar surface of the bone.

"In the posterior part of the large mucous sheath of the poison-fang, the successors of this tooth are always to be found in different stages of development; the pulp is at first a simple papilla, and when it has sunk into the gum the succeeding portion presents a depression along its inferior surface, as it lies horizontally, with the apex directed backwards; the capsule adheres to this inflected surface of the pulp. But how the cylindrical cavity of the dilated fold is occupied in the loose growing poison-fang, and by what contrivance it is brought into the same relation with the severed duct of the poison-gland as the displaced fang which it succeeds, is not yet clearly understood."

From the consideration of the teeth we proceed to that of the other organs of nutrition. The os hyoides in the Ophidians bears a strong resemblance to that of some species of Saurians [IGUANA; DRACONINA]; but the anterior part is double, and the two long osseous filaments which form it terminate in pointed cartilages, which introduce themselves, parallel, into the fleshy tissue of the tongue, and are separated by the hypoglossal muscle. The modifications of the muscles of the jaws are varied, and admirably adapted to the purpose assigned to them. Some are appointed to work the venom-fangs by carrying forward the external pterygoid and superior maxillary bones; others again are employed in the separation, approximation, and adjustment of the mandibular bones and the whole of the maxillary articulation; nor are those which act upon the tongue and os hyoides less complicated; whilst the peculiar muscles which come from the vertebrae and ribs all assist in the process of deglutition. The mobility of the tongue of the serpents must have struck every observer, and they have been seen to lap water with it. Serpents cannot be said to have any true pharynx; for the nostrils, as well as the glottis, open in the mouth, and the œsophagus commences immediately after the termination of the jaws; and is capable of great extension, so as to be capable of receiving prey of a very large diameter entire. The stomach is a continuation of the œsophagus, and the intestines are very short, and with but little flexure. The vent or cloaca opens by a transverse slit towards the end of the abdomen, above the origin of the tail, which is often very long. The liver consists of only one lobe of an elongated form, placed on the right, or in the mesial region, in front of the long œsophagus, and accompanies the stomach, furnishing distinct hepatic and cystic canals. The bile is greenish or brown, and the cystic canal comes direct from the liver. The spleen is not large, and is situated on the right near the insertion of the ductus cholechus. The pancreas is situated immediately under the junction of the intestine with the stomachal sac beneath the peritœum.

The absorbent powers of the intestines of serpents are great. Messrs. Duméril and Bibron advert to the state of their dejections as a proof of this. They offer, to use their expression, the dry extract of the animal entire, of which only the parts that could not be liquefied remain unaltered, and absolutely in the same situation that they occupied in the carcass of the animal before it had passed through the whole length of the digestive tube. If, for instance, a rat has undergone this process, one may recognise in the dry and shapeless mass the place occupied by the muzzle of the animal, the long whiskers of its cheeks, the down which covered the delicate cartilages of its ears, the hairs of various lengths and colours which correspond with those of the back, the belly, and, above all, the tail; and, finally, even the claws, which remain in their pristine state of integrity. All that was flesh or soft matter in the body has been completely absorbed; the earthy salt, nevertheless, which gave, by means of its union with the gelatin, consistence to the bones, still indicates by its presence, and especially by its colour, the place they occupied. Dissolution,

compression, and absorption have done their work upon this desiccated mass, which still however contains the elements of nourishment for the larvæ of the insects of the family *Dermestidae*.

In the fæces of the Python which a few years ago devoured its companion in the Gardens of the Zoological Society of London, there were entire scales of the digested serpent.

There are several interesting preparations of the anatomy of these organs in the Museum of the Royal College of Surgeons.

There is no great difference between the heart of serpents and that of Saurians. In the Museum of the Royal College of Surgeons (No. 917 B), the heart of a *Python Tigris* is prepared to show the internal structure as well as the outward form. Professor Owen, who made this preparation, observes that the blood of the general system is collected into a large elongated sinus, formed by the union of the inferior with the right superior cava. The left superior cava winds round the back of the left auricle, receives the coronary veins, and terminates in the lower part of the orifice, which leads from the above sinus to the right auricle. This orifice is protected by two semilunar valves. The whole of the inner surface of the auricle, with the exception of these valves and the opposite valve of the foramen ovale, is reticulated with delicate muscular fasciculi. The left auricle receives the blood from a single pulmonary vein, and has a similar reticulated muscular structure: there is no valve at the termination of the vein in this auricle. The blood enters the posterior or aortic division of the ventricle by two crescentic apertures, which are each provided with a single semilunar valve, extended from each side of the septum of the auricular orifices. The irregular form and small size of the aortic chamber is displayed by the removal of the posterior parietes of the ventricle. On the opposite side the pulmonary chamber is exposed; and the Professor remarks in continuation, that it is of a larger size, of a more regular oval form, and with a smoother surface. The fleshy septum, extending from the base of the ventricle to the space between the roots of the pulmonary and aortic arteries, is incomplete at its upper and anterior part, and there leaves a communication between the pulmonary and aortic chambers: these also, he remarks, inter-communicate by several round apertures of different sizes near the apex of the ventricle, which serve to thoroughly blend together the two kinds of blood before they are expelled thus mixed along the three arteries which separately arise from the ventricles. In this preparation the origins of the pulmonary artery and left aorta only are shown, and they are each provided with a pair of semilunar valves. The carotid arteries are given off from the right aorta, which afterwards unite with the left aorta at some distance below the heart. The gland analogous to the thymus gland is also preserved: its structure is cellular. White tristles are passed through the systemic veins, sinus, and auricle; and a black one through the pulmonary vein and auricle. The two branches of the pulmonary artery which go to the two separated lungs are distinguished by black tristles, which also indicate the situations of the two ductus arteriosi. ('Catalogue,' vol. ii.)

The mode of respiration in the serpents is thus effected:—the glottis, which has two lips, and represents a very simple larynx, opens in the mouth behind the sheath of the tongue; by means of the muscles of the os hyoides, which push it, it is raised so as to be presented in a dilated state behind the back nostrils. The vacuum caused by the action of the ribs in the belly tends to dilate the lung, which, through the medium of the trachea, immediately admits the air which is introduced during an inspiration: this is slow, continuing for some seconds. This air, when it has performed its office, and has been deprived of its oxygen, is expelled in the same manner, but by an inverse mechanism, which is entirely due to the action of the muscles which tend to approximate the ribs to each other. When it is expelled rather briskly, a sort of vibration or hissing is heard. The respiration being voluntarily accelerated or retarded, the chemical and vital actions which result from it must be naturally excited or abated by that cause. (Dum. and Bibron.)

As connected with the faculty of respiration, it will be expected that something should be said relative to the voice of serpents, whose hissing has become proverbial. Messrs. Duméril and Bibron state that they hardly think that these reptiles can, as has been said of some colubers, produce hissings (sifflements) or piercing sounds (sous bieu aigus); for although their lungs have great capacity, and can furnish air for a long time, Messrs. Duméril and Bibron state that they could never bear more than a sort of blowing (soufflement) such as would result from the rapid issue of a current of air through a simple pipe—that of a quill for instance. White, however, who was a very good observer, in speaking of the faculty which snakes have of 'stinking so defendendo,' remarks, in his 'Selborne,' that he knew a gentleman who kept a tame snake, which was in its person as sweet as any animal, while in good humour and unalarmed; but as soon as a stranger or a dog or cat came in, it fell to hissing, and filled the room with such nauseous effluvia as rendered it hardly supportable. These offensive emanations came, no doubt, from the fetid anal glands, which seem, as White observes, to be given to certain serpents as a defence. We, at one time, narrowly watched the habits of serpents, pythons in particular, and have seen them excited in various ways; but we never remember to have heard them hiss, in the popular acceptance of the term.

Serpents are destitute of a urinary bladder, but they possess kidneys. They are oviparous or ovoviviparous.

The shell of the egg in the oviparous serpents, although cretaceous, is soft, like the eggs of the common hen, when she has not enough calcareous matter in her aliments, called soft eggs. They are often more than 30 in number, and are connected by a sort of viscous matter which coagulates and joins them in a kind of chain, as is well known to those who have found the eggs of our British common snake in dung-hills. Their colour is ordinarily yellowish or grayish-white. The yoke or vitellus is absorbed by the embryo; and an abdominal cicatrice indicates the umbilicus in the young.

Brain, Nervous System, and Senses.—The cranium of the Serpents is small in proportion to the other parts, elongated, and narrow; the internal cavity is small. The surface of the brain is nearly smooth, and without sinuities or circumvolutions. The lobes are distinct, and the whole mass is elongated. The mass of the spinal marrow, compared with the brain, is much more voluminous than the latter. The anterior lobes are rather slender, and the nerves destined for the sense of smelling are elongated, and, as it were, pediculated.

Touch.—This sense can hardly exist in a high state of development among the reptiles of this order; though there is no doubt a sufficient degree of it to regulate the progression of the animal, and to indicate to the constricting serpents and those which live in trees the nature of the surfaces with which their bodies are brought into contact.

Taste.—The tongue in serpents is nearly always cylindrical, deeply bifid at its free extremity, and very narrow. It can be protruded from the mouth, and rapidly vibrated in all directions, and is always moist. The sheath into which it is received can be elongated or contracted. As an organ of taste it cannot be very susceptible. The prey is swallowed entire, and under circumstances which give little or no opportunity for the gustatory exercise of the tongue.

Smell.—The evidence derived from the structure of this organ, and from their habits, does not justify the conclusion that the sense of smelling is very acute in serpents.

Hearing.—In the serpents there is no external auditory meatus, nor any appearance of a tympanum; but there is a guttural canal which leads from the pharynx to the tympanic cavity, and there may be observed a single ossiculum auditivum, which is elongated and widened at its two ends. In other respects the internal ear is organised like that of the Saurians. Such a structure does not indicate the enjoyment of a very acute sense of hearing, and the 'deaf adder' is become almost proverbial; but that serpents have a perception of sounds, sufficient at least to warn them of the approach of their enemies or their prey, and something more, may be concluded from the attention that many of them pay to musical sounds. [NAÏA.]

Sight.—The eyes of the serpent are generally very small, and there is a remarkable peculiarity in the disposition of those organs, for the transparent cornea apparently forms part of the skin and epidermis with which it is detached at each moult. There is no appearance of a tunica conjunctiva; but on dissection it has been found behind the cornea, and occupies the place of eyelids; the sac which this mucous membrane forms receives the tears, and conducts them into the nostrils. There being no eyelid, the eye of the serpent always appears to be fixed and on the watch. The sac above mentioned permits the globe of the eye however to be moved under the anterior part or epidermic cornea. Some serpents, *Trigonocephali* and *Crotali* for instance, have above the eye external cavities, which have been considered as lachrymatory sinuses, like those of the Ruminants: their only analogy however appears to be that of locality, for they receive no tears, and their cavity is always dry. Vision, excepting for some time previous to the change of skin or moult, when it is evidently less perfect, seems to be sufficiently acute in this order.

Serpents can creep, glide, grasp, suspend themselves, erect themselves, leap, dart, bow, swim, and dive. [LOCOMOTION IN ANIMALS.]

Cold latitudes do not agree with the *Ophidia*; it is in warm climates that their numbers, their venom, and their volume attain their maximum.

The following list of the distribution of the species of *Ophidia* is given by Dr. J. E. Gray in his 'Catalogue of Snakes' in the British Museum. In this list the *Colubridæ* are not included:—

EUROPE.

Vipera aspis.
V. ammodytes.
Pelias berus.
Eryx jaculus.

ASIA AND ITS ISLANDS.

Trimacrus viridis.
T. albolabris. China.
T. carinatus.
T. purpureus.
T. maculatus. Borneo.
T. subannulatus. Philippines.
T. philippensis.
T. strigatus. Ceylon.
T. sumatranus. Sumatra.
T. formosus. Borneo.
T. ceylonensis. Ceylon.
Paria faromaculatus. Philippines.
P. ornatus. Philippines.
P. variegatus. Philippines.
Megara trigonocephala. Ceylon.
Atropos acotia. Java.
Trigonocephalus halys. Tartary.
T. blomhoffii. Japan.
T. rhodostoma. Java.
T. hypnale. Ceylon.
T. vara.
Iaboa elegans.
D. russelli.
D. xanthina. Xanthus.
Echis carinata.
Pelamis bicolor.

The following is Dr. J. E. Gray's arrangement of the Snakes (*Ophidia*):—Mouth dilatable, all the facial bones movable. Jaws toothed: lower jaw-bones only united by ligaments in front. Eyes without eyelids. External ears none. Tongue very long, retractile into a sheath at its base; the apex forked, very long, slender, tapering. Limbs none or only rudimentary, in the form of spurs on the side of the vent. (Meyer, 'Acta Acad. Nat. Cur.', xii.) The body of each vertebra articulated by a convex facet, sitting into a concavity in the front of the following one. The palatine arches mobile, and armed with acute recurved teeth. The windpipe is very long. One of the lungs very large; the other very small or rudimentary. The heart in the hinder part of the body. The mastoid bone is detached in all except the genus *Tortrix* of Oppell.

Ophidia, Rafn., 'Anal. Nat.', 76, 1815. *Ophidii pars*, Oppell, 'Rept.', 47. *Ophidii*, Gray, 'Ann. Phil.', 1825, 204. *Serpents proprement dit*, Cuvier, 'R. A.', ii. 60; ed. 2, ii. 7, 74. *Serpentia gulones* Merrem, 'Tent.', 81. *Ophidii*, section 2, Bibron. *Serpentes Thecioglossi*, Wagler, 'Syst. Amph.', 165.

Synopsis of the Families.

Sub-Order I. *Viperine*. Jaws weak; upper toothless, with fangs in front; lower toothed. Ventral shields broad, band-like. Head large behind; crown flat, generally covered with scales, rarely with shields. Hinder limbs not developed. Eyes lateral. Nostrils apical, lateral.

1. *Crotalidae*. Face with a large pit on each side, placed between the eye and the nostril. [CROTALIDÆ.]
2. *Viperidae*. Face without any pit on the cheek. [VIPERIDÆ.]

Sub-Order II. *Colubrine*. Jaws strong, both toothed, sometimes with some fangs in front or grooved teeth behind. Head moderate or indistinct; crown often covered with regular shields.

Section I. Belly covered with narrow elongate shields or scales, nearly resembling those of the back.

3. *Hydride*. Vent without any spurs like rudimentary feet. Nostrils superior, valvular. Eyes superior; pupil round. Tail often compressed. Belly covered with narrow shields or with scales like those of the back, the central series sometimes united together in pairs, forming a narrow 6-sided shield. [HYDRIDÆ.]
4. *Boidæ*. Vent with spur-like rudimentary feet on each side. Eyes and nostrils lateral. Tail conical, generally prehensile. Ventral shield narrow, transverse, band-like. [BOIDÆ.]

Section II. Belly covered with broad band-like shields. Vent without any spur-like feet. Tail conical, tapering.

5. *Colubridæ*. Nostrils apical, lateral, open. Head generally shielded.

The species of *Colubridæ*, the largest family of *Ophidia*, have not yet (1855) been arranged in the British Museum Catalogue. [REPTILES.]

Fossil Serpents.—Professor Owen, in a paper published in the 'Transactions of the Geological Society of London' (vol. vi., 2nd series), describes some fossils found in the London Clay referable to an order of reptiles which appears to have been very sparingly represented in the fauna of former periods of the history of the earth.

"Vertebrae," observes the Professor, "joined enarthrodially by a deep anterior transversely-oblong cup and a corresponding prominent posterior ball, and further articulated by two projecting flat oblique processes, wedged like the carpenter's tenon into a mortice excavated in the anterior oblique processes of the succeeding vertebra; supporting moreover, on either side of the fore part of the body, an oblong convexity for the moveable articulation of the rib,—belong unequivocally to a reptile of the Ophidian Order."

Professor Owen then states that there is a group of about thirty vertebrae of this description, with a number of long and slender ribs having expanded concave vertebral extremities, cemented irregularly together by a mass of indurated clay, among the fossils left by John Hunter, and now in the Museum of the Royal College of Surgeons; and that a portion of the spinal column of apparently the same species of serpent, measuring 18 inches in length, and including 28 vertebrae, and a smaller group of 7 vertebrae, and a few detached ones, are in the museum of Mr. Bowerbank. The whole of these specimens are from the Isle of Sheppey.

The vertebrae in each specimen are described as presenting the same conformation and nearly the same size, and as being as large as those of a boa constrictor ten feet in length. They belong, it is stated to the ordinary dorsal or costal series, but differ from the vertebrae of both *Boa* and *Python* in their superior length, as compared with their breadth and height. The ridge continued from the lower anterior to the lower posterior processes on each side is stated to be less developed in the fossil Ophidian. The oblique processes themselves do not extend so far outwards; and the spinous process is narrower in its antero-posterior extent, but longer.

Professor Owen observes, that in the first two of the above-mentioned differences the fossil agrees with the Linnæan genus *Coluber* and its sub-genera, but differs from the *Crotalus*; in the remaining points it differs from *Crotalus*, *Coluber*, *Naja*, and *Trigonocephalus*. The long and comparatively narrow spine, the outward and backward prolongation of the upper angle of the posterior oblique processes, the uniform convexity of the costal protuberance, the uneven or finely-wrinkled external surface of the superior arch of the vertebra, are characters which distinguish the Ophidian vertebrae described by Professor Owen from those of any other genus of the order with which he had been able to compare them; and he therefore proposes to designate the species provisionally by the name of *Palaeophis toliapicus*. The ribs, as in all land-serpents, were hollow.

In some respects, as the configuration of the under surface of the body of the vertebrae, and in the anterior tubercle upon this surface, Professor Owen found that the fossils agreed with the *Boa* and *Pythons* more nearly than with the *Colubers*, in which the under

surface of the abdominal vertebrae are traversed by a median longitudinal ridge; and he observes that in none of the differences above noted can there be inferred any obstacle to the practice of the same arts of entrapping and modes of destroying a living and struggling prey. The largest of these Ophidiolites in Mr. Bowerbank's collection exhibits a portion of the vertebral column suddenly bent upon itself, and indicating the usual lateral flexibility of the spine.

"If," says Professor Owen, in conclusion, "we may suppose the species to have had the same number of vertebrae as the existing Boas, it must have exceeded eleven feet in length, and such dimensions would indicate that the species was not provided with poison-fangs. Serpents of these dimensions exist in the present day only in warm or tropical regions, and their food is by no means restricted to animals of the cold-blooded classes. The remains of birds and *Mammalia* are those which are most commonly found in the alimentary canal of such as are brought to this country dead; and living birds or quadrupeds also constitute the favourite food of the Pythons and Boas of similar dimensions, which are exhibited in our menageries. If therefore there had not been obtained direct evidence of both birds and mammals in the London Clay, I should have felt persuaded that they must have co-existed with serpents of such dimensions as the species of which the dorsal vertebrae are here described." ('Description of some Ophidiolites (*Palaeophis toliapicus*) from the London Clay at Sheppey, indicative of an Extinct Species of Serpent.')

A small *Palaeophis* has also been discovered in the Eocene sand underlying the red crag of Suffolk, where the remains of a fossil monkey were found. Another species of *Palaeophis* exists in the collection of Mr. Dixon at Worthing, from the Eocene (London) Clay at Bracklesham, which must have belonged to a boa-like serpent upwards of twenty feet in length.

OPHIDIUM (from *ὄφis*, a snake), a genus of Malacopterygious Fishes belonging to the Eel Tribe. The species have smooth heads; long slender bodies, margined by the united dorsal, anal, and caudal fins; the jaws, palate, and pharynx are all furnished with teeth; the branchial aperture is large. The species vary in form and colour, and in the presence, absence, and number of filamentous appendages or beards attached to the under jaw. Two species inhabit the British seas, but are both very rare. In the Mediterranean the Bearded Ophidium is common, and is used for food.

OPHIOCOMA, a genus of Animals belonging to the order *Echinodermata*, to the family *Ophiuridae*, and to the tribe *Ophiuræ*. The rays are simple, squamose, not prolonged into the disc superiorly, and separated at their origins beneath by small pentangular plates. The species are called Brittle-Stars on account of their fragility. They are very difficult to preserve. Professor E. Forbes recommends their being placed in fresh-water as soon as caught, which quickly destroys them; and after they have been in it an hour or so, to dip them rapidly in boiling water. They are then to be dried in the sun, or in a current of air. The following are the British species of this genus recorded by Mr. Forbes in his 'History of British Star-Fishes':—

O. neglecta, Gray Brittle-Star. Disc round, flat, imbricated with small smooth scales; two oblong parallel touching plates opposite the origin of each ray; upper ray-scales square; lateral ray-plates bearing four or five spines each, which are equal in length to the breadth of the ray. This species is not uncommon on all parts of the British coast.

O. Ballii, Ball's Brittle-Star, was first discovered in Ireland by Dr. Ball.

O. punctata (Forbes), Dotted Brittle-Star. This species, first described by Edward Forbes, was found by Henry Goodsir in the stomach of a cod.

O. filiformis, Thread-Rayed Brittle-Star. The rays are very long and filiform. It is a rare species in Great Britain.

O. brachiata, the Long-Armed Brittle-Star. This also is a rare species.

O. granulata, Granulated Brittle-Star. The rays are covered over with minute spines.

O. Bellis, Daisy Brittle-Star. It is not uncommon on many parts of our coast, and is to be found under stones at low tide.

O. Goodsirii, named after Dr. Goodsir, who took it from a cod's stomach taken off Anstruther in Fifeshire.

O. rosula, Common Brittle-Star. Disc rounded, convex, covered with spines of various lengths; two large triangular parallel plates opposite the origin of each ray; upper ray-scales triangular, carinated, imbricated; lateral ray-plates bearing five spines each, which are much longer than the breadth of the ray. This is the most common of our British Brittle-Stars.

O. minuta, Sand Brittle-Star. This is smaller than the last, and is found buried in the sand.

(E. Forbes, *A History of British Star-Fishes*.)

OPHIOTRACHALUS (from *ὄφis*, a snake, and *κεφαλή*, head), a genus of Fishes belonging to the division of *Acanthopterygii*, characterised by having labyrinthiform pharyngeals, and capable of living for a long time out of the water. The species inhabit India and China. [ANABAS.]

OPHIODES, Wagler's name for a genus of Scincoidean Lizards (*Pygopus*, Spix; *Bipes*, part. Cuvier; and *Pygodactylus*, Fitzinger and Wagler—according to Messrs. Duméril and Bibron).

OPHIOGLOSSACEÆ, Adder's Tongues, a natural order of *Aerogenous Plants*, belonging to the alliance *Filicales*. They have an erect or pendulous stem, with a cavity in the middle instead of pith, and two or three woody bundles placed round it in a ring; the stalks of the leaves and the stem become blended together below; the leaves have netted veins; the spore-cases are collected into a spike formed out of the sides of a contracted leaf, 2-valved, without any trace of an elastic ring; spores resembling fine powder.

These plants are a transition from Ferns to *Lycopodiaceæ*. The species are most abundant in the islands of tropical Asia. They occur however in the West Indies and in the tropical parts of Africa, at the Cape, and in Tasmania. They are of little or no known use. The following genera with about 25 species belong to this order:—*Ophioglossum*, *Ophiodema*, *Hedimthostachys*, *Botrychium*.

OPHIOGLOSSUM (from *ἔψις*, a snake, and *γλῶσσα*, the tongue), a genus of Plants belonging to the natural order *Ophioglossaceæ*. The thecae are connate, disposed in a simple distichous spike attached to an undivided frond.

O. vulgatum, Adder's Tongue, is the only British species. It has an ovate obtuse frond, and is from 4 to 12 inches in height; the spike is club-shaped, usually rather longer than the frond, sometimes very long. This plant is generally distributed over England, and in many places is exceedingly common, covering large plots of ground, and is highly injurious to the crop of grass. It is less frequent in Wales, Scotland, and Ireland. It is a common plant on the continent of Europe, and is said to occur in Africa and North America. Like most singular-looking plants, it has been used in medicine. Ray recommended an ointment composed of oil and Adder's-Tongue. Gerard says that the "Adder's-Tongue is dry in the third degree. The leaves of Adder's-Tongue stamped in a stone mortar, and boiled in oyle-olive unto the consumption of the juice and until the herbes be dry and parched, and then strained, will yield a most excellent Greene oyle, or rather a balsame, for Greene wounds comparable to oyle of St. John's Wort, if it do not far surpass it by many degrees, whose beauty is such that very many artists have thought the same to be mixed with verdigris." Lightfoot says that the common people in Scotland make an ointment of the green leaves, and use it as a vulnerary. It is also used in the same way in many parts of England.

(Newman, *British Ferns*; Babington, *Manual of British Botany*.)

OPHIOMORUS, a genus of Reptiles established by Messrs. Duméril and Bibron for a form placed by them in their first sub-family (*Saurophthalma*) of *Scincoidæan Lizards*.

OPHIOPHTHALMES, the named assigned by Messrs. Duméril and Bibron to their second sub-family of *Scincoidæan Lizards*, having all naked eyes, but only one of them (*Gymnophthalmus quadrilineatus*) being completely without the eyelid.

OPIIOPS, a genus of Reptiles belonging to the *Lacertians* (*Pristidactyle Colodonta* of Messrs. Duméril and Bibron; *Amystes* of Wiegmann).

The tongue is arrow-headed in shape, moderately long, notched at the end, covered with imbricated squamiform papillæ; intermaxillary teeth conical, simple; maxillary teeth rather compressed, the anterior simple, the posterior tricuspidate; two slightly convex naso-rostral plates, between which is opened the nostril situated on the line of the canthus rostralis; no eyelids; a tympanic membrane extended within the annular opening; no scaly collar under the neck; a small fold in front of each shoulder; ventral lamellæ quadrilateral, smooth, and disposed quincuncially; femoral pores; feet with five toes slightly compressed, carinated below, but not denticulated laterally; tail cyclo-tetragonal at its root, but rounded throughout the rest of its length.

a, Head of *Ophiops* (profile); b, the same, seen from above; c, throat and lower jaw; d, lower part of the body, interior surface of the thighs, &c.; e, under side of a posterior toe.

O. elegans, Ménières; *Amystes Ehrenbergii*, Wiegmann. Olive or

bronzed above; two yellowish lines extend along each side of the trunk; each of these yellowish or whitish lines separates two rows of black spots, which are small and very distinct in young individuals, but are more or less dilated and confused in adults; white below. It is a native of Smyrna and Bakou.

Ophiops elegans.

OPHIOXYLON (from *ἔψις*, a serpent, and *ξύλον*, wood, because it has a twisted root and stems), a genus of Plants belonging to the natural order *Apocynaceæ*. It has a 5-cleft permanent calyx, a funnel-shaped corolla with a long tube, thickest in the middle, and a 5-cleft oblique limb. The anthers are subsessile, inserted into the middle of the tube. The ovary is double, each lobe with one ovule, a filiform inclosed style and a capitate stigma. The drupes are baccate, black, about the size of a pea, twin, or solitary by abortion, each containing a 1-seeded wrinkled nut.

O. serpentinum, Serpentine Snake-Wood, is a native of the East Indies. In rich soil it becomes a climbing plant, but in poor soil it is a small erect shrub. The leaves are in threes or fives; they are short-stalked, oblong, pointed, wavy, and smooth. The peduncles are long, smooth, round, sometimes nearly erect, sometimes drooping. The pedicels and calyxes are of a bright-red colour, and the corollas white. In India the root of this plant is employed by the Telinga physicians as a remedy in many diseases.

(Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

OPHISAURUS (Daudin), a genus of Reptiles (*Hyalinus* of Merrem) nearly allied to the *Schelopis* (*Pseudopus*, Merrem), and, according to Cuvier, one of the sub-genera of the *Anguider*. It has the tongue arrow-headed in shape, notched triangularly in front, free for one third of its extent anteriorly, which part has granular papillæ, whilst the other two posterior thirds exhibit filiform papillæ. Many rows of palatal teeth. Internaxillary teeth conical; maxillary teeth subcylindrical, simple. Nostrils lateral, each with its opening in a single plate. External orifice of the ear very small. Eyelids; cephalic plates numerous. Body serpentine. No vestige of limbs externally. Two rather deep lateral furrows. No fold across the lower surface of the neck.

This form is one of those transitions by which nature passes from one type to another. The animal, in effect, has the head of a Lizard on a serpentine body. There appears to be but one species, namely, *Anguis ventralis*, Linn. (*Cecilia maculata*, Catesby), the Glass-Snake. The colour is yellowish-green, spotted with black above. Tail longer than the body. Head very small, and the tongue of a singular form, according to Catesby.

a, Head of *Ophiops ventralis*; b, head of the same from Catesby, showing the tongue.

It is probable that this species is subject to slight variations of colour. Catesby says that the "upper part of the body is of a colour blended brown and green, most regularly and elegantly spotted with yellow; the belly yellow, the undermost part of which is brightest. Their skin is very smooth and shining, with smaller scales more closely connected, and of a different structure from other serpents." General length about 18 inches.

The fragility of this animal equals if it does not exceed that of the Blindworm; and hence, probably, its name of *Serpent de Verre*, or Glass-Snake. The author last quoted says, "a small blow with a stick will cause the body to separate, not only at the place struck, but at two or three other places; the muscles being articulated in a singular manner, quite through to the vertebrae. They are generally said to be harmless." There is no doubt that the species is innocuous.

It is found in the southern United States. Catesby states that the Glass-Snakes appear earlier in the spring than any other reptant, and that they are numerous in the sandy woods of Virginia and Carolina.

Glass-Snake (*Ophisurus ventralis*).

OPHIU'RA, a genus of Invertebrate Animals belonging to the family Echinodermata. It has the body discoid, depressed, rather

Common Sand-Star (*Ophiura texturata*).

a, front; *b*, back; *c*, portion of centro and arm magnified (front); *d*, the same (back).

small, subquinelobate, covered with a coriaceous skin, and provided at its circumference with five simple, very long, very slender, squamous

*Ophiura annulosa*.

View of back (principal figure). *a*, portion of arm (under side), magnified; *b*, the same (upper side); *c*, front view of centre.

*Ophiura granulata*.

a, front; *b*, back; *c*, portion of arm at the back, natural size; *d*, the same (front).

rays, without any trace of an inferior furrow, but always accompanied laterally with spines more or less moveable, and with two rows only of large cirrhi, or suckers, one on each side below. Mouth in the midst of five very short slits, not exceeding the demi-diameter of the body, and furnished with a few papilliform suckers (eight), and on the edges with five groups of scales, which are often dentiform. Orifices of the ovaries very large, in the shape of a slit on each side of the root of the rays. No madreporiform tubercle. (De Blainville.)

O. testarata (*Stella lacertosa*, Link.), Common Sand-Star. It is of a brownish or brownish-white colour; rays smoothly subulate; the scales on the lower surface disposed trifariouly; the papille of the sides very small and adpressed.

It is found in the European Seas. Lamarck adds the Atlantic Ocean. It was taken very abundantly in the trawl in Davis's Strait in Sir Edward Parry's first voyage; and occurs sometimes in immense numbers on the British coasts.

O. albida (E. Forbes), the Lesser Sand-Star, is a smaller species, also found on the British coast. It is of a white colour when it is dried.

O. annulosa. Brownish, rays long, smoothly subulate, spinous at the sides, the spines annulose, and subadpressed; back of the disc echinulate.

It is found in Australasia; first made known apparently by the voyage of Péron and Le Sueur.

O. granulata (*Ophiura echinata*, Lam., *Stella granulata*, Link.). Blackish; disc granulated above; rays echinato-spinose; spines thick, rather longer than the width of the rays. It is found in the European Seas, those of the West Indies, the Atlantic, &c.

The *Ophiuræ* swim and creep often with much facility in all directions, agitating the appendages of the arms in a serpent-like manner.

Euryale (*Astrophyton*, Link.; *Goryonocephalus*, Leach), is a genus which De Blainville included with *Ophiura* in his family *Astrophideæ*. It has the body regular, depressed, rather small, pentagonal, provided with five appendages or rays rounded above, flattened below, dividing, dichotomizing, and attenuating more and more to the extremities, which are cirrhou. Mouth at the centre of five converging furrows, in form of holes, not extending to the circumference of the body, and bordered with papilliform suckers. (De Blainv.)

E. palmifera. Rays simple below, dichotomo-palmate at the apex; back mucronated with two rows of tubercules.

ribs; rays beneath planulate, bifariouly papillose; papille very small and submarginal.

It is found in the Indian seas and those of the North. It has also been taken on the coasts of Scotland. (Forbes, 'British Star-Fishes.')

Euryale scutata.

a, back; *b*, front; *c*, central portion of back, natural size; *d*, the same (front), natural size.

E. costosa (*Astrophyton costosum*, Link.). Back of the disc with ten

Euryale costosa.
Centre (front), natural size.

unarmed ribs in pairs, truncate at the apex; rays dichotomous, very ramose, and transversely rugose. It is found in the seas of America.

Though the species do not appear to be numerous, the form seems to be numerous in all seas. [ECHINODERMATA.]

OPHYROESSA. [IGUANIDÆ.]

OPHYRYS, a genus of Plants belonging to the natural order *Orchidaceæ*. It has a patent perianth, a variously-lobed lip without a spur. The glands of the stalks of the pollen masses each in a distinct pouch.

O. apifera, Bee-Orchis, has a tumid 5-lobed lip, the two lower lobes prominent and with a hairy base, the two intermediate reflexed, truncate, terminal, acute, elongated and reflexed; the anthers with a hooked point, the petals oblong, bluntish, downy. It is about a foot high, and has large, few, and rather distant flowers. The sepals are whitish tinged with purple. The lip is velvety, brown, variegated with yellow. It is one of the handsomest species of orchidaceous plants, native of Great Britain, and grows on chalky calcareous soils.

O. arachnites, late Spider-Orchis, is distinguished by a terminal inflexed flat rather heart-shaped appendage, and deltoid downy petals. The sepals are pink, the lip dark purple variegated with yellow and velvety, the appendage green, never reflexed. It is found on chalk downs near Folkestone and Sittingbourne in Kent.

O. aranifera, Spider-Orchis, has 3 obscure lobes, the middle lobe large, emarginate, without an appendage, the petals linear and glabrous. This species is smaller than the preceding, and with fewer flowers. The petals and sepals are green and quite glabrous. The lip is of a dark brown colour, hairy, and covered with pale or yellowish lines. It is found in chalky places in Kent and Sussex.

O. muscifera, Fly-Orchis, has an oblong trifid lip with a large pale spot in the centre, the middle lobe is elongated, bifid, the anthers short and obtuse, and the petals filiform. It is a slender plant and grows about a foot high. The petals are very narrow, and of a purple colour, the sepals green, and the lip of a purplish-brown colour, the spot in the centre of a bluish tinge. It is found in damp calcareous thickets and pastures in Great Britain.

(Babington, *Manual of British Botany*.)

OPISTHOCOMUS. [CRACIDÆ.]

OPIUM. [PAPAVER.]

OPLURUS. [IGUANIDÆ.]

OPOPANAX, a genus of Plants belonging to the natural order *Umbelliferae*; it has an obsolete calyx, roundish entire petals rolled inwards, with a rather acute lobe; compressed fruit with a dilated convex border, bipinnate leaves with unequally cordate segments, crenated and obtuse. The umbels are compound; the involucre both universal and partial, and the flowers yellow.

O. Chironum is a native of the south of Europe and Asia Minor, on dry hills, margins of fields, and thickets. It is a plant 6 or 7 feet high, of a dull-yellowish colour, and resembling a parsnip. The stem is strongly furrowed; the leaves from 1 to 2 feet long, or more, flat, bipinnate, with ovate cordate leaflets, which are usually oblique at the base, often confluent, and surrounded by a cartilaginous crenated border. The calyx is inconspicuous, the styles rather short and stout. Although this plant is a native of the south of Europe, the resinous gum which exudes from the stalk or root when wounded is brought from the Levant and East Indies in roundish drops of a reddish-yellow colour, with specks of white. It is supposed to be an emmenagogue, but it is seldom used; it is similar in its effects to assafoetida. This is a plant of easy culture, and may be propagated either by seeds or dividing at the root.

(Don, *Diichlamydeous Plants*; Lindley, *Flora Medica*.)

OPORINIA, a genus of Plants belonging to the natural order *Compositæ*. It has a subimbricated involucre, the exterior scales much smaller in several rows, a punctured receptacle, attenuated uniform fruit; the pappus of all the fruit in one row, feathery, dilated at the base.

O. autumnalis has radical leaves, linear, lanceolate, toothed, or pinnatifid, nearly glabrous; stalk branched, scaly, and thickened upwards, the involucre glabrous or hairy. This is the *Apargia autumnalis* of Smith, and the *Leontodon autumnalis* of Koch. It

is a native of Great Britain in meadows and pastures and on lofty mountains.

(Babington, *Manual of British Botany*.)

OPOSSUM. [DIDELPHINA; MARSUPIATA.]

OPUNTIA, a genus of Plants belonging to the natural order *Cactacea*. In the gardens the species are called Indian Figs, and are remarkable for their stems consisting of flat joints, broader at the upper than the lower end, but which eventually lose that appearance, becoming both cylindrical and continuous. On one of them, *O. cochenillifera*, the cochineal insect is fed, and others yield a pleasant sub-acid fruit, which is eaten in hot countries. The lavas of *Ætna* are in some places covered with the spiny bushes of *O. vulgaris*, whose large purple juicy fruits are carried for sale to the neighbouring markets. It is however only a naturalised plant, its native country being South America within the tropics.

O. Tuna has been figured in Dillenius's '*Hortus Elthamensis*,' tab. 380, and is the original of what Linnaeus called *Cactus Tuna*; it has been since called *Cactus Bonplandii* by Mr. Kunth. It differs from the two following in the long whitish spines that arm it, in its very broad oval joints, its fully-expanded flower, which resembles that of *O. Hernandezii*, except that it is larger. This is the sort which in the Jardin-des-Plantes at Paris nourishes the wild cochineal: it was brought from Peru by Dombey, and according to Humboldt is in much esteem in that country as the food of a valuable sort of cochineal.

ORANG-UTAN, or ORANG-OUTANG, names by which the *Pithecius Satyrus* of Geoffroy (*Simia Satyrus* of Linnaeus), the Red Orang, is now generally designated. [APE; CHIMPANZEE.] The following are its generic characters:—

Muzzle large, elongated, somewhat rounded anteriorly; forehead sloping backwards; slight supraciliary ridges, but strong sagittal and lambdoidal crests. Facial angle 30°. Auricles small. Twelve pairs of ribs; bones of the sternum in a double alternate row. Arms reaching to the ankle-joint. No ligamentum teres in the hip joint. Feet long and narrow; hallux not extending to the end of the metacarpal bone of the adjoining toe; often wanting the ungual phalanx and nail. Canines very large, their apices extending beyond the intervals of the opposite teeth. Intermaxillary bones ankylosed to the maxillaries during the second or permanent dentition. Height under five feet. It is an inhabitant of the islands of Borneo and Sumatra. (Owen.)

Side view of the skeletons of *Pithecius Satyrus*, young and adult. (Frem Owen.)

Professor Owen remarks that the young individual exhibits the anthropoid character in the relative smallness of the face to the cranium, resulting from the state of dentition, but that it corresponds with the adult skeleton in the number of ribs and in the relative proportions of the upper and lower extremities. With regard to the number of vertebrae, he observes that the figure of the adult skeleton, which was taken by permission of the board of curators from the specimen in the Museum of the Royal College of Surgeons, exhibits

the abnormal number of five lumbar vertebrae instead of four, which is the number existing in the trunk of the mature Orang preserved in the Museum of the Zoological Society of London, and in the Skeleton in the Museum of Comparative Anatomy in the Jardin-des-Plantes. The form of the living animal, and its habits in captivity, have been made familiar by several specimens which have been kept in the Gardens of the Zoological Society in the Regent's Park.

ORANGE. [CITRUS.]

ORANGE-LILY. [LILIUM.]

ORANGE TRIBE. [AURANTIACEÆ.]

ORBICULA. [BRACHIOPODA.]

ORBITOLITES. [MILLEPORIDÆ.]

ORCA. [CETACEA.]

ORCHIDACEÆ, a natural order of Endogenous Plants, with the stamens and style consolidated into a central column, and with an inferior ovary: they constitute the whole of the class *Gynandria monandria* of the Linnean classification. There is no order of plants the structure of whose flowers is so anomalous as regards the relation borne to each other by the parts of reproduction, or so singular in respect to the form of the floral envelopes. [ONCIDIUM.] Unlike other endogenous plants, the calyx and corolla are not similar to each other in form, texture, and colour; neither have they any similitude to the changes of outline that are met with in such irregular flowers as are produced in other parts of the vegetable creation. On the contrary, by an excessive development and singular conformation of one of the petals called the labellum or lip, and by irregularities either of form, size, or direction of the other sepals and petals, by the peculiar adhesion of these parts to each other, and by the occasional suppression of a portion of them, flowers are produced so grotesque in form that it is no longer with the vegetable kingdom that they can be compared, but we are forced to search for resemblances in the animal world. Hence we have such names among our native plants as the Bee, Fly, Man, Lizard, and Butterfly Orchis, and appellations of the like nature in foreign countries. Of these things some idea may be formed by the annexed cut, where 1 represents *Oncidium raniferum*, or the Frog-Oncidium, so called because its lip bears at its base the figure of a frog couchant; 2, *Peristeria elata*, the Spirito Santo Plant of Panama, in whose flower we find the likeness of a dove in the act of descending upon the lip; 3, *Prescottia colorata*, whose lip is a fleshy hood; 4, *Gongora fulva*; 5, *Cirrhaea tristis*; 6, *Cynoches ventricosus*, singularly like a swan, the arched column forming the head and neck; 7, *Oncidium pulvinatum*; 8, *Bolbophyllum barbigerrum*; 9, *Catacnum viride*; and 10, *Peristeria cerina*.

ⁱ In consequence of their singular forms, their gay colours, and the delicious fragrance of many of these plants, they have of late years

been cultivated with great zeal, both in this country and abroad. [EPIPHYTES.]

Orchidaceous plants inhabit all parts of the world, except those which are excessively dry or excessively cold, both of which appear uncongenial to their nature, and they are most abundant in such as have an equable mild climate, moist and warm during the greater part of the year. Thus we have not a single species from Melville Island, or Nova Zembla, or from the upper regions of northern mountains, nor from the deserts of Africa; and the whole province of Mendoza, one of the dry western states of South America, produces but one, and that in a marsh. On the contrary, the woods of Brazil and equatorial America, of the lower ranges of the Himalayas, and of the Indian Archipelago, possess countless myriads of these productions. In general in hot countries the species are epiphytes, inhabiting the branches of trees, or the sides of rocks and stones, to which they cling by means of long twisting fleshy roots; and terrestrial species, that is to say, such as grow exclusively in the ground, are rare and unknown: in colder countries, on the contrary, the former are unknown and the latter only represent the order. Thus in North America, where Orchidaceous Plants are plentiful, the epiphytal species are almost unknown, a single species only occurring in Florida upon the branches of the *Magnolia*. Some of them are true parasites, deriving their food from the roots of trees upon which they grow. In this country we have two cases of the kind, one the *Neottia Nidus-Avis*, or Bird's-Nest Orchis, a brownish scaly plant springing up occasionally in woods, and the other the *Corallorhiza innata*, or Coral-Root, an occasional but very uncommon inhabitant of marshes.

The roots are of the following kinds:—Firstly, annual slender fibres, simple or branched, of a succulent nature, incapable of extension, and burrowing under ground, as in the genus *Orchis*. Secondly, annual fleshy tubercles, round or oblong, simple or divided, as in the various species of the same genus; they are always combined with the first, and appear, from their containing amyaceous granules in large quantity, to be intended as receptacles of matter fit for the nutrition of the plant. Tubercles of this kind have always a bud at their extremity, and may be considered the principal inferior prolongation of the axis. Thirdly, fleshy, simple, or branched perennial bodies, much entangled, tortuous, and irregular in form, as in *Corallorhiza*, *Neottia*, &c., or nearly simple and resembling tubers, as in *Gastrodia*. And fourthly, perennial round shoots, simple or a little branched, capable of extension, protruded from the stem into the air, adapted to adhering to other bodies, and formed of a woody and vascular axis covered with cellular tissue, of which the subcutaneous layer is often green and composed of large reticulated cells. The points of these roots are usually green, but sometimes red or yellow. In a very few instances of leafless species, as *Chiloschista usneoides*, they become entirely green, and then appear to perform the functions of leaves.

The stem is found in its most simple state in the terrestrial *Ophrydeæ*, where it is only a growing point, surrounded by scales and constituting a leaf-bud when at rest, which eventually grows into a secondary stem or branch, on which the leaves and flowers are developed. This kind of stem usually forms every year a lateral bud with a tubercular root at its lower end, and, having unfolded its flowers and ripened its fruit, perishes, to be succeeded by the stem belonging to the lateral bud previously prepared; hence those species to which this kind of stem belongs have always a pair of tubercles, one shrivelling and in progress of exhaustion, the other swelling and in progress of completion.

The leaves are very uncertain in their appearance: usually they are sheathing at the base, and membranous; but in *Vanilleæ* they are hard, stalked, articulated with the stem, and have no trace of a sheath. Frequently they are leathery and veinless, as frequently they are membranous and strongly ribbed, and both these conditions occur in the same genus, as in *Maxillaria* and *Cypripedium*. In a large number of the epiphytal species the leaves are notched unequally at the apex, a singular structure which has not yet been noticed in those with membranous leaves.

Their floral envelopes are constructed irregularly upon a ternary type, and consist of three exterior and three interior pieces. The exterior pieces are usually nearly equal, and less brightly coloured than the interior; but the two lateral ones are often of a somewhat different form from the other, which is anterior as the flower is placed upon the inflorescence when young, but which often becomes posterior when the flower is expanded, in consequence of the flower-stalk being twisted or curved; these parts are occasionally united by their edges into a long tube, as in *Mastodactylus*, or the lateral ones adhere to the ungula of the lip in various degrees, or two of them are consolidated into one, as in *Corycium* and many other genera. Occasionally the intermediate piece is prolonged at the back or base into one or two hollow spurs, as in the genera *Satyrion* and *Disa*; still more rarely the lateral pieces are also spurred, as in *Diaperis*. Various other less important modifications of the exterior pieces occur, but in all cases the whole number, three, is present. The interior pieces are usually three, never more; but in the instances of *Monomeria* and *Ariceps*, the intermediate one only is present. They are generally unequal, the two lateral pieces corresponding in form and size, while that between them, called the lip, is of some other form and size: in the genus *Thelymitra* however, and in *Paxtonia*, they are all alike. Nothing can be more variable than the proportions they bear to each

other and to the exterior pieces. It is only a few of their modifications which it seems important to notice. The lateral pieces are occasionally bifid, as in certain species of *Habenaria*; in *Megactinium falcatum* they are glandular at the apex; in most cases they are distinct from the column; but in *Lepanthes*, *Gongora*, *Disa*, and some others, they are adnate to that organ; in no instance are they spurred or saccate. The lip is either distinct from the column or united to it, stalked at its base, or dilated there, and often extended into a bag or spur, which is sometimes, as in certain species of the genus *Epidendrum*, consolidated with the ovary; very rarely it has two spurs, as in *Diplocentrum*. In the instances of *Camarotis* and *Acropera* it is saccate at the point. Its form is infinitely varied, the extremes of variation being *Paxtonia* for simplicity, and *Coryanthes* or *Stanhopea* for complexity. These and all other complicated forms may, without difficulty, be reduced to a 3-lobed type, the simple form of which is found in *Maxillaria*, *Bletia*, and many *Cattleyas*. The lip is often so slightly articulated with the column as to swing to and fro upon the least disturbance, on which account it sometimes seems as if it were endowed with a power of spontaneous motion: this is particularly apparent in certain species of *Pterostylis*. There is a frequent tendency in the lip to produce tubercles or lamellæ upon its surface; the latter are always confined to the veins, the former are principally found near the base of the lip, and do not appear to have any relation to the veins: it is in the genus *Oncidium*, *Eria*, and *Zygopetalum* that these bodies, the use of which is unknown, are most conspicuous. Not unfrequently the lip is hairy, convex, and so marked and coloured as to bear no little resemblance to an insect.

It is usual to call the exterior series of floral envelopes calyx, and the interior corolla; but the analogy of *Marantaceæ* renders it probable that the so-called petals are a row of outer sterile stamens. This however is a point upon which it is not here necessary to enlarge.

The centre of the flower is occupied by a body called the column, which is formed by the consolidation of the style and true stamens. In the greater part of the order there is but one stamen present, and it is in that case placed opposite the intermediate sepal, and consequently alternate with the lateral petals: when, as in *Cypripedium*, there are two stamens present, then the usual stamen remains in its customary position, in a sterile state; and the two perfect stamens are additional, and placed right and left of it. It is supposed that in those species which have but one anther there are two other stamens present in an incomplete condition, and consolidated with the other; and from the evidence offered by monstrous formations, it is thought that such sterile stamens are represented in *Orchis* and its allies by two tubercles, one on each side of the column; in *Burlingtonia* by two auricles near the apex of the column; and by other signs in other cases. (Bayer, 'Illustrations of Orchidaceous Plants,' 4to., London, 1830-1838, with forty plates, in 4to.)

In the greater part of the order a single anther terminates the column. This is usually two-celled, but often has its cells divided into two or four other cavities by the extension of the endothecium between the lobes of the pollen masses, or is occasionally more or less completely one-celled by the absorption of the connective. In *Ophrydæ* it is erect, with a distinct connective, and with the bases of the cells either parallel or diverging, and then its cells dehisce along their face. In *Neottia* it is also erect, but appears to be dorsal instead of terminal, in consequence of the stigma being placed before it for its whole length. In the remainder of the order it falls prone upon the head of the column, or the clinandrium, like a lid, and often is easily detached. Sometimes this kind of anther originates from the margin of the clinandrium; sometimes from within the margin, in which case it is occasionally covered as by a hood, as in *Cryptarrhena* and other genera.

The pollen consists of lenticular or spheroidal grains, either single or cohering in pairs, threes, or fours, or in larger masses in indefinite number. The grains are usually held together by an elastic filamentous substance, which in all *Ophrydæ* and many others forms an axis round which the grains or masses of grains are arranged, and which in a very large part of the order assumes the appearance of a strap or caudicula. This body either contracts an adhesion with a gland originating on the margin of the stigma, as in *Ophrydæ*, *Neottia*, and *Vandæ*, or it is folded upon the pollen masses, as in *Epidendrea*, or it terminates in an amorphous dilatation, as in many *Malaxidæ*. In all cases it consists of cellular tissue, sometimes very lax and large, and thin-sided, as in *Polystachya ramulosa*, more generally very compact, tough, and thick-sided; towards the end, which adheres to the stigmatic gland, the tissue becomes elongated, but otherwise it is more or less lenticular. In *Ophrydæ* the caudicula is extended towards the base of the anther-cells; but in all the other divisions of the order the caudicula, when present, is lengthened in the direction of the apex of the cells.

The differences in the structure of the column, anther, and pollen now explained, furnish botanists with the best means of classifying the order, and of breaking it up into sub-orders, in the following manner:—

1. *Malaxidæ* (fig. 1), anther opercular; pollen waxy, with neither caudicula nor gland.
2. *Epidendrea* (fig. 2), anther opercular; pollen waxy, with the caudicula folded back upon the pollen grains, and no gland.
3. *Vandæ* (fig. 3), anther opercular; pollen waxy, with a membranaceous cartilaginous caudicula and gland.

NAT. HIST. DIV. VOL. IV.

4. *Ophrydæ* (fig. 4), anther erect; pollen sectile or granular.
5. *Arethuseæ* (fig. 5), anther opercular; pollen granular or powdery.
6. *Neottia* (fig. 6), anther dorsal; pollen powdery.
7. *Cypripediæ*, anthers two, separated by a broad sterile lobe.

The ovary adheres firmly to the tube of the calyx, and is often so twisted, when the flower is about to expand, that its back, with the floral envelopes belonging to it, is turned to the front. It consists of three perfect carpels, stationed alternately with the stamens opposite the petals, and bearing the placenta in their axis, and of three other pieces alternate with the first, destitute of placenta, and eventually separating from them when the fruit is ripe.

The stigma is a viscid excavation in front of the anther, and just below it. In most cases it is quite simple, merely terminating in a glandular dilatation of the upper margin, called the rostellum. It is lined with a lax tissue composed of minute ascending jointed hairs, and has a direct communication with the cavity of the ovary, either open or only imperfectly closed up. The glandular dilatation in all *Vandæ* and *Ophrydæ*, and in many genera, separates from the stigma and adheres to the pollen masses; but it is also in numerous other genera at all times inseparable from it. In *Bonatea*, in *Habenaria*, and in some other genera of *Ophrydæ*, there are two arms to the upper edge of the stigma, each arm being channelled for the reception of the caudicula of a pollen mass, and terminating in a separable gland; between these lies a membrane, very variable in size, sometimes merely a connecting web, sometimes a distinct plicature or lobe, and occasionally fornicate, and extended in the middle into a mucro.

The fruit is usually a capsule of six valves, bursting when ripe, and discharging a multitude of minute seeds, with a netted loose tunic. In *Vanilla* however and some other genera the fruit is succulent, and the seeds have a hard brittle integument immersed in aromatic pulp. The seeds apparently contain an exalbuminous embryo; but from the great minuteness of the parts this point is not yet satisfactorily determined.

Impregnation in *Orchidaceæ* was at one time thought to take place in a peculiar manner by the intussusception of the fertilising principle of the pollen grains. It has now however been proved experimentally by Brown, A. Brongniart, Morren, and the writer of this article, that it in reality takes place only by the application of pollen grains to the mucous surface of the stigma, as in other plants.

This order contains 394 genera and about 3000 species.

The following genera, which are mostly described in this work under their names, are British:—*Orchis*, *Gymnadenia*, *Aceras*, *Habenaria*, *Ophrys*, *Herminium*, *Goodyera*, *Spiranthes*, *Listera*, *Neottia*, *Epipactis*, *Cephalanthera*, *Corallorhiza*, *Malaxis*, *Sturmia*, *Cypripedium*.

(R. Brown, *Prodromus Floræ N. Hollandiæ*, 8vo., 1810; the same author, *Observations upon the Impregnation of Orchidææ and Acaulepidææ*, 8vo.; Endlicher, *Genera Plantarum*, p. 185, 4to., Vienna; Lindley, *Genera and Species of Orchidaceous Plants*, 8vo.; Lindley, *Vegetable Kingdom*.)

ORCHIDALES. [ENDOGENS.]

ORCHIL. [ROCCELLA.]

ORCHIS, a genus of Plants the type of the natural order *Orchidaceæ*, and belonging to the tribe *Ophrydineæ*. The old Linnean genus *Orchis* is now divided into many genera [ORCHIDACEÆ], but a large number of species are still retained under this designation. The tribe *Ophrydineæ* is distinguished by the pollen masses being divisible into lobes, which are waxy and definite in number. The anthers are wholly adnate. The genus *Orchis* belongs to a section of this tribe, in which the cells of the anther have a rostellate process between their bases. In *Orchis* the perianth is ringent and hooded; the lip 3-lobed, spurred; the glands of the stalks of the pollen-masses are in a common pouch. The following is an arrangement of the British species according to Bahington:—

* Glands of the pollen-masses separate; lip erect in æstivation.

† Bracts mostly 1-nerved; root-knobs undivided.

‡ Lip 3-lobed; lobes broad and short.

Orchis Morio, Green-Winged Meadow-Orchis. *O. mascula*, Early Purple Orchis.

∴ Lip 3-lobed; middle lobe dilated, hlfd, and often with an intermediate tooth.

O. fusca. *O. militaris*. *O. Simia*. *O. ustulata*.

†† Bracts with three or more nerves; root-knobs undivided.

O. laniflora.

††† Bracts with three or more nerves; root-knobs palmate.

O. maculata, Spotted Palmate-Orchis. *O. latifolia*, Marsh-Orchis.

** Glands of the pollen-masses united; root-knobs undivided.

† Lip erect in aestivation.

O. pyramidalis, Pyramidal-Orchis.

†† Lip spiral in aestivation.

O. Aircina, Lizard-Orchis.

(Babington, *Manual of British Botany*.)

ORDERS, a group of objects in natural history classifications, subordinate to a Class, or Sub-Class. It is however like many other general terms used very loosely, especially by zoologists. In botany it is more definitely applied, and is used synonymously with Family and Tribe. In zoology Family and Tribe are frequently employed to denote groups subordinate to orders. [FAMILIES OF PLANTS; SPECIES.]

OREOCEPHALUS. [IGUANIDÆ.]

OREOCYNCLA, Mr. Gould's name for a genus of Birds inhabiting the Himalaya Mountains and New Zealand. The species from the latter locality (*O. macrorhyncha*) is nearly allied to, but differs from, *Turdus varius* of authors. ('Zoological Proceedings,' 1837.)

OREODAPHNE, Mountain Laurel (from *Opere*, mountainous, and *daphnē*, a laurel), a genus of Plants belonging to the natural order *Lauraceæ*. It is hermaphrodite, dioecious, or polygamous, with a 6-parted nearly equal calyx, the limb eventually disappearing. It has 9 stamens, oblong anthers, with narrow filaments, 4-celled, the 3 inner looking outwards. The fruit is succulent, more or less immersed in a deep thick cup formed out of the altered tube of the calyx. The flowers are panicled or racemose, axillary, and occasionally umbellulate.

O. epifera is native of the woods of Para and the Rio Negro. It has oblong cuspidate leaves, tapering into the petiole, silky on the under side. The panicles are compact, divaricating, and silky. The fruit is oval in shape, and yields upon distillation a volatile oil, of a yellow colour and peculiar smell. It is used in Brazil as a remedy in pains and contractions of the limbs.

O. cupularis is a very large tree with a strong-scented wood; it has ovate elliptical leaves, acute at both ends, sometimes blunt at the apex, ending in a channelled stalk, obsoletely netted, smooth; the axils of the costal veins without pores. The flowers are in clustered few-flowered rough hoary racemes below the axillary and terminal bud. The calyx of the fruit is nearly globose. This species is the cinnamon of the Mauritius, where it grows, and also in Bourbon and Madagascar. (Lindley, *Flora Medica*.)

OREOTRAGUS. [ANTILOPEÆ.]

ORGANIC REMAINS. By this term geologists understand the numerous remains of plants and animals which occur among the stratified rocks. The same objects receive also the names of Petrifications and Fossils. Some of these objects are obviously parts of animals and plants, and retain their original structure, more or less altered by chemical agencies since their sepulture in the earth; others are earthy, stony, or metallic bodies, moulded within or upon parts of animals or plants, and thus resembling those parts in external aspect, but having none of their internal organic texture. Nor can we exclude from the notion of the remains of organic beings the few cases where marks of vital action and movement occur on the surface and in the interior of rocks, such as the foot-prints of reptiles on the sandstones of Cheshire and Dumfriesshire, and of birds on the Oolite rocks of America, the holes made by lithophagous *Conchifera* in the limestone of Mendip, and the perforations of the valves of Shell-Fish by Zoophagous *Mollusca*.

In 1829, M. Adolphe Brongniart, after examining the richest collections then known of fossil plants, gave the following interesting comparative table of fossil and recent species:—

Class of Plants.	Fossil.	Recent.
<i>Agamia</i>	27	7,000
<i>Cryptogamia cellulosa</i>	2	1,500
<i>C. vasculosa</i>	266	1,700
<i>Phanerogamia gymnospermia</i>	57	150
<i>P. monocotyledonea</i>	49	8,000
<i>P. dicotyledonea</i>	100	32,000
	501	50,350

Or 1 to 100.

Organic remains may be considered in three points of view. 1, What are the tribes of animals and plants which occur imbedded in aqueous deposits of great antiquity, or (as rather improperly termed) in a fossil state? 2, In what condition are they preserved? 3, In what manner are they distributed in the earth?

Judging from published catalogues and the course of discovery, the living creation may be estimated to contain 100,000 plants, and far

more than double that number of animals. In a fossil state we may say, in round numbers, that 1000 plants and 10,000 animals have been accurately discriminated and classified. The numerical proportions vary according to the groups of plants and animals selected for comparison.

In 1830 Professor Phillips drew up some comparative tables of fossil and recent animals, which were inserted in the 'Encyclopædia Metropolitana.' One of these is subjoined:—

	Remains of Animals.		
	In the Strata.	In superficial Accumulations.	Living estimated.
<i>Mammalia</i>	35	109	1,100
<i>Cetacea</i>	8	—	
<i>Birds</i>	few	few	5,000
<i>Reptiles</i>	71	—	2,100
<i>Fishes</i>	183	—	5,500
<i>Insecta</i>	74	—	100,000
<i>Crustacea</i>	104	—	500
<i>Annulosa</i>	104	—	1,000
<i>Cephalopoda</i>	738	—	100
<i>Pteropoda</i>	5	—	50
<i>Gasteropoda</i>	880	—	3,100
<i>Conchifera</i>	20,26	—	1,700
<i>Tunicata</i>	—	—	—
<i>Radiaria</i>	278	—	1,000
<i>Polyparia</i>	476	—	1,000
	6,027	109	122,100

Or 1 to 20.

The relative proportions of recent and fossil animals and plants, taken according to their terrestrial, fresh-water, or marine residence, were thus estimated by Professor Phillips in 1836 in his 'Guide to Geology.'

	Recent.	Fossil.	Proportions.
Terrestrial Plants	59,000	500	118 to 1
Terrestrial Animals	115,500	330	350 to 1
Fresh Water Plants	100	40	2 to 1
Fresh Water Animals	3,560	260	14 to 1
Marine Plants	1,000	40	25 to 1
Marine Animals	11,750	6,065	2 to 1

The progress of discovery shows that all the tables referred to here contain estimates much below the truth; both plants and animals have been found to nearly twice the tabular numbers (fishes, for example, in 1833, were stated by Agassiz to be 800 fossil and 8000 recent); but as the proportions are not very materially affected, it is not necessary to construct new tables suited to the present amount of knowledge.

The extreme paucity of terrestrial plants and animals in a fossil state is a circumstance very easily accounted for by the analogy of modern nature; for if few of the 60,000 plants and hundreds of thousands of animals find their way by inundations or other causes to modern lakes and oceans, we have no reason to expect the remains of the ancient terrestrial fauna or flora to abound in the ancient marine or lacustrine sediments. We must therefore always acknowledge the imperfection of the picture which organic remains present to us of the vegetables and animals which anciently covered the early dry land of our planet. On the other hand, the large proportion which fossil shells and *Zoophyta* bear to the corresponding recent classes (nearly as 1 to 1, if the hard parts of the recent objects are alone considered) is exactly what might a priori be expected in examining sediments from water; and we may confidently affirm that from data so ample (corroborated by fossil fishes already bearing a proportion of 1 fossil to 10 recent), the condition and character of the ancient oceans and lakes may be in a considerable degree known.

The imperfection of innumerable specimens of fossil plants, shells, fishes, &c., is not entirely nor principally owing to the chemical and mechanical agencies which have been exerted to modify their aspect and substance; on the contrary, the broken condition of many fossil trees, and the scattered situations in which their stems, leaves, and fruits occur, and in some cases the loss of part of their structure, are to be ascribed to the turbulent action which accompanied their inhumation, and to the exposure and decomposition which they had previously sustained. Among fossil bivalve shells it is very common to find the pieces separated by the decay of the hinge ligaments; not unfrequently the shells are broken; sometimes they are rolled and worn. These accidents preceded their inclusion in the rocks, and they are indications not to be mistaken of the condition of the waters in which the *Mollusca* lived, and the rate and circumstances of the deposition of sediment.

In whatever condition buried, the remains of plants and animals have been subsequently affected both by mechanical and chemical forces: the effect of the former is evident in the compressed Ammonites of Watchet, Tytherton, and Speeton, in the Goniatites and Pectens of Bradford in Yorkshire, and in the Fishes and *Ichthyosauri* of Charmouth. Some of the most interesting cases of this mechanical compression are commonly witnessed among the shales and gritstones

which cover coal; for the large cylindrical stems of *Sigillaria* and *Lepidodendron* lie flat as paper between the laminae of shale, but appear with a depressed elliptical section when they lie obliquely across the grits, and retain their cylindrical figure whenever they stand erect in the rocks.

The conditions under which the remains of animals are presented vary very much. The conditions of preservation in which fossil plants appear may be thus classed:—

1. The plant little altered; as in the brown coal-formations of the Rhine, and in a particular case at Gristhorpe near Scarborough, among the Oolites, where *Solenites Murrayana* of Lindley is found flexile, elastic, and with its tissues distinct. The same thing was observed by the author at Ardwick near Manchester, in the coal formation.

2. The plant carbonised to jet or coal. This conversion of the vegetable substance is very common in clays of every geological age; plentifully so in the coal formation.

3. The substance of the plant entirely removed from the place that it occupied, leaving a hollow where it was deposited. This happens in coarse gritstone, as near Leeds.

4. The cells of the plant filled with extraneous matter, as carbonate of lime in *Lepidodendron Harcourtii* (see the 'Fossil Flora of Great Britain'), pyrites in the fruits of Sheppey, silica in the wood of Woburn.

The remains of the animal kingdom present a parallel series:—

1. Bones of *Vertebrata* generally, scales of fishes, the coverings of *Crustacea*, are often but slightly changed from their original composition. They often retain the gelatinous parts of their mass.

2. Shells, corals, and *Echinodermata*, composed of carbonate of lime with gelatin, have in some cases (and very often among tertiary strata) not lost the whole of their gelatinous part. From this condition of little change there is every gradation observable, till (in the oolites particularly) the whole of the organic substance has been entirely removed, and a cavity is left in its place. The sides of this cavity retain the impression of the external surface of the coral or shell; and it not unfrequently happens that in the cavity once occupied by a shell is an almost unattached mass of stone, which filled the interior of the shell, and represents the figure of the animal, in several respects, perfectly.

3. Into this cavity carbonate of lime has been again introduced in solution, so as to become clearly crystallised in solitary rhomboids, or in a connected mass, replacing completely the gelatin and carbonate of lime which composed the original shell; in other cases silica, and, rarely, iron pyrites, fill up the vacuity.

4. The greensand formations show abundance of examples of the impregnation of the calcareous substance of shells, corals, and *Echinodermata*, with a siliceous infiltration.

The occurrence of organic remains is not known to be dependent on depth below the surface of the earth or on particular height above it. Fossil plants occur in our deepest collieries, and fossil shells crown very lofty points of the Alps and Pyrenees. Yet, because of the limited thickness of the strata, and the entire absence of organic reliquiae from the granite masses below them, it is evident that at the depth of a few thousand yards below the surface, in most situations, the traces of ancient life end. In like manner, because in general the lower strata, in which few or no organic forms remain, rise to the highest ground, many mountain ranges are almost or absolutely deficient in fossils. Upon the whole these are most numerous in the lower parts of the earth's surface, because the formations there occurring are generally of a later origin than the stratified rocks which are uplifted into mountain chains.

In modern oceans the occurrence of marine *Mollusca*, *Zoophyta*, &c., in a living state, is either known or inferred to be limited to moderate depths, from 10 to 100 or 1000 feet; when therefore we reflect on the vast abundance of shells in the Silurian strata, buried beneath several thousand feet of old red sandstone, or of the comparable phenomena presented by the mountain limestone shells which are covered by 3000 or 5000 feet of coal strata, we see clearly in these cases the probability (independent of the proof deduced from considering the nature and position of the rocks) of the occurrence of great upward and downward movements affecting large breadths of the ancient oceans.

Shells, fishes, and *Polypifera* affect, while living, peculiar situations; the rocky, sandy, and argillaceous parts of the sea-bed yield *Radiata* and *Mollusca* in very unequal abundance; and it is worth inquiry how far such relations and peculiarities can be discovered among fossil reliquiae. If anciently vegetables were swept down by inundations from the land and buried in marine or fresh-water deposits, we ought to find some correspondence between these deposits and the sediments which now, in various parts of the world, are drifted with the trees and herbs to great inland lakes, estuaries, or the open sea. This expectation is justified by observation. It is almost exclusively in arenaceous and argillaceous strata, which for other reasons geologists have inferred to be detrital deposits, that we find the specimens of terrestrial herbs and trees, mostly fragmentary, and often accumulated in irregular patches. This is well seen in the arenaceous strata of the Yorkshire coast. Again, it is principally in limestones that we find the lamelliferous corals and a large proportion of the *Echinodermata*, and this is in accordance with observation of the analogous living races.

But the circumstance to which the laws of distribution of organic

remains in the earth are most distinctly and constantly related, is the antiquity of the strata. This will appear from the following brief statements.

In the oldest of all the strata known to geologists, the gneiss and mica-schist systems, which repose upon the unstratified granites and congeneric rocks, few or rather no traces of organic life appear. Hence it is that fossils appear excluded from particular geographical areas, as for example frequently from the interior parts of great mountain ranges, which are generally composed in a considerable proportion of these ancient primary strata.

On the contrary, among the more recent of the marine strata for example, theocene tertiary strata of London and Paris, the number of organic fossils is prodigiously great. If these contrasted cases were the only ones which appeared to suggest a law that 'the number of organic fossils in the strata continually augmented from the earliest primary to the latest tertiary rocks,' they would deserve attention; but the supposition becomes changed into exact inference by comparing successively the systems of strata on a uniform plan. [GEOLOGY.]

Such being the facts with regard to the number of species of organic remains in the several systems of strata, we may next inquire as to the distribution of the several kinds of fossil plants and animals. Taking the broadest view of the subject, we may represent the distribution of the classes of plants and animals in compendious tables.

Distribution of the Classes of Plants.

Systems of Strata.	Agamia.	Cryptogamia cellulosa.	Cryptogamia vasculosa.	Phanerogamia gymnosperma.	Phanerogamia monocotyledonea.	Phanerogamia dicotyledonea.

Primary

The reader will not fail to remark that the classes belonging to the columns marked † below, are represented in all the fossiliferous strata, and that they all contain hard conservable parts, more abundantly than any other of the classes. They are also principally marine, some of them exclusively so. These facts should make us scrupulous in believing that the full system of ancient organic life is disclosed to us by the series of organic fossils preserved in the earth.

Distribution of the Classes of Invertebral Animals.

Fishes are the only class of *Vertebrata* found in all the systems of strata. Reptiles begin to appear (if not in the Carboniferous system) certainly in the next above. Birds and *Mammalia* appear locally and rarely in the Oolitic rocks. If, lastly, we enquire in what part of the series of aqueous deposits the remains of Man have been found, the answer furnished by modern observation is very different from the fanciful conjectures common in the 17th century. Then the remains of men, "evidences of the deluge" (as Scheuchzer calls his imaginary fossil man, but real fossil salamander!) [AMPHIBIA], were supposed to be common in rocks of every age; now we are not able to quote a single authentic example of any such occurrence except in loose surface

soil, sand, gravel, and caverns, in which, not uncommonly, pottery, fabricated bones, and other marks of rude civilisation accompany the reliques of our progenitors. If this absence of the bones of men from the marine strata were the only evidence which geology had to offer concerning the comparatively late creation of man, we might excuse the singular error which from time to time is revived by speculators little acquainted with the progress of science, the error of attributing to the human race, for whom the present aspect and arrangement of the globe is adapted, the same antiquity of origin as to those numerous tribes of plants and animals which became extinct before the birth of man, and were adapted to other and earlier conditions of the planet.

Distribution of the Classes of Vertebral Animals.

We may produce a few of the proofs necessary to the establishment of this truth, by determining first, what are the degrees of analogy to existing races presented by the organic fossils of the different systems of strata. As before observed, the remains of terrestrial plants and animals occur too rarely, and in a certain sense too accidentally, in the strata of marine origin to be of much importance in this reasoning. Taking then our examples chiefly from marine tribes, we may state that in the Palæozoic Strata none of the species are known to be now living, and about two-thirds of them belong to genera which are also extinct. Among these extinct genera are the whole group of *Trilobites*, the *Clymenia*, *Goniolites*, *Orthocera*, *Phragmocera*, &c., *Producta*, and many lamelliferous corals.

All the species in the Carboniferous System are in the same manner extinct, and fully half of the marine tribes belong to extinct genera, often identical with those in the Palæozoic Series. Here we find some hundreds of terrestrial plants (*Lepidodendron*, *Stigmaria*, &c.), now entirely unknown among the 80,000 which botanists are acquainted with. Nearly the same proportion of the species found in the Saliferous and Oolitic Systems (about 40 per cent.) belongs to extinct genera (all the species being unknown in modern oceans). Among these genera we have the gigantic reptile forms, the Enaliosaurians, the *Iguanodon*, the *Megalosaurus*; the countless Cephalopods, Ammonites, and Belemnites; many *Crinoidea* and *Echinida*, besides plants approaching to *Zamia*, *Equisetum*, and tropical Ferns.

The Cretaceous System, in like manner, contains many extinct genera (*Mosasaurs*, *Turrilites*, *Scaphites*, *Ananchytes*, *Marsupites*, &c.), in which about 40 per cent. of the species yet found may be ranked. All the species are distinct from existing tribes.

But in the Tertiary Strata, which crown the series of marine deposits, a different result has rewarded the diligent comparison between fossil and recent species. The great number of shells in these deposits gives excellent means of judgment, and M. Deshayes has in consequence been able to establish very exact inferences. In the oldest of the Tertiaries (Eocene deposits of Lyell) there occur from 3 to 5 per cent. of existing species. In those of middle age (Miocene deposits) from 7 to 23 (averaging 18) per cent.; but in the uppermost series of Tertiaries (Pliocene deposits) from 40 to 95 per cent.

Thus, by estimates, as exact as can be made, of the whole number of species, geologists are enabled to perceive clearly that the affinity between fossil and recent species of animals and plants is greatest in the most recent strata, least in the most ancient, and in general is inversely proportional to the antiquity of the strata. Not only man is absent from the fossil world of life, but nearly all the actual creation is wanting there, and is replaced by the relics of other and earlier creations.

By considering and comparing the organic remains which fill the successive systems of strata, we find that, as few living forms appear among the lower tertiaries, few or none of the tertiary forms appear in the lower parts of the Cretaceous System: this system is in the same manner distinct from the mass of the oolites, these from the red-sandstones, the latter from the carboniferous rocks, and all from the palæozoic groups.

Each of these systems of strata contains the remains of animals and plants which were in existence in the sea, in fresh waters, or on the

and, at or previous to the time of the production of those strata; and by combining the evidence derived from all, we arrive at a view, incomplete indeed, yet not necessarily inaccurate, of the succession of organic life upon the globe.

It is perhaps a common opinion that the earliest forms of life, those which occur in the fossiliferous primary (or palæozoic) rocks, are of simpler organisation than such as belong to later periods; and a conjectural view of the succession of organic life on the globe obscurely hints at a gradual complication of animal and vegetable organisations in proportion to the elapsed time. In favour of this view, the first occurrence of Fishes in the uppermost of the Silurian Strata, and the first occurrence of Reptiles in the lower beds of the Magnesian Limestone Formation deserve consideration. But, on the other hand, it is not to be concealed that the earliest fishes which do appear exhibit analogies to reptile structure, and betray no mark of inferior organisation; and the earliest remains of reptiles belong to high grades of that class.

On referring to the most ancient known British fossils, those few which lie in the slates of Snowdonia, we find them to consist of Lamelliferous *Polypifera* and *Brachiopoda*, such as *Lingula*, *Producta*, and *Spirifera*—a small assortment certainly, and thus perfectly in harmony with the view of the gradually increasing numerical amount of fossil forms already explained, but not such as to justify a statement of their inferiority of organisation. In the next stage of organic life, the Silurian System, the fossil species amount to several hundreds, and among them are many *Polypifera*, many *Echinodermata*, *Brachiopoda*, and other *Conchifera*, *Gastropoda*, and *Cephalopoda*, with *Crustacea* and Fishes. It cannot be said that these organisations, compared with others of the same class now living, are, in any just sense, inferior or less complex; nor do we find reason to qualify this assertion while reviewing the similar and larger series of fossils from the Carboniferous System, in which Fishes become numerous and varied in structure.

If we pursue this subject, the result of our inquiries is to establish the fact of the successive introduction of all the classes and most of the great divisions of marine animals in the successive geological periods, not by the improvement or expansion of one original general type, but by addition of new organisations to meet new physical conditions of the globe.

This important result, which presents to us a series of great revolutions in organic life anterior to the desiccation of our present land (which is the bed, or rather exhibits many successively obliterated beds of the ancient seas, with their extinct inhabitants), and adapted to the chain of physical phenomena which preceded and prepared the actual arrangements of nature, may be confirmed by a brief notice of the duration of certain extinct races. By this expression it is not meant to state or to insinuate definite periods of time, but the space occupied on a scale of successive geological events, by the whole traceable duration of particular races of animals. For this purpose we shall take two genera of *Brachiopoda* (*Producta*, *Spirifera*), four of *Cephalopoda* (*Goniolites*, *Orthoceras*, *Ammonites*, *Belemnites*), three of *Crustacea* (*Calymenne*, *Asaphus*, *Glyptia*), three of Fishes (*Holoptychus*, *Palæoniscus*, *Tetragonolepis*), and three of Reptiles (*Ichthyosaurus*, *Pterodactylus*, and *Mosasaurs*). The systems of strata being, as before, represented by horizontal lines, and the particular fossils ranged in vertical columns, the asterisks denote the occurrence and geological duration of the groups.

Here then is a representation of very numerous facts known to geologists, which demonstrate that each group of extinct organisation, each genus of such a group, each species of such a genus, has a definite geological range, appears at a particular point in the scale of geological events, and ceases at another point. From these facts, investigated and collected, it is a clear and positive inference that, during the period which elapsed in the production of the stratified rocks, many combinations of animals and plants—in this sense many systems of organic life—came into being and passed away, not by violent catastrophes or universal revolutions, but by partial substitutions distinctly traceable, often coincident with or consequent on

changes of the strata, and more or less referrible to previous remarkable changes in the physical condition of the globe.

From such a view, which we regard as fully established in truth, the 'Identification of Strata' by organic remains (as geologists, following Dr. William Smith, term the employment of Zoological and Botanical Evidence to determine the geological age of formations or systems of strata) follows as a natural and simple consequence. But in employing this powerful instrument of research, geologists must not overlook ascertained facts which limit the extent and modify the rigour of the application:—

1. The geographical area within which any one species of fossil has been found is limited, and seldom (except in the palæozoic strata) extends beyond a few degrees of latitude and longitude. (The same thing applies to living species.)

2. The geographical range of fossil genera and larger groups is much greater, but their geological range is also greater, and the evidence which they furnish of geological age is diminished in precision.

3. Difficulties hence arise of a very serious nature where strata really contemporaneous, or nearly so, but widely separated (as in North America and Europe), are to be compared. Of 100 species of fossils found in the cretaceous rocks of America, only two or three are identical with European species in the same rock.

4. In all cases where distant deposits are to be classed in age by their organic contents, a prudent geologist will not decide by what is called a characteristic fossil, since this may only have a local value; he will not be satisfied with a few fossils of one genus or group; he will not pronounce a positive opinion, unless several species of characteristic groups, and belonging to different organisations, are presented for examination. On such evidence, embodying the characteristic combinations of organic life for each geological period, a just and secure inference may rest, and thus employed, 'Organic Remains' become a clue to many of the darkest pages in the ancient history of our planet.

ORIGANUM (from *ὀρίανον*), a genus of Plants belonging to the natural order *Labiata*, or *Lamiaceæ*. It has an ovate tubular calyx, 10-13 nerved, striated, with nearly 5 equal teeth, the throat villous inside. The corolla has a tube equal in length to the calyx; the upper lip sub-erect, emarginate; the lower spreading, trifold, with nearly equal lobes. There are 4 protruding stamens, distant, somewhat didynamous. The lobes of the style are nearly equal. The species are herbs.

O. vulgare, Marjoram, has stalked ovate-obtuse leaves, ovate bracts longer than the calyx, the heads of the flowers roundish, panicked, and crowded. The bracts are usually purple, ovate-obtusoid, and at least half as long again as the calyx. It is a native of Great Britain in dry uncultivated places, and of Europe, North of Africa, and of Middle Asia and America. It is an ornamental and aromatic plant, and yields what is sold as oil of thyme in the shops, a common remedy for toothache. It is frequently used mixed with olive oil as a stimulating liniment against baldness, in rheumatic complaints, and against strains and bruises. The dried leaves used instead of tea are very pleasant; they are likewise employed in fomentations. The essential oil is so acrid that it has been used by farmers as a caustic. It is the *ὀρίανον μέλαν* of Theophrastus, lib. vi., cap 2, and the *Ἀγροπίανον* of Dioscorides, 3, 31.

O. heracleoticum is a very variable species, but is recognised by the bracts being longer than the calyxes, by the loose spikes, and small flowers. The stamens are more or less villous, the leaves pale-green, glabrous, or pubescent. The flowers are white and one-half the size of the preceding species. This, the Winter-Sweet Marjoram, seldom ripens seed in this country, and is propagated by slips and cuttings. It requires a dry and sheltered situation. It is a native of the region of the Mediterranean, Greece, and about Odessa on the Black Sea. It has an aromatic sweet flavour, and is much used as a relishing herb in cookery. This is the *Culina gallinacea* of Pliny, 20, 16; Cato, 'De Re Rustica,' c. 127; Seren, v. 909; and the *ὀρίανον ἱρακλεωτικόν* of Dioscorides, 3, 20.

O. creticum (Linnaeus), is the *ὀρίανον* of Hippocrates, 'Morb. Mul.' 1, 609; the *Ὀρίπτις* of Dioscorides, 3, 30; and the *Λευκὸν ὀρίανον* of Theophrastus, 6, 2.

O. Marjorana of Linnaeus is the *Marjorana hortensis* of Moench, and the *Ἀμάραντος* of Theophrastus, 'Hist. Plant.' 6, 7; the *Σάμφυρον* of Dioscorides, 3, 41. It has nearly glabrous racemously panicked branches, petiolate oblong-ovate leaves clothed with heavy tomentum on both surfaces, oblong sessile spikelets glomerate on the branchlets. This plant is a tree or shrub in its native country, but an annual in our gardens. It is native of the North of Africa near Mascara, on hills, and of Asia, on the mountains of Kumaon. The bracts and calyxes are complanate, closely imbricate. The corollas small, purplish or white. As the seed seldom ripens in this country, it is generally procured from France. When in blossom, the plant is cut and dried for winter use, as a savoury ingredient in cookery.

O. dictamnus, the *Amaracus dictamnus* of Beutham: the *Δίκταμνος κρητικός* of Hippocrates; the *Δίκταμνος* of Theophrastus, 'Hist. Plant.' 9, 16; and the *Δίκταμνος* of Dioscorides, 3, 37. It has almost sessile leaves, clothed with dense wool on both surfaces as well as the branches. The leaves are broad, ovate-obtusoid, quite entire, rounded at the base; the floral leaves are small, almost glabrous. The corolla purple, without a spur. The heads of the flowers nutant.

O. Smyrnum vel *Syriacum* is the *ῥόσωνος* of Dioscorides, 3, 27,

and of Hippocrates, 'Morb. Mul.' 3, 490. The ancient plant is usually referred to *Hyssopus officinalis*, but according to Fraas this plant does not grow in Greece, Asia Minor, or Syria. *O. sipyleum* of Linnaeus is the *Μάρον* of Dioscorides, 3, 42.

(Babington, *Manual*; Lindley, *Flora Medica*; Fraas, *Synopsis Pl. Fl. Classicæ*).

ORIOLE. [MERULIDÆ.]

ORIOLE'NÆ. [MERULIDÆ.]

ORITHY'IA. [OXYSTOMÆ; ACALEPHÆ.]

ORNATI. [AMMONITES.]

ORNISMYA. [TROCHILIDÆ.]

ORNITHICHNITES, the name for the footmarks of birds impressed on the surface of sandstone in the valley of the Connecticut, first discovered by Professor Hitchcock. [GRALLATORES; BIRDS.]

ORNITHOCE'PHALUS. [PTERODACTYLE.]

ORNITHOGALUM, a genus of Plants belonging to the natural order *Liliaceæ* and the tribe *Asphodeleæ*. It has a perianth of six patent leaves, the stamens inserted upon the receptacle, and adhering only slightly to the perianth. The anthers are incumbent, attached by their backs. The flowers are white or yellow, never blue.

O. umbellatum, Common Star of Bethlehem, has corymbose flowers, the peduncles longer than the linear-lanceolate bracts, lanceolate simple filaments, linear glabrous leaves. The flowers are white, with a broad green longitudinal band externally. It is found in meadows and pastures in Great Britain, and is the *Βολβίτη* of Theophrastus, 'Hist. Plant.' 7, 13; the *Ὀρνιθόγαλον* of Dioscorides, 2, 173; and the *Bolbine alba* of Pliny, 29, 5.

O. Pyrenaicum, Spiked Star of Bethlehem, has flowers in an elongated raceme; the peduncles at first spreading, afterwards erect; lanceolate acuminate bracts; the filaments dilated below with an elongated point. The flowers are of a greenish white, the segments of the perianth variable in breadth. The leaves wither before the stalk appears; they are rarely contemporaneous. It is extremely common near Bath, and in Sussex and Bedfordshire. This species is the *Ἐπιμενίδειος σκίλλα* of Theophrastus, 'Hist. Plant.' 7, 10; 7, 11.

O. nutans has but few leaves in a lax nodding raceme; the peduncles shorter than the bracts; the filaments flat, membranous, and trifid; the lateral points acute, the middle one very short, bearing the anther; the leaves linear-lanceolate; the flower large, white, and greenish externally. It is occasionally found in fields and orchards in Great Britain. It is the *Βολβὸς ἑρμυκὸς* of Dioscorides, 2, 201.

O. maritimum, Squill. [SCILLA.]

(Lindley, *Flora Medica*; Babington, *Manual*; Burnett, *Outlines of Botany*; Fraas, *Synopsis*, &c.)

ORNITHO'LOGY, the science which teaches the natural history and arrangement of Birds. This term is derived from the Greek words *ὄρνις*, a bird, and *λόγος*, a discourse; signifying literally 'a discourse upon birds.' [BIRDS.]

ORNITHOPUS, a genus of Plants belonging to the natural order *Leguminosæ*. The species are found in pastures and wild places in Europe. They are characterised, among other things, by a cluster of curved pods which are jointed something like a bird's toe, on which account they are called Bird's-Foot Trefoil. The species found in this country is a plant from two to six inches high, with pinnated leaves and small white flowers striped with red, and is of no economical importance; but in Portugal occurs the *O. sativus*, an annual growing as much as two or three feet high, with stems as succulent and nutritious as those of vetches or lucerne, and cultivated in that country as food for cattle under the name of Serradilla. It succeeds in loose sand, and is capable of yielding an abundant produce in the poorest soils.

O. purpurillus, Bird's-Foot, is a common species in Great Britain.

ORNITHORHYN'CHUS, Blumenbach's name for the extraordinary animal known as the Duck-Bill, or Duck-Billed Platypus—*Platypus anatinus* of Shaw; Mallangong, Tambreet, and (according to the French) Moufengong, of the natives of New South-Wales; Water-Mole of the English colonists.

When this animal was first described, and even after its skin was received in this country, its structure was so strange that naturalists hesitated to believe in its existence. Evidence however gradually accumulated, and fortunately fell into the hands of those capable of using it; and we now know, principally by the labours of Professor Owen, that the *Ornithorhynchus* is an ovoviviparous animal, that it suckles its young, and that its proper place is among the *Monotremata*, or Monotremes, a group to which no animal hitherto discovered belongs, excepting that which forms the subject of this article and *Echidna*. [ECHIDNA; MONOTREMES.]

Both these forms appear to have been first presented to the public by Dr. Shaw—*Echidna* under the appellation of *Myrmecophaga aculeata*; and the duck-billed animal under the name of *Platypus anatinus*. This was at the close of the 18th century; at the commencement of the present, Blumenbach described the latter form more at large under the title of *Ornithorhynchus*; and Mr. Home (afterwards Sir Everard) gave an account of some anatomical peculiarities connected with the head and beak, in 'Phil. Trans.' (1800). Sir Everard's subsequent papers on the anatomy of *Echidna* and *Ornithorhynchus* ('Phil. Trans.' 1802) went more at large into the subject, and disclosed numerous affinities between two forms differing much in

external appearance. He therefore grouped them both under the same generic name; and at the same time expressed his opinion that the generative process differed considerably from that of the true *Mammalia*, resting that opinion on the peculiarities of the organs destined for reproduction, and on the absence of nipples in both sexes, especially in the female *Ornithorhynchus*.

Geoffroy St-Hilaire was not tardy in adopting the opinion of Sir Everard. He constituted a new order for these strange forms, and a hasty dissection having led him to conclude that the genital products of both sexes, as well as the urine and faeces, had their issue by a common outlet, he gave to that order the name of Monotremes. His inferences were that both mammary glands and nipples were wanting, and certain accounts of the discovery of eggs of the *Ornithorhynchus* strengthening his belief in the oviparous character of the Monotremes, he separated that order from the *Mammalia*.

Many different opinions were entertained by subsequent anatomists and zoologists, and it was not till the papers of Professor Owen were published that many doubtful points in the structure and habits of this animal were settled. The first of these papers, 'On the Mammary Glands of the *Ornithorhynchus Paradoxus*,' was read before the Royal Society (21st June, 1822), and published in 'Phil. Trans.' for 1832, part ii.; the second, 'On the Ova of the *Ornithorhynchus Paradoxus*,' was read before the same society on the 19th June, 1834, and is published in 'Phil. Trans.' for 1834, part ii.; and the third, 'On the Young of the *Ornithorhynchus Paradoxus*,' was communicated to the Zoological Society of London on the 27th May, 1834, and is published in the first volume of the 'Transactions' of that society.

From these papers we derive the following details of the structure and economy of this creature.

The dental formula of *Ornithorhynchus* may thus be noted— $\frac{2-2}{2-2} = 8$; although the organs thus noted are really not true teeth.

Teeth of *Ornithorhynchus*. F. Cutler.

The cranium, though widely differing from that of other mammals, approaches more closely to the cranial type of that class, as Cuvier observes, than to any other. It is rounded, wider than it is high, and without either sagittal or occipital crest. It is narrowed and flattened between the orbits, which are small and directed upwards. The muzzle afterwards becomes flattened and widened again, and presents on each side a small hook or process above the suborbital hole; it then becomes bifurcate, and its two flattened and slightly-divaricating branches terminate each by an involute kind of hook. The zygomatic arches are rectilinear and high vertically, and at their upper border is a marked post-orbital apophysis. Under their anterior base the maxillary bone forms a nearly horizontal flattened surface, to which the two molars adhere. Their posterior base above the glenoid facet is pierced with a hole which communicates from the temple to the occiput. The entire palate is plain, and is continued (narrowing suddenly behind the molars) to the oval holes; up to this point the septum of the nostrils remains bony. The tympanic cavities are very small, and hidden as it were under the mastoid apophysis in the form of a small crest. Cuvier could only detect in his specimens two clear sutures; that which divides the anterior hooks, and that which separates the maxillary from the palatine bones. The position, the implantation of the teeth, and the passage of the suborbital canal, well define the maxillary bone. The hook-like bones, which are as it were set in them anteriorly, appear to be the intermaxillary bones. Between them there is suspended, in the midst of the cartilages of the upper mandibles, a small bone, which has an upper plane divided into two

by a furrow, a lower plane notched on each side, and a vertical plane uniting the two others. In the neighbourhood of this bone the nostrils are pierced, and it may be taken to represent the nasal bones and the palatine portion of the intermaxillary bones. In the anterior angle of the orbit is a very small lacrymal and a large suborbital hole. This last gives origin to a canal which opens in front of the small hook on the side of the muzzle; it is divided into two by the lateral cartilage of the beak. There comes besides from this canal a hole which opens in the palate under the preceding, and another which, after having formed a long canal, opens at the side of the intermaxillary bone, and consequently in the edge of the osseous beak. Between the first of these three suborbital holes, a little higher, is a small hole which communicates with the aperture of the orbit, pierced in front of the optic, and which Cuvier believes to be analogous to the anterior orbital hole. The first he thinks answers the supra-orbital hole in man. The single hole, analogous to the spheno- and pterygo-palatine, is pierced in the lower part of the orbit, a little behind the suborbital canal. It enters also in the nasal canal and in the palate near the first molar. The optic hole is very large, and the spheno-orbital equals it; the oval hole is very large and distinct. Between the two oval holes are two membranous spaces. There are behind two very large holes at the place of the condylodians, but Cuvier supposes that they comprise also the jugulars. Internally the inequalities are but little marked. The sella, which is but little elevated, is hollowed out in the middle by a longitudinal canal, and terminated backwards by a clinoid and very elevated lamina. The most curious internal part is the ethmoidal fossa, which is small, and has only a single hole of no great size for the olfactory nerve, and perhaps another very small one; on each side are spaces, purely membranous, to separate it from the canal of the suborbital nerve. The three semicircular canals project far inwards, and intercept a very remarkable hollow. Here may be traced many characters in which the skull of the *Ornithorhynchus* approaches those of birds. The bony tentorium is scarcely perceptible, but there is—and this is very remarkable—a large longitudinal osseous falx.

Skull of *Ornithorhynchus*.

a, seen from above; b, seen from below; c, seen from behind.

Lower jaw of *Ornithorhynchus*, seen from above.

In both of the Monotremes the most remarkable part of their osteology is perhaps the shoulder, which answers to that of birds, and still more to that of certain lizards. The external surface of the scapula is concave, so that it is far from adapting itself to the ribs. Its form and relative position will be better explained by the cuts than by words. The whole of what may be termed the sternal apparatus appears to be formed more after the model of the Saurians than after that of the Mammals; indeed it very much resembles that of the *Ichthyosaurus* [ICHTHYOSAURUS], and, like it, is admirably adapted for an animal destined to collect its food at the bottom of lakes and rivers, and requiring machinery to enable it to rise continually to the surface for a supply of air.

Sternal apparatus of *Ornithorhynchus*, two-thirds of the natural size.

The bones of the arm and fore arm, &c., have nothing so remarkable about them as to require particular description, especially as their conformation and relative position will be seen below; but it is deserving of notice that the carpus reminds the observer of the same part in the *Carnivora*. The number of the phalanges is the same as in the other mammals, two for the thumb and three for the fingers.

The pelvis and posterior limbs of the Monotremes are framed more according to the Marsupial type; and the animal presents the supernumerary bones which are articulated to the pubis and embedded in the muscles of the abdomen, and are characteristic of that group. Their locality is the same and they are as well developed as in the Opossum. [MARSUPIATA.] They are remarkable for the width of their base, which occupies nearly the whole of the anterior border of the pubis. But besides these marsupial bones there are in the external part of the pubis of the *Ornithorhynchus* two external pointed apophyses, one directed outwards, the other forwards. The ossa ili are short, prismatic, and a little enlarged on their anterior border; the pointed tuberosities of the ossa ischia are directed backwards, and the ischium itself is not soldered to the sacrum as in the other *Edentata*; the three bones join as usual at the cotyloid fossa, but it is to be remarked that the pubis and ischium equally concur to form the symphysis, so that this part of the pelvis is very large and divided crucially by their suture. The oval holes are moderate and very nearly round. The cotyloid fossa is not notched on the side of the oval hole; but in the *Echidna* its bottom is not ossified, and a great aperture is left in that part of the skeleton.

Skeleton of *Ornithorhynchus*: a, the supernumerary bones.

Though the anterior part of the sternum and shoulder in the Monotremes bears a resemblance to those of the Lizards, the rest of that portion of the skeleton exhibits a conformation analogous to that of quadrupeds. The composition of the sternum is effected by successive pieces, and not by a cartilaginous dilatation as in the Saurians, or a disc composed originally of five pieces, as in Birds. There are four of these pieces, without reckoning either the Y-shaped bone or the xiphoid cartilago, which in the *Ornithorhynchus* is ossified and forms a fifth, making six in all. The piece which immediately follows the Y-shaped bone is larger than the others, and in the *Ornithorhynchus* exhibits traces of longitudinal division. The sternal portion of the ribs is ossified as well as the other, as in Birds, and is joined to the sternum by a cartilaginous portion, but there is no recurrent apophysis to the dorsal ribs as in Birds. The sternal portion of the fifth and sixth ribs is very much dilated in the *Echidna*, and it is also very much dilated but not ossified in the first five or six false ribs; these dilatations extend as far as the eighth in the *Ornithorhynchus*, and become imbricated or laid over each other like tiles. In both genera the last three false ribs have only very small inferior portions. In

Echidna there are six true and nine false ribs on each side; in *Ornithorhynchus* there are two more false ribs, but only two lumbar vertebrae, whilst *Echidna* has three. Both genera have seven cervical vertebrae, like the rest of the Mammals. In *Echidna* they are flat below, but have a sort of median crest in that direction in *Ornithorhynchus*, and in the latter, even in the adult state, may be still discerned the sutures which unite the transverse apophyses to the body of the vertebrae; here again is an analogy to the Reptiles. The first four dorsal vertebrae in the latter genus have also small inferior crests, which are wanting in *Echidna*; and in the caudal vertebrae a still greater difference exists—*Echidna* has only twelve, rapidly diminishing conically, whilst *Ornithorhynchus* has twenty at least, with large and dilated transverse apophyses, forming a depressed tail, which reminds the observer of that of the Beaver. The spinous processes throughout have but little elevation, especially in *Ornithorhynchus*. The vertebrae, with the exception of those of the neck, do not retain the sutures which join their parts longer than those of other Mammals.

In the Museum of the Royal College of Surgeons in London are preparations displaying the internal structure of the *Ornithorhynchus*. The cardiac and pyloric orifices of the stomach are closely approximated, as in the stomachs of birds. The greater part of the cavity extends beyond these orifices, and increases as it descends into the abdomen. The parietes are thin; the two layers of muscular fibres run in opposite directions, and are thickest along the curvature of the pylorus. The intestines terminate in a common cloaca.

The reproductive system is very characteristic of these animals. In five apparently adult and full-grown *Ornithorhynchi* examined by Professor Owen, the mammary glands presented as many different degrees of development. The number of lobes composing each gland amounted from 150 to 200; they were elongated, sub-cylindrical, disposed in an oblong flattened mass, and converged to a small oval areola situated in the abdominal integument between 3 and 4 inches anterior to the cloaca, and about an inch from the mesial line. The lobes in the smaller glands preserved the same breadth to near the points of insertion, but in the larger ones they were broadest at the free extremity, measuring three or four lines across, and becoming narrower to about one-third from the point of insertion, where they ended in slender ducts. The lobes were almost all situated to the outer side of the areola, and consequently converged towards the mesial line of the body. The panniculus carnosus was interposed between the glands and the integument, closely adhering to the latter, but connected with the glands by loose cellular membrane. This muscle was here nearly a line in thickness; its fibres were longitudinal, and separating, left an elliptical space for the passage of the ducts of the gland to the areola.

Portion of the integument from the abdomen of *Ornithorhynchus paradoxus*, with the hairs removed so as to exhibit the mammary areola. (Owen, 'Philosophical Transactions'.)

Magnified view of the mammary areola, showing the orifices of the ducts of the glandular lobules. (Owen, 'Philosophical Transactions'.)

From the minuteness of the orifices of the ducts in the specimens with the small glands, the situation of the areola could hardly be detected without previously dissecting the gland; whilst in those in which the glands are fully developed, the areola is easily discovered on the removal of the hair by a practical eye.

Professor Owen states that, on compressing the glands in a specimen in the Museum of the Zoological Society of London, where they had arrived at the maximum of development, minute drops of a yellowish oil, which afforded neither perceptible taste nor smell, except what was derived from the preserving liquor, escaped from those orifices.

The differences in the state of the female organs of generation observed in the *Ornithorhynchi*, presenting the different conditions of the abdominal glands above described, were such as to indicate that the period of the full activity of those glands was subsequent to that of the uterine functions; whereas, on the hypothesis of their being scent-glands, the relation should have been reversed.

The following cut exhibits the mammary gland fully developed.

Mammary Gland of *Ornithorhynchus*, reduced below the natural size. (Owen, *Philosophical Transactions*.)

The female organs are well displayed in the preparations preserved in the Museum of the Royal College of Surgeons. The most remarkable feature in this part of the structure of this creature is the double uterus which open like the os tincæ in the *Mammalia*, and like the oviduct in the Turtle (*Chelonia Mydas*). In the common external passage of the cloaca the clitoris is situated, which has an elongated preputium: the clitoris is bilobed. The season of sexual congress is at the latter end of September or the beginning of the month of October. The precise period of gestation and the condition of the excluded product, strictly speaking, still remain to be determined; but in the first week in December, Mr. G. Bennett found in a nest of an *Ornithorhynchus* three small naked embryos, not quite two inches in length, and which he therefore supposed, with apparently good ground, to have been recently born. The young *Ornithorhynchi* were not preserved, for want of the necessary means of preservation. But Dr. Hume Weatherhead presented to the Zoological Society of London two young specimens a little further advanced than those found by Mr. Bennett. They were of different sizes. The smallest rather exceeded two inches in length, measured from the end of the bill to the end of the tail in a straight line. The largest was double that size, and was one of the two young *Ornithorhynchi* taken with the mother from a nest on the banks of the Fish River by Lieutenant the Honourable Landerdale Maule, and kept alive for about a fortnight by that gentleman. These specimens were placed in the hands of Professor Owen for examination, and form the subject of his paper in the first volume of the *Transactions of the Zoological Society*. Our

Smaller specimen of young *Ornithorhynchus*; a, nostrils; b, prominence on the upper beak; c, the vent; f, the orifice and rudimentary spur of the hind foot.

Front view of mandibles of the same, a little open to show the tongue; a, nostrils; b, prominence of the upper beak; c, the eyes; d, the ears; e, the membrane at the base of the mandibles; f, the tongue.

Magnified figure of the hind foot of the female, showing the rudimentary spur, f, projecting from the socket.

Larger young specimen of *Ornithorhynchus* (two views): a, the nostrils; b, the prominence on the upper beak; c, the eyes; d, the ears; e, vent; f, orifice and rudimentary spur of hind foot; g, membrane at the base of the mandibles. (Owen, *Zoological Transactions*.)

limits will not permit us to follow the Professor throughout this interesting memoir, to which we refer our readers; but there are some points which must be noticed. The stomach of the larger specimen was found full of coagulated milk. On carefully inspecting the whole contents with a lens, no portions of worms or bread could be detected; which, Professor Owen observes, solves the doubt entertained by Lieutenant Maule as to whether the mother nourished this young one with the food which was given to her for her own support, or with the secretion afterwards discovered to escape from the mammary pores; for the mother having been killed by accident on the 14th day after her captivity, it was observed, on skinning her while yet warm, that milk oozed through the fur on the stomach. A portion of the coagulated milk from the stomach of the young one was diluted with water and examined by Professor Owen under a high magnifying power, in comparison with a portion of cow's milk coagulated by spirit and similarly diluted. The ultimate globules of the *Ornithorhynchus*'s milk were distinctly perceptible, detaching themselves from

the small coherent masses to form new groups; the corresponding globules of the cow's milk were of larger size. With the milk globules of the *Ornithorhynchus* minute transparent globules of oil were intermixed. So far the experiment may be considered to have been decisive; but to prevent the possibility of doubt, Professor Owen took a little mucus, and added a drop of water to it, when it instantly became opaque; and its minutest divisions under the microscope were into transparent angular flakes, entirely different from the regularly-formed granules of the milk of the *Ornithorhynchus*.

The circumstances particularly worthy of attention in these young animals are the total absence of hair, the soft and flexible condition of the mandibles, and the shortness of these parts in proportion to their breadth as compared with the adult, as Professor Owen pointed out. The tongue, which in the adult is lodged far back in the mouth, advances in the young animal close to the end of the lower mandible, and its breadth is only one line less in an individual four inches in length than it is in fully grown animals; a disproportionate development which is plainly indicative, as Professor Owen remarks, of the importance of the organ to the young *Ornithorhynchus*, both in receiving and swallowing its food.

With regard to their food and habits, Lieutenant Maule says he fed the female which he kept in captivity on worms and bread and milk. Mr. G. Bennett, in his paper 'On the History and Habits of the *Ornithorhynchus Paradoxus*' ('Zool. Trans.,' vol. i.), gives the following account of one when feeding, which he had secured by a cord fastened to the hind leg:—"It was exceedingly lively, swam in the centre of the stream, and appeared in excellent health and spirits. The water at one part of the river being very clear, I saw its motions distinctly under the water. On diving, it sank speedily to the bottom, swam there for a short distance, and then rose again to the surface; it ranged the banks, guiding itself in its progress according to the impressions received by the mandibles, which appeared to me to be used by it as very delicate organs of touch. It seemed to feed well; for whenever it inserted its beak into the mud, it evidently procured some food from thence, as, on raising the head, after withdrawing the beak, the mandibles were seen in lateral motion, as is usual when the animal masticates. Although several insects were basking and fluttering about the surface of the water, close to it, no attempt was made to capture them, either from its not seeing them, or from its preferring the food which the mud afforded. The motions of the mandibles in this animal, when seeking its food in the mud and water, are the same as those of a duck when feeding in similar situations. After feeding, it would lie sometimes on the grassy bank, and at others partly in and partly out of the water, combing and cleaning its coat as usual with the claws of the hind feet. After permitting it to swim, feed, and clean itself for an hour, it was replaced, although with great reluctance on its own part, in its box; it did not however, as before, betake itself to repose, but commenced and continued a scratching on the sides of the box." The same author states that these animals feed on the minute *Testacea* which may be found about the water-plants and in rivers. On examining the cheek-pouches or the stomachs of these animals, he always observed the food to consist of river insects, very small shell-fish, &c., which were constantly found comminuted and mingled with mud or gravel, probably to aid digestion. River weeds have also been found in their pouches, and the natives say they feed on them also. In the Museum of the Royal College of Surgeons are preserved the debris of insects belonging to a genus of the *Nauceriidae*, which were found in the cheek-pouches of an *Ornithorhynchus*. ('Physiological Series,' No. 541, B.) We owe to Mr. G. Bennett, who has contributed so much to our knowledge of the natural history of this and other scarce animals, a description of the hurrows of these extraordinary creatures. They were traced up a bank of a river, where, amongst some long grass, the entrance of a burrow was discovered, and the internal construction of it was laid open by digging. The entrance was large, particularly when compared with the width of the passage continued from it, measuring 1 foot 3 inches in depth, and 1 foot 1 inch in breadth. As it receded from the entrance, the burrow became narrower, being about the usual breadth of the animal when uncontracted. "After having traced it," continues Mr. Bennett, "for the distance of 10 feet 4 inches, and having just delved down upon it so as to perceive it still continuing its course up the bank, the beak and head of a Water Mole were seen protruding for an instant from the upper part, as if it had been disturbed from its repose, and had come down to see what we were about with its habitation. It only remained for an instant; for, as soon as it beheld us, . . . it immediately turned up to take refuge in that part of the burrow which yet remained unexplored. In turning round however it was seized by the hind leg and dragged out. The animal appeared very much alarmed when it was hauled out of its subterranean dwelling; it discharged its urino (which had rather a strong odour) and its faeces, when first caught, which I attributed to fear, for this is not usual with other living specimens that I have since seen. It uttered no sound, nor did it attempt to bite; and proved to be a full-grown female. When I held the unfortunate *Platypus* in my hands, its bright little eyes glistened, and the orifices of the ears were expanded and contracted alternately, as if eager to catch the slightest sound, while its heart palpitated violently with fear and anxiety. . . . This animal uttered, when disturbed from its sleep, a noise something like the

NAT. HIST. DIV. VOL. IV.

Ornithorhynchus feeding. (Bennett, 'Trans. Zool. Soc.')

Ornithorhynchus sleeping. (Bennett.)

Ornithorhynchus combing itself with its claws. (Bennett.)

growl of a puppy, but perhaps in a softer and more harmonious key. Although quiet for the greatest part of the day, it made efforts to escape, and uttered a growling noise during the night." But we must return to the burrow, the distance of the entrance of which from the

K

water's edge was 5 feet. It ran up the bank in a serpentine course, approaching nearer to the surface of the earth towards its termination, at which part the nest, composed of dried grass, and weeds strewed over the floor, is situated; but none has as yet made in this burrow. The termination, of the form shown in the cut, measured 1 foot in length by 6 inches in breadth. Mr. Bennett found the whole extent of the burrow, from the entrance to the termination, to be 20 feet by actual measurement. He observes that the burrows are situated above the usual river height, but do not appear to be above the extensive floods of the river, which frequently take place during the winter season.

Barrow of *Ornithorhynchus*. (Reduced from Bennett, 'Zool. Trans.')

Authors generally describe two species, namely, *Ornithorhynchus rufus*, and *Ornithorhynchus fuscus*; but the probability is that they are but varieties of one species, if indeed the difference may not be merely that of age or sex. The males are rather larger than the females, and Mr. Bennett considers the average length to be from 1 foot 6 inches to 1 foot 8 inches. A male shot in the Yas River measured, from the extremity of the mandible to the extremity of the tail, 1 foot 7½ inches, and a female shot in the same river was 1 foot 7 inches, measured in the same way.

The spur of the male has been pretty generally considered as a weapon of offence, and a very venomous one; but Mr. G. Bennett's experiments go far to prove that this idea is unfounded. He thus relates his experience in the case of a wounded male just taken out of the water:—"Having heard so much related about the injurious effects resulting from a puncture by the spur, I determined to avail myself of the opportunity to ascertain the correctness of the assertion. The wounded state of the animal presented no objection to the experiment, as in one published account, in which the poison is reported to have produced such terrible effects, the animal was also mortally wounded. As soon therefore as it became lively I put its 'poisonous spur' to the test. I commenced by placing my hands in such a manner, when seizing the animal, as to enable it, from the direction of the spurs, to use them with effect: the result was that the animal made strenuous efforts to escape, and in these efforts scratched my hands a little with the hind claws, and even, in consequence of the position in which I held it, with the spur also. But although seized so roughly, it neither darted the spur into my hand, nor did it even make an attempt so to do. As however it had been stated that the creature throws itself on the back when it uses this weapon (a circumstance not very probable to those who have any knowledge of the animal), I tried it also in that position; but though it struggled to regain its former posture, no use was made of the hind claw. I tried several other methods of effecting the object I had in view, but as all proved futile, I am convinced that some other use must be found for the spur than as an offensive weapon. I have had several subsequent opportunities of repeating the experiments with animals not in a wounded state, and the results have been the same."

ORNUS. [FRAXINUS.]

OROBANCHACEÆ, Broom-Rapes, a natural order of Monopetalous Exogenous Plants, growing parasitically upon the roots of other species, and, as is very usual in such cases, producing no true leaves, but furnished with brown or reddish scales in their place. They have a didynamous structure, irregular flowers, and a superior ovary with four or more parietal placentae, which spring up from the surface of the carpels in parallel lines covered with microscopic seeds containing a minute embryo lying in abundant albumen. On account of their didynamous monopetalous flowers, they are usually stationed by systematical writers in the vicinity of *Scrophulariaceæ*, but in many respects they correspond better with the typical form of *Gentianaceæ*. In this country the order is represented by the genus *Orobanche* itself, the various species of which, called Broom-Rapes, are found in fields, upon the roots of broom, furze, hemp, clover, bed-straw, &c. *O. rubra*, the handsonest of them, has hitherto been discovered only upon basalt and trap-rocks in the Hebrides and adjacent shores, and near Belfast. [OROBANCHE.] The quality of these plants seems to be generally astringent, but they have been little investigated. The order contains 12 genera and 116 species.

Orobanchaceæ.

A plant of *Anoploanthus uniflorus*. 1, a corolla slit open; 2, the ovary with its style and stigma; 3, the same, cut across to show the placentation.

OROBANCHE (from *ὄρος*, a kind of vetch, and *ἄγχι*, to strangle, because its species grow on the roots of vetches, and were supposed to destroy them by strangulation), a genus of Plants, the type of the natural order *Orobanchaceæ*. It has 2 lateral, undivided or cloven permanent sepals; a ringent withering corolla, the upper lip concave, notched, the lower reflexed, in three unequal wavy lobes; a gland under the ovary; the anthers sagittate with the lobes pointed at the base; the filaments almost as long as the tube of the corolla, downy and glandular; the capsule ovate, pointed, with four parietal parallel placentae. The species are parasitical, usually simple, rarely branched, scaly erect herba. Eleven species of this genus are British.

O. major (*O. Rapum*), Greater Broom-Rape, has the sepals 2-nerved, equally hid, nearly as long as the tube of the corolla, the corolla bell-shaped, ventricose at the base, in front arcuate; the lips wavy, obsolete denticulated (not fringed), upper lip helmet-shaped, scarcely emarginate; sides patent, middle lobe of the lower lip much longer than the lateral lobes; the stamens inserted at the base of the corolla, glabrous below, their upper part and the style glandular pubescent. This plant is a native of Europe, growing parasitico upon broom, furze, and other shrubby leguminous plants, on a barren and dry soil. It is abundant in some parts of Great Britain. It is very bitter, and is a powerful astringent.

O. minor, Lesser Broom-Rape, has the sepals many-nerved, the lobes of the lower lip equal, the stigma bi-lobed. The lobes of the stigma are purple, the anthers yellow when dry. It is found in Europe parasitico upon the roots of the *Trifolium pratense*. Although it is sometimes very abundant, it does not appear to injure the crop of clover. It is constantly found in many parts of England with the clover crops.

O. rubra has the corolla glandular, pubescent externally, and the upper lip internally, the lips acutely denticulated, the stamens inserted near the base of the corolla. It is a native of the north of Ireland and of Cornwall in England. It has a sweet scent, and is found parasitico upon the *Thymus Serpyllum*, Common Thyme.

O. caryophyllacea has the corolla tubular, bell-shaped, curved on the back; the stamens inserted above the base; the corolla hairy within. The stigmas are of a dark purple, the anthers at first purple, yellow when dry. It has been found in Siberia and Italy, and on the Himalaya. It has been found also in the county of Kent in England, where it is parasitico on the roots of *Galium Mollugo*.

O. elatior has the corolla curved, tubular, slightly compressed above; the upper lip 2-lobed, toothed; the lobes inflexed; the stigma yellow. It is a native of Europe, and is parasitico on the *Centaurea Scabiosa*. It grows in Great Britain, but is a rare plant.

O. Hedera has the middle lobe of the lower lip of the corolla longest; the stigma yellow. Found in Europe, parasitico upon Ivy (*Hedera Helix*).

O. carulea has a calyx of 4 sepals, tubular, with triangular subulate teeth shorter than the tube of the corolla; the corolla tubular, slightly curved in front, the middle of the tube compressed on the back; the throat slightly inflated externally; glandular lobes of the lips obtuse with reflexed margins, lower lip hairy within, suture of the anther hairy. It is a native of Europe, in Austria, Italy, Germany, and the

south of France. It has been rarely found in Great Britain in the fields of Hampshire and Norfolk, and in Jersey. The flowers have a bluish colour.

O. ramosa has a calyx of 4 sepals, tubular, with triangular ovate acuminate teeth, the anthers glabrous, the stem branched. This plant is a native of Europe, and has been found in Great Britain in Norfolk and Suffolk, where it grows on the roots of hemp and the *Galeopsis Tetrahit*.

The other British species are—*O. amethystea*, parasitical on *Daucus Carota*. *O. Picridis*, found upon *Picris*. *O. arenaria*, on *Achillea millefolium*.

(Babington, *Manual of British Botany*.)

OROBUS, a genus of Plants belonging to the natural order *Leguminosae* and the tribe *Vicieae*. It has a style linear, cylindrical, and downy above; the calyx is obtuse at the base, its upper segments being deepest and shortest.

O. tuberosus, the Tuberous Bitter Vetch, is a smooth plant with winged stem; leave with 2-3 pair of elliptico-lanceolate mucronate dotted leaflets; the peduncles few-flowered, hardly exceeding the length of the leaves; the teeth of the calyx unequal, ovate, bluntish, shorter than the tube; the legumes terete and obsoletely reticulated; the style joined and the seeds globose. This plant is a native throughout Europe, and is abundant in Great Britain. It has creeping roots, which swell out into tubers at irregular intervals. The tubers are highly esteemed in the Highlands of Scotland, where they are called *Cormeille*; the inhabitants dry them and chew them, in order to give a better relish to their whiskey; and they are also supposed to be good against diseases of the lungs, and to prevent hunger and thirst in those who chew them. In Breadalbane and Ross-shire they bruise and steep them, and distil an agreeable fermented liquor. The tubers have a sweet taste, something like liquorice, and when hoiled are not unpleasant. They have been used as food in times of scarcity. In Holland and Belgium they are roasted and eaten in the same manner as chestnuts. In England this plant is also known by the names of Wood-Pea and Heath-Pea, and in Scotland Knapperts.

O. luteus, Yellow Bitter Vetch, is a smooth plant with simple angular stems, 3-5 pairs of leaflets, roundish semi-sagittate stipules, elongated many-flowered peduncles, equal in length to the leaves; the legumes compressed, the seeds globose. This plant is a native of the Alps of Switzerland, France, Italy, and Siberia. It has handsome orange and yellow flowers, and Haller has expressed his opinion that it is the handsomest of all the plants with papilionaceous flowers.

O. niger, Black Bitter Vetch, has pinnate leaves with from 3-6 ovate or elliptical leaflets; linear-lanceolate acute stipules; with an angular, erect, and branched stem. It is a native of subalpine districts in Europe. It is found in Forfarshire and Inverness-shire in Scotland. The flowers are purple, and the plant turns quite black on drying.

There are about 40 other described species of *Orobus*. They are all of them elegant-flowering plants, and being hardy, may be cultivated on the open flower-border.

ORONTIACEÆ, *Orontiadæ*, a natural order of Endogenous Plants, under which Lindley, in his 'Vegetable Kingdom,' includes the *Acorina* of Link and other authors. This order embraces the genera *Calla*, *Orontium*, and *Acorus*, which are the types of three separate tribes. They are related to *Juncaceæ*, *Liliaceæ*, *Piperaceæ*, and *Araceæ*. It contains 13 genera and 70 species. Some of the species are used by man. *Symplocarpus foetidus*, the Skunk Cabbage, yields a fetid volatile oil. The rootstocks of *Calla palustris* are eatable. [ACORINÆ.] (Lindley, *Vegetable Kingdom*.)

ORPHEUS. [MERULIDÆ.]

ORPIMENT. [ARSENIC.]

ORPINE. [SEDUM.]

ORRIS-ROOT. [IRIS.]

ORTALIDA. [CRACIDÆ.]

ORTHAGORISCUS, a genus of Plectognathous Fishes belonging to the family *Gymnodontidæ*. On account of their round form the species are called Sun-Fishes. The genus has the following characters:—Jaws undivided, forming a cutting edge; body compressed, deep for its length, short, truncated, without spines; tail short and very high vertically; rays of the dorsal and anal fins long and pointed, both united at the caudal fin at the base. Two species of this curious genus have been taken on the British coasts.

O. mola, the Short Sun-Fish, the Molehut, although only occasionally seen, has been taken around all the shores of Great Britain. When observed in our seas they have generally appeared as though they were dead or dying, and floating along on one side, presenting the broad surface of the other side to view. This seems to be a natural position.

O. oblongus, the Ohlong Sun-Fish, Ohlong Tetradon, Truncated Sun-Fish. This fish is larger, longer, and rarer than the last.

(Yarrell, *British Fishes*.)

ORTHITE, a Mineral consisting of Silicate of Cerium, Iron, &c. This mineral occurs in minute, slender, columnar imbedded masses. Fracture conchoidal. Hardness 6·0 to 7·0. Colour gray, inclining to black. Streak brownish-gray. Lustre vitreous. Opaque. Specific gravity 3·238. Before the blow-pipe it swells and fuses into a blackish globule; with borax it gives a transparent glass; gelatinises in acids, and yields a solution of cerium. It is found at Finbo, near Fahlun in

Sweden, and also in Greenland, &c. The analysis of the mineral from Finbo, by Berzelius, gives—

Silica	36·25
Protoxide of Cerium	17·39
Protoxide of Iron	11·42
Alumina	14·00
Lime	4·89
Yttria	3·80
Oxide of Manganese	1·36
Water	8·70

—97·81

ORTHOCERAS. [ORTHOCERATIDÆ.]

ORTHOCERATIDÆ, a family of Cephalopodous *Mollusca*. It has the following characters:—Shell straight, curved, or discoidal; body-chamber small; aperture contracted, sometimes extremely narrow; siphuncle complicated. This family is fossil. It includes the genera *Orthoceras*, *Gomphoceras*, *Onoceras*, *Phragmoceras*, *Cyrtoceras*, *Gyroceras*, and *Asoceras*.

The *Orthoceratidæ* are connected on the one side with *Nautilidæ*, and on the other with *Ammonitidæ*. These families are all many-chambered, and have been called *Cephalopoda polythalamacea*.

Three principal considerations have guided the geological naturalists, to whom principally the divisions of the Nautiloidal *Cephalopoda* are due, in the arrangements which they have proposed:—

1. The spirality of the shell. In *Nautilus* it is involute or convolute; in *Orthoceras* straight; and between perfect involution and absolute straightness we have every degree of curvature.

2. The form in which the septa, whereby the cavity becomes concamerated, meet the inner surface of the shell. In most *Nautili* this is a gentle and simple curve; in many *Orthocerata* it is waved; in many *Clymenia* undulated, or deeply and angularly notched.

3. The situation of the siphuncle on the disc of the septa. In most *Nautili* the siphuncle is nearly in the centre of the disc; in *Clymenia* it is on or near the inner or ventral edge; in *Cyrtoceras* generally near to the outer or dorsal line.

To these Mr. C. Stokes ('Geol. Proceedings') has added, in the case of the *Orthocerata*, the consideration of the form of the siphuncle itself; and Mr. Broderip ('Silurian Researches') has noticed, in the character of *Phragmoceras*, the form of the aperture and last chamber.

It is difficult to be satisfied, while attempting the arrangement of Nautiloidal *Polythalamacea*, with following out to its remote consequences any one of these principles exclusively. From the general figure we derive three main groups, namely:—

A. *Orthocerata*, &c. Straight.

B. *Cyrtocerata*, &c. Incurved or convoluted near the apex, ending in a straight or recurved limb.

C. *Nautili*, &c. Altogether convoluted.

A. To subdivide these groups, we may take in *Orthocerata*, not the septal edge, but the siphuncular structure; and, with Mr. Stokes, separate *Ormoceras*, because of its tumid interruptal siphuncle; and, with Bronn, *Actinoceras*, because of its radiating siphuncular processes. Species of *Ormoceras* belong to the Upper Palæozoic Strata generally, namely, to the Upper Silurian Rocks of Murchison, the Devonian and Carboniferous Systems in Europe and North America, above which they are unknown. *Actinoceras* have the same or a more limited range. *Orthoceratites* proper (excluding curved species, like *O. paradoxicum*, Sow.), have the same geological range, and exhibit so great variation in the form of the cone, the disposition of the septa, and situation of the siphuncle, as to furnish many helps to recognise the otherwise undistinguishable forms of the numerous species which fill the older rocks.

For example, the cone is nearly a circular base, the septa are transverse, and the siphuncle is nearly central, in *O. giganteum* and *O. cinctum* of the Mountain Limestone; the cone has an elliptic base, oblique septa, and an excentric siphuncle, in *O. laterale*, *O. Breynii* of the Mountain Limestone, and *O. imbricatum* of the Ludlow Rocks.

The last chamber and the mouth also vary in form. In one species from the Ludlow Rocks the form of these parts has suggested to Mr. Sowerby the generic name of *Gomphoceras* ('Silurian Researches'); and another, from the Mountain Limestone, has received the specific designation of *O. fusiforme*.

It may be remarked that the cases are few in which the apex of *Orthocerata* has been actually observed: in several cases of supposed straight shells the apical part is seen to be curved, and it is our conviction that this is very much more common than the heedless application of *Orthoceras* would lead to suppose.

The following are the characters of some of the genera:—*Orthoceras* (ὀρθός, straight, combined with κέρας, a horn), Breynius.—A straight concamerated shell, with septa regularly concavo towards

Orthoceras laterale.

the mouth, perforated by a simple nearly cylindrical siphuncle, either in or not far removed from the centre of the disc (never marginal).

a. Last chambers cylindrical, as *O. giganteum*.

β. Last chamber contracted towards the aperture, as *O. fusiforme*.

Ormoceras (*ὄμπος*, a head, combined with *κέρας*). Stokes.—A straight conoconcerated shell, with septa as in *Orthoceras*, perforated by a siphuncle similarly situated, but much dilated in each chamber, and contracted at the parts where the septa are attached to it. The inner part of the siphuncle is divided into chambers, corresponding in number with the chambers, and deeply indented in the middle, where the septa of the shell are attached to them; so that one-half of each division of the siphuncle is in one chamber, and the other half in the next chamber.

The typical species are from Drummond Island, in Lake Huron. (Stokes, in 'Geol. Proceedings,' 1838, and 'Geol. Transactions,' 1840.)

Actinoceras (*ἀκτίς*, a ray, combined with *κέρας*). Stokes.—A straight conical conoconcerated shell, with septa as in *Orthoceras*, and siphuncle shaped, as to its external face, as in *Ormoceras*. Within the siphuncle is a continuous tube, which appears to have been capable of expansion and contraction, and is furnished with verticillate radii, which connect the tube with the walls of the siphon.

The species are from Lake Huron and other parts in North America, and Castle Espie in Ireland.

Conoceras (Bronn) is included in *Actinoceras* (Stokes).

Conularia (Miller).—A straight or slightly bent (?) pyramidal 4-sided conoconcerated (?) shell.

C. quadrilucata is a common shell in what were called Transition Rocks in Sweden, Wenlock, Dudley, &c.; and a similar species occurs in the Carboniferous Rocks of Coalbrook Dale and Rutherglen.

B. In classing the bent or partially convoluted *Polythalamacea*, we may find advantage in attending to the situation of the siphuncle. For example, the siphuncle is subdorsal or approaches the outer line of curvature in *Cyrtoceras* (Goldfuss) and *Gyroceras* (Meyer); it is subcentral in *Lituities* (Breyn); and it is subcentral or approaches the inner line of curvature in the genus *Phragmoceras* (Broderip).

The geological distribution of these forms is nearly as in the true *Orthocerata*. They are all peculiar to the strata below the new red system; and mostly occur below the carboniferous or Mountain Limestone. *Phragmoceras* prevails in the Ludlow Rocks; *Cyrtoceras* specially abounds in the strata of South Devon, the Eifel, and the Mountain Limestone; and *Gyroceras* and *Lituities* follow nearly the same rule; a few species of *Lituities* occur in the Silurian Rocks.

Cyrtoceras (*κύρτος*, curved, and *κέρας*, a horn), Goldfuss.—Bent, arched, or partially convoluted, the free end being sometimes elongated and straight. Septal edges seldom free from a slight waving; siphuncle subdorsal, or even marginal, seldom quite round; aperture nearly orbicular.

C. depressum is found in the Eifel.

Several other species occur in Devonshire, near Ludlow, &c.

Cyrtoceras depressum.

Gyroceras (*γυρός*, incurved, *κέρας*, a horn), Meyer.—Coiled like a tendril, so that the volutions do not touch. Septal edge even, siphuncle dorsal, marginal. Aperture nearly round.

G. gracile, Meyer. Bronn, in 'Leth. Geog.,' vol. 1. fig. 6. From the States of Dillenburg.

Lituities, Breyn.—Convoluted, so that the volutions touch in all the inner part, but afterwards extended into a straight or bent portion. Septa pierced by a subcentral siphuncle. Aperture nearly round.

L. articulatus, Sowerby, is an example.

Lituities articulatus.

Phragmoceras (*φράγμα*, septum, *κέρας*, a horn), Broderip.—Shell incurved and compressed, more or less conical; septal edges entire, crossed externally by the lines of growth; siphuncle near the inner margin; aperture contracted at the middle, its outer extremity produced into an elongated beak. Two figures are given below to show the singular contraction of the aperture.

P. ventricosum. Broderip, in 'Silurian Researches.'

Phragmoceras ventricosum.

C. Among the completely spiral and convoluted *Polythalamacea*, the situation of the siphuncle and the form of the septa become useful guides.

The siphuncle is dorsal in some *Nautili* of the Mountain Limestone, which ought perhaps therefore to be distinguished; subcentral in most of the *Nautili* of the Oolitic, Cretaceous, and more recent deposits, as well as in recent species; ventral in *Clymenia* (Munster) and in some otherwise true *Nautili* of the Coal Formation and Magnesian Limestone.

The septa are simply concave, with their edges even, in most *Nautili*; but in some species (*N. bilobatus*, from the Coal Formation and Mountain Limestone) they are deeply undulated, as in the simplest *Clymenia* [GONIATITES]; in a remarkable fossil from the London Clay (*Nautilus Zieglæ*), deeply and angularly folded, nearly as in some *Goniatites*. Finally, in the *Clymenia* of Count Munster, all having a ventral siphuncle, the septal edge is simply waved, or has rounded inflexions, angular bands, or a mixture of these in the same shell.

Taking a general view of the distribution of the *Polythalamacea* we find—

In a living state	<i>Spirulidæ</i> and <i>Nautilidæ</i> .
In the Tertiary Series . .	Some of the <i>Nautilidæ</i> .
In the Cretaceous Strata .	<i>Nautilidæ</i> , <i>Belemnitidæ</i> , <i>Ammonitidæ</i> .
In the Oolitic Strata . .	<i>Nautilidæ</i> , <i>Belemnitidæ</i> , <i>Ammonitidæ</i> .
In the Siliferous Strata .	<i>Nautilidæ</i> (not including <i>Orthocerata</i>), <i>Ammonitidæ</i> (of the type called <i>Ceratites</i> only).
In the Carboniferous Strata	<i>Nautilidæ</i> , including <i>Cyrtocerata</i> , <i>Orthocerata</i> , <i>Ammonitidæ</i> (of the type called <i>Goniatites</i> only).
In still Lower Strata . .	<i>Nautilidæ</i> (including <i>Cyrtocerata</i> , <i>Phragmocerata</i> , <i>Orthocerata</i> , and <i>Clymenia</i>); <i>Ammonitidæ</i> of the type of <i>Goniatites</i> only.

Finally, in strata lower than these, as the Snowdonian Slates, where shells and Polythalamacea remains occur, none of the *Polythalamacea* are known. [AMMONITES; CEPHALOPODA; NAUTILIDÆ; BELEMNITES; BACULITES; BELLEROPHON.]

ORTHONYX, M. Temminck's name for a genus of Birds arranged by Mr. Swainson with *Buphaga* under *Buphaginae*; these two genera

forming the whole of that sub-family. It has the following generic characters:—Bill very short, straight, but the culmen arched from the base; sides considerably compressed; nostrils large, basal. Wings moderate, but considerably rounded; the first four quills graduated, and shorter than the fifth. Tail rather lengthened, rounded; the feathers very broad, and the webs soft, but the shafts stiff, very rigid, and terminating in naked points. Feet enormously large and strong; the outer toe rather longer than the middle, which is again longer than the inner toe; hinder toe shorter than the middle. Tarsus longer than either of the toes; claws strong, very slightly curved; the anterior all of the same length; the hinder one longest. (Sw.)

The only species is *O. spinicaudus*, Temm., *O. Temminckii*, Vig. and Horsf. It is rufous brown above, lined with black; lesser coverts of the wings gray, streaked with brown; plumes of the top of the head slightly prolonged into a sort of false crest, which is however but little apparent; tail rounded, of a tarnished brown-colour, each feather-stem terminated by a point furnished with small stiff bristle-like appendages. A bright orange patch covers the breast of the male, which part is white in the female.

Orthonyx spinicaudus.

Upper figure, male; lower figure, female.

M. Lesson states that this bird is said to be a native of New Zealand. A specimen in the Museum of the Linnæan Society of London was presented by Mr. Brown, who met with it near Hat Hill in 1801.

Messrs. Vigors and Horsfield speak of this genus ('Linn. Trans.,' vol. xv.), which consists of the single species above noticed, as holding the same place in Australia as the true *Certhia* fills in the ancient continent, and the numerous group of *Dendrocolaptes*, Herm., in South America. They observe that it possesses the strong and lengthened shafts of the tail feathers which support the typical scanorial birds in climbing, and that it immediately connects the whole group by a strong affinity to the woodpeckers.

Mr. Swainson ('Classification of Birds,' vol. i.) describes the bird as rather larger than a sparrow, but with the general form and proportions of *Manura*, except in the tail, the rigidity of which, he remarks, would imply that it feeds in a semiperpendicular attitude.

ORTHOPTERA, one of the orders into which Insects are divided. This order, of which we have familiar examples in the common Cockroach (*Blatta*), the House-Cricket, and the Grasshopper, is distinguished by the following characters:—The superior wings are semi-coriaceous, usually displaying numerous nervures in a longitudinal direction, and having the interspaces filled up with transverse, or reticulated, smaller nervures; the anterior portion of the inferior wings is generally of a different substance from the posterior portion, the nervures are more crowded, and in character, and often even in colour, it nearly resembles the anterior pair of wings; the hinder portion of these wings is almost always more transparent, and, when not in use, is folded like a fan. The superior wings often overlap horizontally, as in the cockroaches, but in many species they meet at an angle like the roof of a house, as in the grasshoppers and locusts. The legs in some are formed for running; in others, the hinder pair of legs are very long and the thighs of these legs are thick, and in fact formed for leaping. The antennæ do not vary much; they are usually filiform; in many, extremely long and slender, in which case they are composed of innumerable minute joints; in others, they are shorter and thicker, and the joints are less numerous and consequently more distinct. The parts of the mouth are well developed and approach in structure those of the order *Coleoptera*; they are usually however less firm and compact, especially the labial apparatus. The upper portion of the prothorax is generally very large. The metamorphosis of the *Orthoptera* is semi-complete, that is to say, the larvæ and pupæ resemble the perfect insect, excepting that in the larvæ there are no wings, and in the pupæ the wings are in a rudimentary state. Some species however in the perfect state are wingless, in which case it is extremely difficult, and perhaps impossible, to distinguish the perfect insect from the pupæ or even the larvæ.

Latreille divides the order *Orthoptera* into two sections, to which he applies the names *Cursoria* and *Saltatoria*, or runners and jumpers. In the *Cursoria* all the legs are usually alike and fitted for running, and they are thus easily distinguished from the *Saltatoria*, in which the hinder legs are long and the thighs thick. The males of the species belonging to the second section have the power of producing a shrill noise, but this is not always effected in the same manner.

To the section *Cursoria* belong the families *Forficulidæ* (or Earwigs) [*FORFICULIDÆ*], the *Blattidæ* (Cockroaches) [*BLATTIDÆ*], the *Mantidæ* (or Mantis tribe) [*MANTIDÆ*], and the *Phasmidæ* [*PHASMIDÆ*]. The section *Cursoria* may be divided into three families—the *Gryllidæ* (of which the Common House-Cricket affords an example) [*GRYLLIDÆ*], the *Locustidæ* (Locusts), and the *Acrididæ* (or Grasshoppers) [*LOCUSTIDÆ*].

The principal characters of these families are given under the proper heads; they may be distinguished by the following arrangement:—

- A. Tarsi 3-jointed.
 - a. Abdomen furnished with a forcep-like appendage *Forficulidæ*.
 - b. Abdomen without forceps.
 - * Antennæ filiform or prismatic *Acrididæ*.
 - ** Antennæ very long and setaceous *Gryllidæ*.
- B. Tarsi 4-jointed, antennæ setaceous *Locustidæ*.
- C. Tarsi 5-jointed.*
 - a. The prothorax the longest of the three thoracic segments *Mantidæ*.
 - b. The prothorax the shortest of the three thoracic segments *Phasmidæ*.
 - c. The prothorax broad, more or less rounded, and generally covering the head *Blattidæ*.

ORTHOTOMUS. [*SYLVIADÆ*.]

ORTOLAN, the French and English names for a species of Bird belonging to the family *Fringillidæ*, much esteemed by epicures for the delicacy of its flesh when in season. It is the *Hortulanus* of Gesner and others, *Miliaria pinguis* of Frisch, *Emberiza hortulana* of Linnaeus, Ortolano of the Italians generally, Tordinio Berluccio of the Venetians, Garten Ammer and Fellammer of the Germans, and Gerste Kneuf of the Netherlands. Willughby writes the name Hortulane; and Montagu terms it the Green-Headed Bunting. [*EMBERIZIDÆ*.]

This bird is found in the south of Europe, which may be considered

* In one genus which is placed in this family (*Heteronytarsus*), the posterior tarsi have only three joints.

the summer and autumnal head-quarters of the Ortolan, though it is a summer visitor in the central and northern parts. In Italy it is said to be common by Temminck and others. Prince C. L. Bonaparte states that it is found in the Sabine Mountains, but not commonly, in the summer, and that it rarely occurs in the plain of Rome, but that it is frequent in Tuscany. Lapland, Russia, Denmark, Sweden, and Norway are among the countries visited by it. In these islands it seems to be only entitled to rank as an accidental visitor, but it is by no means clear that it does not occur more frequently than is generally supposed: for, especially to an unpractised eye, it might be mistaken for the Yellow-Hammer, and in some states of its plumage for other Buntings. It has been taken in the neighbourhood of London; and one of these specimens was alive in 1837, in the aviary of the Zoological Society in the Regent's Park. Bewick's figure ('Green-Headed Bunting,' last edition, Supp., p. 24) was captured at sea off the Yorkshire coast, in May, 1822. In southern Europe it is common from May to August, and every spring and autumn may be observed at Gibraltar on its migration. Mr. Strickland saw it at Smyrna in April. North Africa is its winter residence. Colonel Sykes notes it in his 'Catalogue of the Birds of Dukhau' (Deccan).

When properly fed, for which purpose there are large establishments in the south of Europe, where they are placed after having been trapped and furnished with plenty of millet-seed and other grain, till they become sheer lumps of fat, they are delicious morsels. Mr. Gould states that this is effected in Italy and the south of France in a dark room. Prince C. L. Bonaparte says, "Nella vicina Toscana, dove gli Ortolani sono frequenti, si mantengono nelle Uccelliere illuminate giorno e notte finchè restino soffocati dalle pinguedine." (In the neighbouring districts of Tuscany, where the Ortolans are numerous, they are kept in aviaries which are illuminated day and night, where the birds are fed till they are suffocated by their fatness), and he adds the relishing words, "carne squisita" (flesh exquisite).

Ortolan.

Upper figure, male; lower figure, female. (Gould.)

ORTYGIS. [TETRAONIDÆ.]

ORVET, the French name for the Blindworm (*Anguis fragilis* of Linnaeus). [BLINDWORM.]

Messrs. Duméril and Lignon ('Histoire des Reptiles'), who place the form among the Scincoidan Lizards, and next to *Ophiodes*, state that up to the time of their publication all authors have denied an external auditory opening to the *Anguis fragilis*, Linn., whereas this Scincoidan has one, very small it is true, but distinct nevertheless when pains are taken to search for it, even without the aid of a lens. They state that this orifice, which is linear, and from one to two millimetres in length, is situated behind the commissure of the lips, at a distance equal to the length of the muzzle; sometimes it is uncovered, some-

times it is hidden under the scales; and in the latter case they must be raised before it is perceptible. [OPTHIDIA.]

ORYCTEROPUS. [AARD-VARK.]

ORYX. [ANTILOPÆ.]

ORYZA, a genus of Plants belonging to the natural order of Grasses. It is the name by which rice was known to the Greeks and Romans, and which has been adopted by botanists as the generic name of the plant yielding that valuable grain. The Greek name would appear to be derived from the Arabic Aruz, and this is allied to Uri, the Telinga name of cultivated sorts; but the Sanscrit names are Unoo, Dhanya, and Vrihi; the wild kind being called Nivara, while the great tanks are called Erays in the Tamul language. The European names are evidently all derived from the same sources, but the name Paddy is applied to the rice in its natural state, or before being separated from the husk. The natives of India call it Dhan in this state, as well as the plant, and the rice itself is called Chanwul.

The genus *Oryza* has two glumes to a single flower; palea two, nearly equal, adhering to the seed; stamens six, and styles two. Dr. Roxburgh describes two species; one, *O. sativa*, distinguished by its diffuse panicle; the other, *O. coarctata*, has the panicle contracted, the valvules of the calyx subulate, and the leaves culm-clasping. This species is a native of the delta of the Ganges, and was first discovered there by Dr. Buchanan in 1796, but was not found to be applied to any use.

The Common Rice, *O. sativa*, unlike many long cultivated grains, is still found in a wild state in and about the borders of lakes in the Rajahmundry Circars of Hindustan, though never cultivated, because the produce is said to be small compared with that of the varieties in cultivation. [RICE, in ARTS AND SC. DIV.]

Common Rice (*Oryza sativa*).

a, panicle of the rice-plant, with ripe grains; b, a single grain enveloped in its husk and awned.

OSCILLATORIA. [ALGÆ.]

OSIER. [SALIX.]

OSMAZOME, a name given by Thénard, and adopted by most chemists, to a spirituous extract of meat; according to Berzelius it is not a peculiar substance, but a mixture of several different bodies, among which are lactic acid and lactates. In the opinion of Berzelius the name ought to be abandoned. According to the experiments of Chevreul however Osmazome contains a peculiar substance, to which he has given the name of Créatin (from *créas*, flesh).

Creatin is solid, inodorous, insipid, colourless, and has a pearly lustre; it does not act upon test papers, and crystallizes in right prisms. Its specific gravity varies from 1.35 to 1.34. When heated

it crackles, loses water at 212°, and melts without being discoloured; but on continuing the heat it decomposes, yielding ammonia. At 65° Fahr., 100 parts of water dissolve about 1·2 part; this solution is scarcely at all acted upon by saline or metallic substances. The solution slowly decomposes, exhaling a distinct ammoniacal odour and becoming turbid. Alcohol and most acids also dissolve it.

OSMERUS. [SALMONIDÆ.]

OSMIUM. [LATINUM.]

OSMUNDA, a genus of Plants belonging to the natural order *Filices*, and to the sub-order *Osmundaceæ*. It has clustered thecæ arranged in a branched spike terminating the frond.

O. regalis, the Flowering Fern, has bipinnate fronds, pinnules oblong, nearly entire, dilated, and slightly auricled at the base; the clusters panicled, terminal. This fern is a native of Great Britain in boggy places, and often attains a height of from 1 to 8 feet. It is very common in many parts of England, and especially on the lakes of Killarney in Ireland. It is common throughout Europe, and a plant of the same name is found in the United States.

(Bahington, *Manual of British Botany*; Newman, *British Ferns*.)

OSPREY. [FALCONIDÆ.]

OSSEOUS BRECCIA. [OSSIFEROUS BRECCIA.]

OSSIFEROUS BRECCIA, OSSIFEROUS CAVERNS. The existence of large fissures and caverns in rocks is a fact known to miners and quarrymen in all parts of the world; that these cavities are frequently filled with stalactitical sparry and earthy accumulations, and sometimes with the bones of animals, is another fact on which modern geologists have based a long train of ingenious inferences. Fully to examine these facts and inferences would be to discuss one of the most comprehensive and unsettled problems of geology. It is possible however to present in a small compass the leading considerations which belong to the subject.

Great fissures and caverns, though not absolutely confined to limestone rocks, are yet by far of most frequent occurrence in these deposits. They are not common in all limestones, but have certain determinate relations to their mass and the positions which they occupy. It is peculiarly in thick masses of limestone (whether magnesian or purely calcareous) that we find great caverns in England, Ireland, France, Belgium, North Germany, the Tyrol, Carinthia, Italy, Greece, North and South Africa, India, Australia, North and South America. It is sometimes observed that great cavities abound in limestone rocks, not so much at as near to points and lines where the ordinary position of the strata is violently disturbed by great faults, and axes of elevation and depression. Thus the numerous caverns of Derbyshire and Yorkshire, and of the Meudip Hills, are situated in or near to situations of violently-disrupted strata; and by accumulating observations of this nature we gradually come to perceive, in many cases, a real dependence of the chasms in the rock on the fractures which have broken it.

But there are few caverns or great fissures all whose features can be thus explained. The disturbance has not so often produced the caverns as the conditions necessary for their production. On the contrary, in very many cases we perceive, even in caverns now dry, forms of internal surface which mark the decomposing influence of air and moisture, and the erosive power of running water. Through many of them water now runs, through more of them it formerly ran, conducted into these subterranean channels by the fractured condition of the strata. The great caverns of the Peak at Castleton and Buxton may be quoted as examples. Other caverns occur, nearly or entirely exempt from the direct influence of fractures passing through them. Such a case occurs at Kirkdale in Yorkshire; a cave which has for great lengths an even floor and roof, and is connected, not with faults or axes of movement, but with great joints in the limestone. This cave has been traversed by water conducted by these joints. Water dropping, trickling, or running through the fissured limestone rocks, dissolves (by the almost constant carbonic impregnation which it derived from the atmosphere and decomposing vegetation) its calcareous channels, and transports away to the surface of the ground the materials of petrifying springs, the tufaceous mounds of Matlock, and the travertine of southern Europe. In certain classes of limestone rocks there is reason to conjecture that the caverns have not been occasioned by violent fractures, nor yet by the influence of joints, but that they are a part of the original structure of a coral reef (in which cavities were left by the polypæan builders), or have been generated by those chemical processes which we have as yet imperfectly traced and classed as metamorphic effects. This may be the case in certain magnesian (dolomitic) limestones in Derbyshire, Franconia, &c.

In regard to the filling of these cavities, we must again, in a great majority of instances, appeal to the action of water—an inverse action, new circumstances causing water to deposit where once it excavated; or an indirect action, occasioning new accidents. Stalactitical depositions and many varieties of sparry accumulations, which are now happening in caverns and fissures, exemplify the former case; and as an instance of the latter, we may describe what is happening on a part of the Yorkshire coast. Here the chalk is cavernous; the caverns, connected above with small fissures reaching to a mass of diluvial clay, pebbles, &c., are continually enlarged by the waves and spray of the sea; and sometimes their roof, thus weakened, falls in, and the diluvial masses from above pour down into the cave, but are soon removed by the agitation of the tide.

Another instance is of familiar occurrence in the mining districts of the north of England, where limestone, more or less cavernous and fissured, is covered by shales or argillaceous sandstones. Near the edge of these argillaceous beds many rather regular pits ('swallow-holes') occur, through which the surface drainage reaches the limestone, and carries into its cavities some of the materials which are dislodged in its course.

The geologist who takes into consideration the possible origin of caverns in limestone from original hollows, the influence of joint-fissures, and the effect of violent displacements—and considers further the various degrees and circumstances of their communication to the surface, the various action of water within them, their level in relation to that of the sea, and the nature of the strata or other matter superincumbent on the limestone—will be at no loss to comprehend how various, complicated, and interesting are the sparry and earthy contents of subterranean cavities. These contents have in some cases fallen in, so as to constitute confused heaps or masses of breccia; in other cases they have been drifted by water, and arranged into shallow and irregular beds; and in addition, certain matters have been dissolved, and deposited in crystallised and stalagmitic forms.

The occurrence of bones in these breccias, sediments, and stalagmitic incrustations, is sometimes to be explained by supposing them to have fallen with the other materials of breccia, or to have been drifted with sediments by water; but in a considerable proportion of the cases which have been examined there is no avoiding the conclusion that animals retired by choice, or through fear, or were dragged by violence into these cavities, and there have left their bones. This conclusion, established by the sagacity of Buckland for the hyæna caves of Kirkdale and Torquay, applies to the numerous bear caverns of the Harz, Franconia, and Westphalia, and to some caves in Brazil and Virginia. It is a conclusion of the highest importance in geology and zoology. It assures us of the habitat of many extinct races or quadrupeds, and thus furnishes authentic data for a survey of the geographical distribution of *Mammalia* in one definite period of high antiquity, under physical and climatal conditions of the globe much different from what we now behold. Thus for instance we find among the perished races of British quadrupeds the lion, hyæna, and bear; the elephant, rhinoceros, and hippopotamus; the urus and the elk.

To allow of the introduction of these animals to Britain, we must suppose this island joined to the continent; to allow of their long-continued existence here (which the phenomena in Kirkdale cave substantiate), we must suppose certain climatal and physical conditions of the country, and certain habits of life among the animals. Migrations may be supposed for the deer and the lion, but settled abodes must be ascribed to the hyæna and perhaps to the *Pachydermata*. The extinction of these animals requires other admissions. It is not a local, but a general phenomenon, extending over a great part of the northern zones of the world, and of such startling magnitude, as to have suggested hypotheses of diluvial catastrophes and glacial periods to geologists; while zoologists may perhaps regard it as a great example of the law of limited duration and successive predominance, to which, judging from the whole course of paleontological discovery, all the races of the animal creation are made subject.

(Cuvier, *Ossemens Fossiles*; Buckland, *Reliquiæ Diluvianæ*; Meyer, *Paleogeologia*; Owen, *On British Fossil Mammalia*, in *Transactions of the British Association*; Mantell, *Petrifications and their Teachings*; and a variety of Memoirs by different authors in the *Transactions and Proceedings of the Geological Society of London*.)

OSSIFICATION. [BONE.]

OSTRACEÆ, or OSTREIDÆ, a family of Conchiferous *Mollusca*, embracing, according to some authors, the following genera, *Ostrea* (to which the common oyster belongs), *Anomia*, *Placuna*, *Pecten*, *Lima*, *Spondylus*, and *Plicatula*. To these genera are sometimes added *Gryphea*, *Exogyra*, *Carolia*, *Pododesmus*, *Placunamonia*, and *Enigura*. *Pecten* is often regarded as the type of this family. [PECTINIDÆ.]

OSTRACION. [SCLERODERM.]

OSTRACODA. [BRANCHIOPODA.]

OSTREA. [PECTINIDÆ.]

OSTRICH. [STRUTHIONIDÆ.]

OSTROCODA. [BRANCHIOPODA; ENTOMOSTRACA.]

OSTRYA, a genus of Plants, the species of which are called Hop-Hornbeams. They derive their English name from their inflorescence consisting, in the female, of scales packed closely over each other so as to resemble very much the head of a hop, and to its foliage being similar to that of the hornbeam. Two species are known; the one, *O. vulgaris*, a native of the South of Europe; the other, *O. Virginica*, of the United States; these are possibly mere varieties of each other. They both form handsome deciduous trees, usually of small size, but sometimes acquiring a height of 60 feet. (Loudon, *Arboretum Britannicum*.)

OTARIA. [PHOCIDÆ.]

O'TILOPHES (*Otilophi*), Cuvier's name for a group of Batrachian Reptiles [AMPHIBIA], which have the muzzle angular, and the head furnished on each side with a crest which extends over the parotid portion.

Rana margaritifera is an example (see cut, col. 143). It inhabits Brazil, where, according to Seba, it is called Aquagua.

*Rana marmorata*.

a, seen from above; b, placed on its back to show the under parts.

OTIS. [BUSTARD.]
OTOCRYPTIS. [DRACONINA.]
OTOLICNUS. [LEMURIDÆ.]
OTOMYS. [MURIDÆ.]

OTOPTERIS, a genus of Fossil Ferns, of which several species have been described. Its distinguishing character is to have simply pinnated leaves, whose leaflets are auricled at the base, where they join the rachis by a narrow stalk, and are furnished with veins which proceed directly from the base to the apex, without any attempt at

1, *Otopteris dubia*; 2, *Otopteris obtusa*; 3, *Otopteris acuminata*; 4, *Otopteris cuneata*.

forming a midrib. Five species are known, from the beds above the coal-measures, and chiefly from the lias and oolitic formations, of which they are a characteristic feature; these are *O. cuneata*, *O. Beani*, and *O. acuminata*, from the Oolite, *O. obtusa* from the Lias, and *O. Dufrenoyi* from the New Red-Sandstone. There is moreover an *O. dubia* from the Knowlesbury Coal-Field, and an *O. ovalis* from the Scarborough Oolite, both of which are doubtful species; the latter in particular must be excluded from the genus, and probably belongs to *Neuropteris*.

OTTER. [LUTRA.]

OTTRELITE is a Mineral occurring in small rounded brilliant plates, with a perfect basal cleavage. Colour grayish or greenish. Streak pale green. Fracture uneven. Scratches glass with difficulty. Specific gravity 4.40. It is found near Ottreux on the borders of Luxembourg. Its analysis by Damour gives—

Silica	43.34
Alumina	24.63
Protoxide of Iron	16.72
Protoxide of Manganese	8.18
Water	5.56
	—98.43

OTUS. [STRIGIDÆ.]

OUNCE. [FELIDÆ.]

OURARI. [STRYCHNOS.]

OURAX. [CRACIDÆ.]

OVALIA. [LEMNODÆ.]

OVEÆ (Gray), a sub-tribe of the tribe *Bovina* and family *Bovide*. It includes the common Sheep and allied species. The following is Dr. J. E. Gray's definition of this family:—Forehead flat or concave. The horns are more or less spiral, wider than deep at the base, and slightly annulated in front. The females are often hornless. The skull has a more or less deep rounded suborbital pit, without any fissure; the masseteric ridge ascending high before the orbit: the auditory bulla small; the basioccipital flat, more or less expanded anteriorly by the extension of the anterior pair of tubercles, the posterior ones small; the cutting-teeth are nearly equal-sized and shelving; and there are no supplemental lobes to the grinders. The hoofs are triangular, and being shallow behind, they have distinct interdigital fossae. Males emitting no stench.

The genera included in this family are—

1. OVIS. Crumen distinct. Tail elongated. Skin covered with wool or adpressed hair.
2. CAPROVIS. Crumen distinct. Tail very short. Skin covered with thick hair, covering the wool.
3. PSEUDOS. Crumen none. Tail rather elongated. Forehead convex. Skin covered with thick hair.
4. AMMOTRAGUS. Crumen none. Tail rather elongated. Forehead concave. Skin covered with short hair, and elongated tuft of hair.

Ovis Arics, the Common Sheep, is subject to great variety, and many of its forms have been raised to the rank of species. Dr. Gray, in the 'British Museum Catalogue,' enumerates no less than 33 varieties of this species.

In the ARTS AND SCIENCES DIVISION of this work an article is devoted to the SHEEP as the subject of the art of the grazier. We here present a few of the varieties which are more interesting to the zoologist. The Sheep is one of those animals which man has domesticated, and which, like the horse, dog, cat, pig, and ox, is subject to the greatest possible variety. These varieties have been often described as species; but the most distinguishing zoologists of the present day regard all the forms of *Ovis* as belonging to the species *O. Arics*.

The following is a list of the varieties from the 'British Museum Catalogue':—

1. The Spanish Sheep. It is the *Ovis Hispanicus* of Linn.; called also the Merino Sheep and the British Middle-Wooled Sheep.
2. The Common Sheep (*Ovis rusticus*, Linn.; *O. Gallica*, Desm.; *O. brachyurus*, Pallas; *O. lepturus*, Schreb.): the Hornless Sheep (*O. Anglicana*, Linn.). Of this variety there are numerous forms, such as the Muggs Sheep and Shetland Sheep, the Southdown Sheep, the Old Lincoln Sheep, the Rounney Marsh Sheep, the Cobwold Sheep, the New Leicester Sheep, the Cheviot Sheep, the Old Teeswater Sheep, the Improved Teeswater Sheep, the Dunky Sheep, the Zetland and Orkney Sheep, the Welsh Mountain Sheep, the Soft-Wooled Sheep of Wales, the Wicklow Mountain Sheep, the Kerry Sheep, the Exmoor Sheep, the Black-Faced Sheep, the Black-Faced Heath-Sheep, and the Rasc or Roosh (*Ovis Polii*, Blyth).
3. The Barwall Sheep, *Ovis (Arics) Barwalli*, Hodgson; *Ovis Barual*, Hodgson; *O. Ammonoides* var. 1, Gray. It inhabits Nepal.
4. The Hunia Sheep (*Ovis Hunia*, Hodgson); The Hoonia, or Black-Faced Sheep of Tibet. Also a native of Nepal.
5. The Cago (*Ovis Cagia*, Hodgson); the Kago, or Tamo Sheep of Cabul region; the Cago Sheep of Gray. A native of Nepal.
6. The Seling. A native of Nepal.
7. The Curumbar Sheep of Mysore.
8. The Sheep called Gârâr in India.
9. The Dukhun Sheep.
10. The West-Indian Sheep.

11. The Brazilian Sheep.
12. The Demerara Sheep.
13. The South American Sheep (*Ovis Aries*, Reuger).
14. The Smooth-Haired Sheep (*O. Africanus*, Ray; *O. Æthiopica*, Charlet; *O. Africana*, Sloane).
15. The African Sheep (*O. Guineensis*; *A. longipes*, Desm.; *Capr Mambrius*); the Sheep of Sahara.
16. The Guinea Sheep (Belier et Brehis des Indes, Buffon; *O. A. Guineensis*, Schreh.).
17. The Morvant de la Chine, Buffon.
18. The Shaymliar Sheep of Mysore.
19. The Sheep of Zeyla, of Buckingham.
20. The Fezzan Sheep, of Beunett, from Tripoli.
21. The St. Helena Sheep.
22. The Morocco Sheep (*O. A. Numida*, H. Smith).
23. The Congo Sheep (*O. A. Congensis*, H. Smith).
24. The Angola Sheep (*O. A. Angolensis*, H. Smith).
25. The Zenu or Goitred Sheep (*O. A. Steatinion*, H. Smith).
26. The Ixalus (*Ixalus probaton*, Ogilby; *O. Ixalon*, Sundevall).
27. The Cretan Sheep (*O. Strepsiceros*, Ray; *O. A. Strepsiceros*, Schreh.; *O. Cretensis*, Jonst.; *Capra Cretensis*, Brisson; *Strepsiceros Cretica*, Besch.; Belier et Brehis de Valachie, Buffon; Zackl of the Austrians; Wallachian Sheep of Bewick).
28. The Long-Tailed Sheep of Russia (*O. longicaudatus*, Brisson; *O. Dolichura seu Tscherkessica*, Pallas).
29. The Broad-Tailed Sheep (*O. laticaudatus*, Erxl., Geoff., 'Mem. Egypt'; Lesson, 'Comp. Buffon,' x. 312; *O. laticauda platyceros s. Arabica*, Linn.; *O. Turcica*, Charlet; *O. cauda obesa*, Lndolf). It is a native of Barbary. There are several forms of this variety, of which the following are most prominent:—The Fat-Rumped Sheep (*O. Steatopyga*, Pallas; the Tartarian Sheep of Bewick); the Persian Sheep (*O. A. caudatus*, Geoff.); the Fat-Tailed Sheep (*O. A. macrocerus*,

Fat-Tailed Sheep (*Ovis Aries macrocerus*).

Schreh.); the Aora Fiyel, or Abyssinian Sheep; the Bucharian Sheep (*O. Bucharica*, Pallas); the Thibetan Sheep (*O. Thibetanus*, Fischer); the Cape Sheep (*O. Capensis*, Erxleb.); the Sheep of Belkah.

30. The Many-Horned Sheep (*O. polyceratus*, Linn.). It is also called the Four-Horned Ram, and the Dumba Sheep. It is a native of Nepaul.

31. The Puchia, or Hindustan Dumba (*O. puchia*, Hodgson).

32. The Short-Tailed Sheep (*O. brachyura borealis*, Pallas). It is a native of Northern Russia.

33. The Sheep of Tartary. They are said to eat bones like a dog.

The genus *Caprovis* embraces the following species:—

C. Vignei, the Sha, or Koch. It is the Mountain Sheep of the north of India, and is found in Tibet.

C. orientalis, the Armenian Sheep. It is the *Egoceros Musimon* of Pallas; the *Ovis Musimon* of Brandt. It is a native of Armenia.

NAT. HIST. DIV. VOL. IV.

C. Musimon, the Monflon. This animal has a multitude of synonyms. It is the *Capra Ammon* of Linnæus, and the *Ovis Musimon* and *O. Musmon* of other authors. It is the Wild Sheep and Siherian Goat of Pennaut. It is found in Cyprus, Candia, and Corsica.

Mouflon (*Caprovis Musimon*).

C. Ammotragus, *A. Tragelaphus*, the Aoudad of the Moors of Barbary and the Kechsch of the Arabians, is a native of North Africa.

Kechsch (*C. Ammotragus*).

C. Canadensis, the Taye or Big Horn. It is the *Ovis montanus* of Geoffroy; and a variety, the *O. Californiana* of Douglas. Dr. Gray says it is probably the same as the Ammon of Northern Siberia.

There is only one species of *Pseudois*, the *P. Nahoar*, the Nahoar Nervate or Sna. It is a native of Nepaul.

C. Argalis, the Argali. It is the *Egoceros Argali* of Pallas, and often confounded with the former. It is a native of Siheria. Dr. Gray says of this species—

"The Nyens or Bambheras, or Wild Sheep, seldom or never cross the Hemachal, the Indian side of which range is the special habitat of the Nahoors, while to the north and west beyond Thihet our animal is replaced by other species, so that Thihet may be considered as the special habitat of one species (*Ovis Ammonides*), and the plateaux north of Thihet as far as the Altai of another (*Ovis Ammon*), cited as types of the true ovine form; and it may be added, that the six sorts of tame sheep of Thihet and the Sub-Himalayas all without exception exhibit the essential characters of that form.

"There are several species that may be confounded under this head: the Siherian Argali is found in the most northern part of that country, and it is probably different from the Himalayan animal; but I have not been able to discover any difference between the specimen

Argali (*Capra Argalis*).

received from Mr. Hodgson and those which were sent from Siberia by the Russian naturalist."

OVIPOS. [BOVIDÆ.]

OVI'PAROUS. An animal is said to be oviparous when the ovum, or egg, is excluded from the body entire, and hatched after such exclusion. Birds and the great majority of reptiles are oviparous animals.

OVIS. [OVÆ.]

OVOVIV'IPAROUS. An animal is said to be ovoviviparous when the egg is hatched within the body, and the young one is excluded alive. Thus, among the Reptiles, the young of the Lizard known by the name of *Zootoca vivipara* (the Viper, the Rattlesnake, and the Blindworm), are hatched before they are excluded from the body, and not long before such exclusion; indeed it is probable that the rupture of the egg takes place during the parturition. The Monotremes (*Ichidna* and *Ornithorhynchus*) and the *Marsupials* are examples of ovoviviparous mammiferous quadrupeds.

OVULE. [SEED.]

OVULUM. [CYPRIDE.]

OWL. [BUBO; STRIGIDÆ.]

OX. [BOVIDÆ.]

OX-BIRD. [SCOLORACIDÆ.]

OX-EYE. [CHRYSANTHEMUM.]

OX-HOOF. The leaves of species of *Canotretus* and *Bauhinia* are thus called in Brazil, where they are used as mucilaginous remedies.

OX-LIP. [PRIMULA.]

OX-TONGUE. [HELMINTHIA.]

OXALIDACEÆ, Wood-Sorrels, a natural order of Polypetalous Exogenous Plants with a superior ovary, a small number of hypogynous stamens, which are usually monadelphous, and distinct styles. Their fruit contains five cells, in which there are numerous seeds, occasionally expelled with violence by a sudden contraction of the sides of the pericarp. The order is so very nearly allied to *Geraniaceæ* that it can hardly be considered distinct. The genus *Oxalis* itself is called Wood-Sorrel, from the acidity of the leaves and the natural habitation of the European species in a wild state; it is however most common at the Cape of Good Hope, where the species are extremely ornamental. In the East Indies the genus *Acerrhoa* produces a fruit (the Carambola or Blimbing), used for pickling and preserving; but its extreme acidity renders it unsuitable to many persons. Our *Oxalis Acetosella*, or Common Wood-Sorrel, has been supposed to be the true Shamrock of the Irish, instead of the trefoil to which the name is more commonly applied. In the tropical parts of India is an annual *Oxalis*, called *O. sensitiva* in consequence of its pinnated leaves being irritable like the sensitive plant; it has been lately ascertained that the European trefoil-leaved species have the same property, only in a more feeble degree. ('Bulletin de l'Académie Royale de Bruxelles,' vol. vi., No. 7.) This phenomenon is most conspicuous in a hot sunny day.

O'XALIS (from *ὄξος*, sharp, acid; the leaves have an acid taste), a genus of Plants belonging to the natural order *Oxalidæ* or *Oxalidaceæ*. It has 4 sepals connected below, and 5 petals which are likewise frequently connected below. The stamens are 10 in number, and monadelphous; the 5 outer ones shorter than the rest. The styles 5, and the capsule oblong and 5-cornered.

O. Acetosella, Common Wood-Sorrel, is a small perennial plant with

a subterranean rootstock consisting of many scaly joints; the leaves are ternate, leaflets obcordate and having the peduncles longer than the leaves, with two scaly bracts at about the middle; the corolla is about 4 times as long as the calyx, and of a white colour beautifully veined with purple. Mr. Curtis remarks that the leaves are often purplish beneath, and that the fruit darts forth its seeds at the smallest touch when ripe. This species of wood-sorrel has a pleasant acid taste, dependent on the presence of oxalic acid, and is frequently used in salads; its flavour approaches near to that of lemons or tartaric acid, with which its medicinal effects also correspond, as it is esteemed a refrigerant antiscorbutic and diuretic. The expressed juice of this species, evaporated and set in a cool place, affords a crystalline salt, which may be used whenever vegetable acids are wanted. It is sold in the shops under the name of Essential Salts of Lemons, and is employed to take iron-moulds and ink-spots out of linen.

O. corniculata, Horned Wood-Sorrel, has a decumbent stem, branched and rooting; the leaves are ternate with obcordate leaflets; oblong stipules united to the base of the petioles; the peduncles are two-flowered, and shorter than the leaves. It is a native of Europe, particularly in Spain, Italy, and Greece, as well as of Japan, Mexico, North America, and England. The flowers are yellow. The flowers of the North American plant are larger than the European.

O. violacea is a North American species.

*Oxalis violacea.*

1, the stamens and styles after the calyx and corolla have been removed; 2, the ovary with the five distinct styles; 3, a transverse section of an ovary.

O. stricta has an erect leafy stem, umbelliferous peduncles rather shorter than the leaves. It is a native of North America, and is naturalised in Cornwall and Devonshire in England. The flowers are yellow and about the size of those of *O. corniculata*. Browne says, this plant is also a native of Jamaica, and he recommends it as a pleasant cooler and diuretic; formerly it was given in inflammatory cases, but has been superseded by the more agreeable fruit-acids which are now cultivated in the West Indies. Professor Morren of Liège attributes to this species of *Oxalis* the peculiar properties of a sensitive plant. He also observed the same movements in *O. acetosella* and *O. corniculata*, and some other species. The *O. sensitiva*, called by De Candolle *Biophytum* on account of its sensitive properties, has long been known to possess this quality. The whole genus of *Oxalis* is curious and beautiful, and well worthy cultivation. There are above 220 species described, which are distributed in every quarter of the globe.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Lindley, *Flora Medica*.)

OXYBELUS. [NYSSONIDE.]

OXYCOCCUS, a genus of Plants belonging to the natural order *Ericaceae*.

O. palustris, the English Crauberry, is found wild abundantly in the fens of Norfolk, Lincolnshire, and many other parts of England, always by the side of little rills, and not among stagnant water; it has slender trailing thread-like shrubby shoots, clothed with tiny linear leaves, and has a 5-parted pink corolla with the segments sharp-pointed and turned back. The fruit is a round austere red berry, which makes excellent tarts and oos of the many kinds of marmalade. The Russian cranberries of the shops are borne by this species. They are not gathered till after the disappearance of winter. Near St. Petersburg the cranberry plant is so common, that the snow is stained crimson by the berries crushed to pieces by the passage of sledges over them.

O. macrocarpus, the American Cranberry, is very like the other, but its leaves, flowers, and fruit, are larger; and the latter has a more medicinal taste. It is imported from the United States, in hogheads, in considerable quantity, and used for the same purposes as the other; but it is considered of inferior quality. [VACCINIUM.]

OXYLOPHUS. [CUCULIDÆ.]

OXYNASPIS. [CIRRIPEDIA.]

OXYNOTUS. [LANIADÆ.]

OXYRHYNCHUS, a name given by M. Latreille to a great division of Brachyurous *Crustacea*, consisting of the *Naiades*, the *Oxystomes*, and many of the *Anomura* (Anomoures) of M. Milne-Edwards. The latter zoologist however remarks that as the classification in which the term was employed has been long abandoned even by its author, he (M. Milne-Edwards) had thought that it would not be inconvenient to apply it to another family, and so avoid the necessity of adding a new name to zoological nomenclature.

The natural group to which M. Milne-Edwards applies the name 'Oxyrhinque,' is that which presents a nervous system more centralised than he has as yet discovered among the Crustaceans, and it is principally for that reason that he places the Oxyrhynchs at the head of the series formed by these animals. In fact, he observes, the different oedullary ganglions of the thorax do not, in this instance, form more than a single solid mass in the form of a disc, whilst in the other Decapods, of which the internal anatomy is known, these same ganglions remain more or less distinct, and only unite so as to form a circular ring. In many of the Oxyrhynchs M. Milne-Edwards has also remarked that the two portions of the liver, instead of being completely separated as in the other Decapods, are united on the median line by an unequal lobe: this viscus is well developed and extends over a great part of the vault of the branchial cavity. The number of branchiæ is always nine on each side of the thorax; seven of these organs, the last of which is inserted above the third foot, are very much developed, and rest on the vault of the sides, whilst the two others are often reduced to the rudimentary state, and are hidden at the base of the first. Lastly, the vault of the respiratory cavity is but slightly elevated, and throughout its extent, nearly comes in contact with the upper surface of the branchiæ. The rest of the internal organisation offers nothing peculiar.

But the same assertion cannot be made with regard to the external

organisation of these animals. The general form of their body approximates to that of a triangle, of which the base is rounded and turned backwards. The first pair of feet are generally of the same size on each side; but their dimensions are very different in some species and also in the sexes. The succeeding feet are often of enormous length, and are nearly always slender and cylindric; this disposition is even carried so far in some of the Oxyrhynchs that it has obtained for them the name of Sea-Spiders. The second or third last pairs are sometimes subcheliform; but these organs never take the form of natatory fins, and in general those of the last three pairs diminish gradually in length.

The Oxyrhynchs are all essentially marine. None are known to live in fresh-water or to frequent the shores of the sea; but all inhabit great depths, and are generally obtained when dredging for large fish. Their long feet would convey an idea of nimbleness, but these *Crustacea* are in general slow in their motions, and soon die out of water. No swimmers are known among them.

OXYRHYNCHIUS. [PICIDÆ.]

OXYRIA, a genus of Plants belonging to the natural order *Polygonaceae* (?). It has a 4-parted perianth, the 2 interior segments larger; 6 stamens; 2 stigmas; a 1-seeded nut, compressed, with a membranous wing, larger than the persistent segments of the perianth; embryo central.

O. reniformis, Mountain-Sorrel, is the only species. It is found on the highest mountains of Great Britain, and is an inhabitant of Europe. It is the *O. digipita* of many botanists.

(Babington, *Manual of British Botany*; Koch, *Flora Germanica*.)

OXYSTOMA, or OXYSTOMES, a name applied by M. Milne-Edwards to the fourth and last family of Brachyurous *Crustacea* (type, *Leucosia*, Fabr.), comprising all the *Crustacea* which most resemble the type in their general organisation, and especially in the conformation of the buccal apparatus.

The apertures for the passage of the intromissive organs of the males are hollowed out in the basilar joint of the posterior feet, as in the Oxyrhynchs and the Cyclometopes. The disposition of the branchiæ is also nearly the same as in the last-named group, but sometimes the number of these organs is less considerable, and does not amount to more than six on each side. In most of these crustaceans the branchial cavity does not present at the base of the feet any aperture for the entrance of the water necessary for respiration, and this liquid only arrives there by a gutter hollowed out on each side of the prelabial space, serving as a passage for the water expelled from the branchial cavity. This canal is very long in nearly all the Oxystomes, and is converted into a species of tube by a prologation of the anterior jaw feet. The internal soft parts have not as yet been discovered to present any particular organisation. M. Milne-Edwards divides the family into the following tribes—the *Leucosians*, the *Calappians*, the *Corystians*, and the *Doripians*.

The *Leucosians* embrace the following genera:—*Arcania*, *Philyra*, *Myra*, *Ilia*, *Guaia*, *Leucosia*, *Persephona*, *Nursia*, *Ebalia*, *Oreophorus*, *Iphis*, and *Ixa*.

The *Calappians* embrace the genera *Calappa* [CALAPPA], *Platymera*, *Mursia*, *Orythia*, *Matuta*, and *Hepatus*. [HEPATUS.]

The *Corystians* include the following genera:—*Atelycycus*, *Thia*, *Polydectus*, *Corystes* [CORISTES], *Nautilocystes*, and *Pseudocorystes*.

The *Doripians* include the following genera:—*Dorippe* [DORIPPA], *Cynopolia*, *Caphyra*, and *Ethusa*. [ETHUSA.]

OXYSTOMUS. [STURNIIDÆ.]

OXYURA. [DUCKS.]

OXYURUS (Swainson), a genus of Birds.

OYSTER. [OSTRACEA; PECTINIDÆ.]

OYSTER-CATCHER. [CHARADRIADÆ.]

OYSTER-GREEN. [ULVA.]

OZOKERITE, a Mineral, consisting of Carburet of Hydrogen. Colour yellowish-brown; translucent; has a slight bituminous odour, and softens by the heat of the hand, so that it may be kneaded. Fuses readily, emitting a stronger bituminous odour; burns with a clear bright flame without residue. Insoluble in water, only slightly in alcohol, but readily in ether and oil of turpentine. It is found in considerable masses at Slanik in the Buchau district of Moldavia, and is used for fuel. It contains Carbon, 85.204; Hydrogen, 13.787. It appears to be similar in composition to Hatchetine.

P

PACA. [CELOGENTS.]

PACHYCEPHALA. [VIREONIDÆ.]

PACHYCEPHALINÆ, Swainson's name for the 'Great-Headed Chatterers,' which form, according to his first arrangement, the second sub-family of the *Amphelide*, or family of Chatterers, and are placed between *Leiotrichanæ* (Long-Legged Chatterers) and *Bombycilline* (Swallow Chatterers), the other two sub-families being the *Ampheline*, or True Chatterers, and the *Piprine*, or Manakin Chatterers. Of these

sub-families he considers *Leiotrichanæ*, *Pachycephalinae*, and *Bombycillinae* to be aberrant.

PACHYCOERMUS (Agassiz), a genus of Ganoid Fossil Fishes. [FISH.]

PACHYDERMATA (literally Thick-Hides; Dickhäuter of the Germans; Pachydermes of the French), the seventh order of *Mammalia* according to the system of Cuvier.

The first family of Pachyderms in this arrangement consists of those which have a proboscis and tusks, and which are named Proboscideans.

The Proboscideans, in the opinion of Cuvier, have many resemblances to certain Rodents; for instance, their great incisors (so to speak) or tusks; their jaws, which are often formed of parallel laminae; the form of many of their bones, &c. The whole of this family have five toes on each foot, completely formed in the skeleton, but so incrustated in the callous skin which surrounds the foot, that there is no appearance of them externally, except as they may be traced by the nails attached to the border of this species of shoe. The canines and incisors, strictly speaking, are wanting; but there are two tusks implanted in the incisive bones, which two tusks project from the mouth, and often grow to an enormous size. The proportions necessary for the alveoli or sockets of these tusks, render the upper jaw so high, and so much shorten the bones of the nose, that the nostrils are found in the skeleton towards the upper part of the face; but, in the living animal, they are prolonged into the well known proboscis or trunk. [ELEPHANT.] The parietes of the cranium contain large spaces for rendering the skull light; and the lower jaw has no incisors; as may be seen in the same article. The intestines are voluminous, the stomach simple, and the cæcum enormous. The mammae, two in number, are situated on the breast; and the young suck with the mouth, and not with the trunk, as some had erroneously supposed. The only living genus of Proboscideans is *Elephas*. [ELEPHANT.]

The other genus is extinct, and consists of the *Mastodons*. [MASTODON.]

The second family, the Ordinary Pachyderms, have either four, three, or two toes.

I. Those which have the toes equal are in some sort cloven-footed, and, in many respects, approximate the ruminants in the skeleton and in the complication of the stomach.

Living genera, *Hippopotamus* [HIPPOPOTAMUS] and *Sus* (Linn.). [SUIDE.] Extinct genus *Anoplotherium*. [ANOPLOTHERIUM.]

II. Those which are not cloven-footed form genera which very much resemble each other in the jaws, in having on each side seven upper molars with square crowns and various projecting lineaments, and seven lower ones with a double crescent on the crown, the last of all having a triple crescent; but their incisors are different.

Genera—*Rhinoceros*; *Hyrax*; *Palaotherium*; *Lophiodon*; and *Tapir*. [RHINOCEROS; PALEOTHERIUM; LOPHIODON; TAPIR.]

The third family consists of the *Solidungula*, which apparently have but one toe and a single hoof or shoe to each foot, but on each side of the metacarpus and the metatarsus are bony points or processes which represent two lateral toes.

Genus *Equus*, Linn. [EQUIDE.]

To these may be added the following extinct genera:—*Chalicotherium*, allied to the *Tapirs* [TAPIR]; *Cheropotamus* [SUIDE]; *Anthracotheum*, allied to *Cheropotamus* and *Dichobunus* [PALÆOTHERIUM]; *Algomotherium*, placed by Fischer between *Rhinoceros* and *Hyrax*; *Calodonta*, arranged by Meyer between *Rhinoceros* and *Dinotherium*; *Cainotherium*, placed by Meyer between *Anoplotherium* and *Palaotherium*; *Adapis* [ANAPIS]; and *Hippotherium*, an animal allied to the horse. [HIPPOOTHERIUM.] *Dinotherium* is considered by Professor Kaup and others to be nearly allied to the *Tapirs*, in which case the extinct animal must doubtless find a place among the *Pachydermata*. [DINOTHERIUM; TAPIR.]

PACHYMYA (J. Sowerby), a genus of Fossil *Conchifera*. [MYTIDIDÆ.]

PACHYODON, a genus of Fossil *Conchifera*.

PACHYPTERIS (Brongniart), a genus of Fossil Ferns.

PACHYRHIZUS. [DOLICHOS.]

PACHYSTOMA (Goulding), a genus of Gastropodous *Mollusca* belonging to the family *Ampullariadæ*.

PACHYTES. [SPONDYLIDÆ.]

PACHYTHERIUM. [MEGATHERIIDÆ.]

PA'CLITES (De Montfort), a genus of *Delemmites*.

PACO. [LLAMA.]

PACTOLIUS, a genus of *Crustacea* belonging to the tribe *Pactolians* of Milne-Edwards. This tribe belongs to the *Apterurous* family of the *Anomurous* section of *Crustacea*. The other tribes belonging to this family are the *Dromians*, the *Hemulians*, the *Raninians*, the *Porcellanians*, the *Hippians*, and the *Pagurians*. The *Pactolians* are placed between the *Hemulians* and the *Raninians*.

Pactolus has the following generic characters:—First joint of the external antennæ long and cylindrical. Feet moderately long and rather stout, the two anterior shorter than the others, not terminated by a manus or pincers, but only provided with a simple hooked nail; the second pair terminated in the same way; the third pair unknown; fourth and fifth pair didactylous. Carapace triangular, elongated, rather convex on each side behind, not thorny above, and terminated anteriorly by a very long, sharp, delicate and entire rostrum, similar to that of the *Leptopodia*. [MACROPODIDÆ.] Abdomen of the female composed of five joints, the first narrow, the three following transverse and linear, and the fifth very large and nearly rounded. Eyes very large, situated behind the antennæ, always projecting from their socket; a single point behind each orbit.

P. Boscii. Length eight lines, nearly two of which belong to the rostrum, which is furnished with small spines directed obliquely on

the sides; carapace smooth, brownish; feet variegated with ruddy and whitish. Country unknown.

Pactolus Boscii.

PADDY-BIRD. [RICE-BIRD.]

PADOLLUS. [HALIOTIDÆ.]

PAEDERIA, a genus of Plants belonging to the natural order *Cinchonaceæ*. It has a small 5-toothed permanent calyx, a funnel-shaped corolla, hairy inside, 5-lobed, and with a plaited restriction. There are 5 stamens, sometimes abortive; the anthers oblong, nearly sessile in the middle of the tube. The style is not protruded, and the stigma bifid. The berry is small, roundish, and globose, tricelled, with a seed in each cell. The flowers are small, white, and usually unisexual.

P. fatida has a woody twining stem, round and smooth. The leaves are oblong or lanceolate, cordate at the base, and glabrous. The panicles axillary, terminal, opposite, short, and few-flowered. The flowers are usually of a deep pink, the bracts ovate, the calyx 5-toothed, the corolla with a long tube somewhat gibbous and woolly inside; the limb narrow and divided into 5-cordate crenulate segments. The berry is dry, compressed, having 5 lines on each side, 1-celled, and 2-seeded. The seeds are smooth, compressed, enlarged with a somewhat membranous ring all round. The leaves have a very fetid and alliaceous odour when bruised, yet they are used to impregnate baths, and are administered in a decoction medicinally in cases of retention of urine and some febrile complaints. According to Roxburgh the root is used by the Hindoos as an emetic. It is a native of the East Indies, and of Japan and the Moluccas.

P. ternata has an erect smooth trichotomous stem, with triangular branchlets; leaves 3 in a whorl; oblong-lanceolate axillary trichotomous corymbs, shorter than the leaves; the limb of the calyx campanulate and obscurely 5-toothed. It is a native of the East Indies on the mountains which border on Silhet. The flowers are rather large, funnel-shaped, white, on long filiform pedicels, each pedicel having a pair of linear ciliated bracts above the middle. The flowers are said to be fragrant when fresh, but emit a very offensive smell on being steeped in water after they have been dried.

(Lindley, *Flora Medica*.)

PÆONIA is a genus of Plants belonging to the natural order *Ranunculaceæ*. The species are very generally cultivated in gardens for the sake of their large gaudy flowers. They are characterised in their order by a permanent leafy calyx of 5 unequal sepals, 5 petals, stamens whose anthers split open by two fissures along their face, a fleshy elevated disc, and from 2 to 5 many-seeded carpels, terminated by a fleshy recurved stigma. Their fruit consists of leathery foliicles, splitting on one side, and exposing to view a number of round, black, shining seeds adhering to a crimson placenta.

P. Moutan is a shrub, of which several varieties, with beautiful whitish flowers stained with pink, are now in our gardens. Of these the most showy is that called *P. papaveracea*, which has a broad crimson stain at the base of each petal. If grown on the north side of a wall, or in a situation where it is but little exposed to the sun in the early part of the day, this species will bear the open air of England without protection; but it sprouts so early in the spring, if exposed to the sun, that it is very liable to be cut off by the late frosts of England. It is a native of China. Of the other species, *P. Brownii* and *P. Californica* are remarkable for being the only species inhabiting America; they are natives of California and of the country to the northward, and have little beauty: the first exists in our gardens, but is extremely rare. The rest of the genus consists entirely of European and Asiatic plants, which, according to De Caudolle, form fifteen species; but there can be no doubt that the greater part of these supposed species are mere varieties, chiefly of *P. officinalis*, *P. albiflora*, *P. tenuifolia*, and *P. peregrina*.

All these plants are liable to produce double flowers, which, by the conversion of their numerous stamens into petals, are generally

extremely beautiful: they have however no smell, or not an agreeable one. Being quite hardy, growing readily in any kind of soil, and easily multiplied, either by seeds or by division of the roots, they are generally favourites in gardens.

All the species have an acrid principle concentrated in their roots and seeds, which are accordingly emetic and cathartic in moderate doses. They were formerly in great repute as a medicine; and Dioscorides, whose *Placoria* was probably both *P. officinalis* and *P. peregrina*, gives no fewer than sixteen names by which it was known.

PÆONY. [PÆONIA.]

PAGELLUS, a genus of Fishes of the order *Acanthopterygii*, and family *Sparidae*. This genus, established by Cuvier, contains all those sparoid fishes in which the front teeth are small and prickly, and very numerous; the molars are of a round form, and there are sometimes more than two rows of them; but the two outer rows in these cases are always much the largest. The foremost teeth form a dense mass, and are compared by Cuvier to the bristly points of the carding-machine used in combing wool, a character which distinguishes these fishes from those of the genus *Pagrus*, in which the foremost teeth are conical; the molar teeth moreover are smaller than in the last mentioned genus. The body is usually of an elongate-ovate and compressed form, and the dorsal fins are continuous. About six European and five extra-European species of *Pagellus* are known. Two species occur on our own coast, *P. erythrinus*, Cuv. et Val., the Spanish Bream, which is of a fine carmine red-colour above, passing into rose-colour on the sides of the body, and tinted with silvery-white beneath; *P. centrodontus*, Cuv. et Val., the Sea-Bream, is also known by the names of the Gilt-Head and Red Gilt-Head. The former of these two species is very common in the Mediterranean, but occurs rarely off the British coast. Mr. Yarrell states that he has never seen above two or three specimens, and these were taken with the Sea-Bream, which is also common in the Mediterranean, and by no means uncommon on our own coast.

The following is the description of the Sea-Bream given by the author of the 'History of British Fishes.' The jaws are short, and equal in length; the eye is very large, irides golden-yellow; the head short; the line of the profile descends rapidly; cheeks, operculum, and interoperculum covered with scales; the preoperculum and part of the space before and under the orbit have a metallic tin-foil appearance: two narrow stripes are observable on each side behind the head, and these meet on the central line at the top; at the origin of the lateral line, behind the edge of the operculum, is a conspicuous dark patch made up of small spots; the colour of the body is reddish, tinged with gray; lighter on the sides, which are golden-gray, and marked with faint longitudinal bands, which extend the whole length of the body: the belly is nearly white, and the dorsal and anal fins are brown, each appearing as if lodged in a groove from the rising edges of the skin and scales along the base: the pectoral fins and tail are red, and the ventrals are gray.

The Sea-Bream is not highly esteemed for the table. It is found most abundantly in the summer and autumn, and apparently leaves the coast in the cold weather. Mr. Yarrell moreover states that the spawn is shed in the beginning of winter in deep water; and in January the young fish, which are called Chads, of about one inch in length, are found in the stomachs of large fishes taken two or three leagues from land: in summer, when from four to six inches long, they abound in innumerable multitudes, and are taken by anglers in harbours, and from the rocks; for they bite with great eagerness at any bait, even of the flesh of their own species. The food, both of the young and adult fish, is not however confined to animal substance, for they devour the green species of sea-weeds, which they bite from the rocks, and for bruising which their molar teeth are well suited, as are their long and capacious intestines for digesting them.

The Spanish Bream is rather more slender in its form than the commoner British species, the eyes are smaller, and the mouth has a wider gape. The colouring is also different; it has not the dark patch which is observable on each side of the body near the head in the Sea-Bream.

PAGRUS, a genus of Fishes belonging to the family *Sparidae*, with the following characters:—Four or six strong conical teeth in front, supported by smaller conical teeth behind them, with two rows of rounded molar teeth on each side of both jaws. [PAGELLUS.]

P. vulgaris is the Braize or Becker of the English coasts. It is also called Pandora and King of the Sea-Breams. It is not a common fish on our coasts, and is easily known by its conical teeth and red colour.

PAGURIDE, or PAGURIANS, a tribe of the apterous section of the Anomalous family of *Crustacea*, composed of a considerable number of species, the greater part of which are remarkable for the more or less complete softness of the abdomen, the want of symmetry in the appendages of this part of the body, the shortness of the two posterior pairs of feet, and many other characters. In the greater number, the abdomen is small, nearly entirely membranous, and partially rolled upon itself; and for the protection of this defenceless part the animal lodges it in the turbinated shell generally of some gastropod. The crab is retained in the shell by the aid of the posterior feet, and a pair of crustaceous appendages at the end of the abdomen. In some species it is further fixed by means of certain organs on the lower side of the abdomen, to which we shall hereafter allude. The popular

names by which these Crustaceans are known in Britain and the West India Islands are Hermit-Crabs and Soldier-Crabs; and in France they are called Bernards L'Hermites. They are held so firmly in the shell of which they have possessed themselves, that they move about with it more or less briskly according to its comparative size or aptitude.

Organisation.—The carapace is divided into many portions by lines, which are more or less membranous; one of these depressions or furrows separates it transversely into two halves, the anterior of which constitutes the stomachal region, and is very nearly confluent with the hepatic regions, which are very small, and occupy its posterior angles. The last or posterior half is divided longitudinally into three portions; the median portion constitutes the cardiac and intestinal regions, and the two lateral portions form the branchial regions, which last are separated by a similar line from the lateral parts of the carapace, which descend towards the base of the feet. The ophthalmic ring is sometimes hidden above by a rostriform prolongation of the carapace, but is always free, and has above two small prolongations in the form of scales; the ocular peduncles, which are directed forwards, are not retractile, and are inserted directly above the internal antennæ, which present very variable dimensions, but always have the basilar joint either small or elongated, and are fixed by two short or moderate multi-articulate filaments. The external antennæ are inserted on the outside of the internal ones, on the sides of the ocular peduncles; their second joint has above a spiniform piece, which is ordinarily moveable, and seems to be analogous to the palp. The external jaw-feet are pediform. The sternum is nearly linear forwards, and is a little enlarged posteriorly; the last two rings of the thorax are entirely free and moveable, and the last reaches beyond the carapace, and is completed above by a tergal horny piece. The anterior feet are large, and nearly always of unequal dimensions; they are terminated by a large manus, the claws of which are short and very stout. The two succeeding pairs are very large; the fourth pair on the contrary are short, elevated above the others, and nearly always terminated by a didactylous hand; the fifth pair are equally short, elevated on the sides of the body, and terminated by a more or less well-formed pincer. The first five rings of the abdomen are represented by horny plates of greater or less size, the first of which ordinarily is nearly confluent with the last thoracic ring; sometimes this first abdominal segment is in both sexes furnished with a pair of rudimentary appendages applied against the base of the posterior feet; but in general it is without them. In the male the second segment also is sometimes furnished with a pair of false feet, but in general only gives insertion to an appendage placed on the left side; the three succeeding segments are always deprived of appendages on the right side, and sometimes present none on the left in the male; ordinarily they each support a false foot composed of a basilar cylindrical stem and one or two terminal blades; these appendages, which are consequently four in number generally, are always very small in the male and rather large in the female, whose eggs they serve to fix. At the extremity of the abdomen are two horny plates, which represent the sixth and seventh segments, and a pair of appendages, nearly always non-symmetrical, and terminated by two stout and short branches, which are fixed to the plate holding the place of the sixth abdominal ring. (Milne-Edwards.)

Mr. Broderip ('On the Habits and Structure of Paguri,' 'Zool. Journ.,' vol. iv.), points out two beautiful provisions in their animal economy. Their backs are towards the arch of the turbinated shell occupied by them, and their well-armed nippers and first two pair of succeeding feet generally project beyond the mouth of it. The short feet rest upon the polished surface of the columella, and the outer surface of their termination, especially that of the first pair, is in some species most admirably roughshod, to give 'the Soldier' a firm footing when he makes his sortie, or to add to the resistance of the crustaceous holders at the end of his abdomen or tail, when he is attacked and wishes to withdraw into his castle. On passing the finger downwards over the termination of these feet, they feel smooth; but if the finger be passed upwards, the roughness is instantly perceived. The same sort of structure (it is as rough as a file) is to be seen in the smaller caudal holders. The second provision he observed in a very fine and large species of *Pagurus* from the Mauritius. Two specimens were in his possession, one of which is housed in a very large young shell of *Pterocera truncatum*, the other (nearly a foot long) is naked, and on examining the under side of the abdomen or tail of this specimen, a great number of transverse rows of acetabula were to be seen, even without the aid of a glass. Dr. Bright has another naked specimen, in which the same formation, which must very much assist the hold of the *Pagurus*, is visible.

Several dissections of the internal organs of the *Paguri* exist in the Museum of the Royal College of Surgeons.

Modern writers recognise several genera of this family.

The *Pagurus* of Aristotle is not a Hermit-Crab; but he describes three kinds of hermit-crabs under the name *Kaplinov*. They are termed *Kaplinas* by Oppian, Elian, and Galen. Pliny seems to confound them with the Pinnotheres or *Pinnophylax*, as is noticed by Aldrovandus. Rondeletius, Belon, and Gesner describe them, the latter very particularly. Jonstou's account is little beyond a compilation from the authors above named. Charlevoix ('History of Hispaula') says, "that kind which is called a Soldier (Soldat) is,

as well as the Crabs, a species of Crawfish (*Écrevisse*), or of that sort which is called *Canceller Marinus*. It is found all along the sea, and is good to eat. It has its name from being armed all over the body, except at the lower extremity, where it is naked, and where it seems to possess great sensibility; it therefore sheaths itself as soon as it is born in the first shell it meets with; but to dislodge it, it is only necessary to place it near the fire."

Labat mentions the Soldiers among the animals that descend every year to the sea to bathe themselves and change their skin or their shell. The old 'French Encyclopædia' defines Bernard l'Hermite to be *Canceller*, an animal of the Crustaceous genus also called Soldier. After a very particular description, the account proceeds thus:—"There are in the isles of America Hermit-Crabs (Bernards l'Hermite) which are three or four inches in length. They relate that this animal comes once a year to the edge of the sea to lay its eggs and change the shell; for it is obliged to quit the shell in which it is lodged, because, having increased in size during the year, it finds itself incommoded in that shell. It therefore comes to the shore and seeks a new shell which may be convenient for it. As soon as it meets with one it comes out of the old one and tries the new lodging, and, if that suits, it remains there; but it is often obliged to enter many shells before it finds one proportioned to it. If it happens that two hermit-crabs stop before the same shell a dispute arises, and the weakest yields to the strongest." The same author states that it pinches hard and does not let go its hold easily, and that the inhabitants eat it, finding it very good, though it does not agree with strangers. This account appears to have been taken from Du Tertre's 'Voyage.'

Sloane thus describes the Soldier:—"This small lobster or crab differs in very little from the European Souldier or Hermit-Crab. It hath two large forked claws like those of an ordinary lobster, one of which is bigger than the other, both rounded, more tumid, less prickly, and of a paler red than that of Europe, &c. They fit themselves with any shell they find empty, whether it be of the land or sea, and cover themselves almost over in it, carrying it on their backs wherever they go, like a snail. It is not possible to believe how quick the land-crabs and this crab will run upon the least appearance of danger. Till they are turned up nothing appears but a dead shell, the mouth of which lies undermost, out of which some little part of the crab appears after it is taken up." ('Jamaica.') Sloane figures two of these animals (apparently *Cenobita Diogenes*) in Land-Shell (*Helices*); and we saw an individual of the last-named species alive in the shell of a *Helix* at the Gardens of the Zoological Society in Regent's Park.

Catesby, who figures a *Cenobita Diogenes* in the shell of *Turbo Pica*, says—"They crawl very fast with their shell on their back; and at the approach of danger draw themselves within the shell; and, thrusting out the larger claw in a defensive posture, will pinch very hard whatever molests them. They frequent most those parts of the seashores which are covered with trees and shrubs producing various wild fruits, on which they subsist, though I have seen them feed on the fragments of fish and other animal substances cast on shore. They being roasted in the shell are esteemed delicate. I do not remember to have seen any of them go into the sea." ('Carolina.')

Browne notices the Soldier and the Common Soldier, and states that the latter is very common in all the harbours of Jamaica.

Linnaeus says of the *Diogenes* that it inhabits the Asiatic and American oceans in various shells of *Cochlea*.

Cuvier, after mentioning univalve shells as the usual covering of the genus *Pagurus* (Fabr.), remarks that some species lodge themselves in *Scapula*, *Acyonia*, &c.; and we have seen individuals lodged in *Acyonia*. Cuvier also observes that it would even seem that some of the *Paguri* are terrestrial.

Sir Henry De la Beche, in a letter to Mr. Broderip, dated August 1st 1825, says—"When I was in Jamaica, about three years since, some of the persons on my estate at Nine Hall brought me specimens of *Paguri*, which they said they had obtained from a savannah, distant about a quarter of a mile from the house. This savannah is a plain formed of what I have elsewhere termed Savannah Sandstone and conglomerate. It is very dry, and covered for the most part with logwood, green ebony, *Lignum l'iter*, the cashew-tree, and here and there with patches of grass and other plants. After heavy rains the surface of the ground is nearly covered with herbage; but after dry weather a considerable portion of the soil is exposed. The savannah, which is of great extent (my portion consists of at least 2000 acres), is about 30 feet above the Rio Minho, which runs round the border of it, and about 200 feet above the level of the sea, from which it is distant at least 10 miles. The tide only penetrates just within the mouth of the river, and rises there about 11 inches at the height of the springs, so that there is not even brackish water at a nearer point than 10 miles. When the *Paguri* were brought to me they were alive, and I observed they were housed in marine shells, and at first thought they must have been brought from the sea. Upon inquiry however I found that these animals, under the name of Soldiers, were frequently taken alive for food in the savannah, to which I immediately proceeded. On its northern side, and at its junction with the hill that rises above it, I found in the little hollows of the white limestone several of these *Paguri*, all in marine shells, and in full health and activity. I afterwards learnt that they were by no means uncommon in such situations all over the island. When I saw them there had been a good deal of

wet weather. They were in moist places, but there were no pools of water."

Another gentleman, who resided some time in the West Indies, informed Mr. Broderip that he had seen the first-mentioned species (*Diogenes*) about his house when he lived at Port Henderson, and that he had also observed them about the houses at Spanish Town, a place about six miles distant from the sea.

Pagurus (Fabricius).—A great resemblance exists among all the *Paguri*, properly so called, not only in the details of their organisation, but in their habits. The cephalo-thoracic portion of their body is shorter than the abdominal portion. The carapace is nearly as large before as it is behind, and is but little or not at all prolonged laterally above the base of the feet; posteriorly it is strongly notched in the middle, and anteriorly it is either truncated or armed with a single rudimentary rostrum. The basilar portion of the ocular peduncles is exposed. The internal antennæ are placed directly above these peduncles; their first joint is convex and nearly globular; the two next are delicate and cylindrical, and only go a little beyond either the peduncular portion of the external antennæ, or the eyes; the terminal stemlets of these organs are very short, and have the same form as those of the Brachyurous Crustaceans. The external antennæ are inserted on the same line as the ocular peduncles, and have above a stout moveable spine which represents the palp; the last joint of their peduncle is slender and cylindrical, and they are fixed by a multi-articulate filament, which is very long. The external jaw-feet are moderate in size, their stem is pediform, and their palp very much developed. The anterior feet are in general very unequal, and one of the hands very convex. The fourth pair of feet are very short, and their penultimate joint, furnished above with a somewhat oval warty plate, is in general very large, and prolonged above the next joint, so as to constitute with it a didactylous pincer. The fifth pair are longer, more slender, more recurved upwards, present also towards the end a granulous plate, and are terminated by a more or less well-formed didactylous pincer. The abdomen is of considerable size and membranous, the plates of its dorsal surface are nearly symmetrical, but very delicate, and distant from each other. Sometimes there is at the base of the abdomen of the female a pair of rudimentary false feet, and two pairs of appendages more developed in the male; but in general the first segment is without any, and the second, as well as the three succeeding segments, has a single one placed on the left side, and fixed to the border of the dorsal plate. These appendages are always small, and terminated by one, two, or even three ciliated lamellæ upon their edges, which in the female are of considerable dimensions, and serve for the insertion of the eggs. The appendages of the penultimate ring of the abdomen are each composed of a basilar joint, which is short and stout, supporting two other short and hooked pieces, one of which is inserted at its inferior border, the other at its extremity and each furnished with a warty plate similar to that on the posterior feet. These two false caudal feet have not exactly the same form, and are of very unequal size, that of the right side being much smaller than the other. (Milne-Edwards.)

Common Hermit-Crab (*Pagurus Bernardus*).
1, out of the shell; a, right jaw-foot; b, in the shell.

The species are numerous, and are divided by M. Milne-Edwards into the following sections:—

§ Species whose ophthalmic ring is not armed above with a median rostriform piece.

A. Ocular peduncles large, and shorter than the basilar portion of the external antennæ.

a. Spiniform palp of the external antennæ going beyond the extremity of the ocular peduncles.

P. Bernardus, the Common Hermit-Crab, may be taken as an example. It has the following characters:—Hands strongly tuberculo-granulated; terminal joints of the second and third pair of legs spinous on the upper side, slightly tortuous.

It is an inhabitant of the coasts of England, France, and of northern Europe as far as Iceland.

P. striatus. The anterior feet of this species are very large, especially that of the right side. They are covered nearly throughout with transverse lines, which are curved, tubercular, and furnished with small rather thick-set hairs on the upper part of the member; many of the tubercles of these squamiform lines acquire sufficiently large dimensions to become large pointed spines. Colour red mixed with yellow. Length from 7 to rather more than 8 inches.

It is a native of the Mediterranean Sea.

B. Ocular peduncles reaching beyond the basilar portion of the external antennæ.

a. No rostriform prolongation on the anterior border of the carapace.

P. deformis. Ocular peduncles very stout and short, rather longer than the basilar portion of the external antennæ, but much shorter than the anterior border of the carapace; cornea large, and occupying half the length of the terminal joint of the ocular peduncles. Anterior feet short and stout, especially on one side, smooth externally but spiny above; a denticulated crest on the upper border of the larger moveable finger. Succeeding feet smooth, and with but little hair, furnished externally with a projecting crest, which extends over the two first joints, and which, in the third foot, is very much developed and finely denticulated. Nothing similar on the opposite side. Abdomen furnished with four large transverse plates, each with an oviferous false foot, the first three of these are large, and terminated by three elongated and ciliated laminae in the female. In the male all these appendages are small, and terminated by a single lamina. Length 5 inches.

It is a native of the Mauritius and the Seychelles.

Pagurus deformis.

a, one of the crested claws; the under side of which is towards the spectator.

Six other species are arranged by M. Milne-Edwards under this sub-section, besides *P. sanguinolentus* (Quoy and Gaim.), which he believes to be merely a variety of *P. guttatus*, and not to differ from the *P. Hungarus* figured by Herbst, pl. 23, f. 6.

b. Anterior border of the carapace armed on the median line with a more or less projecting rostral tooth.

c. No pairs of appendages on the anterior part of the abdomen.

P. oculatus. Rostriform tooth scarcely developed. Ocular peduncles shorter than the peduncular portion of the internal antennæ, but longer than the anterior border of the carapace, and with their basilar scales small, curved, nearly oval, and approximated.

Found at Noirmoutiers.

Ten other species are arranged under this sub-section, and *P. Chilensis*, one of these, which is nearly allied to *P. clegans*, and inhabits the coast of Chili, is here figured.

Pagurus Chilensis.

c. c. Abdomen, with one or two pairs of appendages under its base.

P. maculatus is an example, and four other species are arranged under this sub-section.

§§ Species having the ophthalmic ring armed above with a moveable rostriform tooth, which advances between the ocular peduncles, and is denticulated on its edges.

P. Miles and two other species are arranged under this sub-section.

In Beale's 'British Stalk-Eyed Crustacea,' six species, besides *P. Bernardus*, are figured as British. There are *P. Prideauxii*, which is often mistaken for *P. Bernardus*, *P. Cuanensis*, *P. Ulidianus*, *P. Hyndmanii*, *P. lavis*, four small species described by W. Thompson, and *P. Forbesii* of Beale.

Cenobita (Latreille).—This genus, in the opinion of M. Milne-Edwards, establishes the passage between the *Paguri*, properly so called, and *Birgus*. The abdomen is conformable with that of *Pagurus*; the antennæ resemble those of *Birgus*; the carapace is equally characteristic, for it is much more solid than it is found in the *Paguri*, is narrowed and compressed forward, and presents in its posterior half a projecting border, which separates its upper surface from the lateral portion, which descends vertically towards the feet.

Under side of carapace, &c. of *Cenobita* (*Cenobita*).

The *Cenobites*, which are all the inhabitants of warm climates, are thus divided by M. Milne-Edwards.

§ Species having the ocular peduncles nearly cylindrical, rounded on the upper border, and terminated by a hemispherical cornea which reaches beyond the prolongation of the peduncular joint received into the notch of its upper border.

C. Diogenes. Stomachal region hardly convex. Ocular peduncles only of the length of the anterior border of the carapace, and nearly triangular; their basilar scale moderate and oval; tarsi very short; a trenchant and very projecting crest on the lower edge of the two last joints of the third left foot. Length about three inches; colour, especially of the large claw, red or violaceous.

It is a native of the Antilles.

Only one other species is placed by M. Milne-Edwards under this section.

Cenobita Diogenes.

a, partially out of shell, showing the arrangement and structure of the antennae, carapace, feet, &c. Among these last, what may be called the roughshod pair (the fourth) are well displayed; *b*, large claw, external view. (Milne-Edwards).

c, Cenobite in shell (*Turbo Pica*), showing the disposition of the first pairs of feet when the animal has retired as far as it can, and the large claw acting as a kind of operculum to protect the aperture.

Species whose ocular peduncles are very much compressed, terminated above by a rather sharp border, and supporting a nearly triangular cornea, which does not sensibly reach beyond the prolongation of the peduncular joint received into the notch of its upper border.

C. rugosa. Stomachal region nearly flat; labial border of the branchial regions very projecting, and slightly curved. Ocular peduncles nearly twice as long as they are high; their basilar scale moderate and pointed. Feet granulous and slightly muricated; the great claw moderate, and furnished above with a row of small, oblique, and parallel crests. Tarsi short and triangular. Upper and external edges of the two last joints of the third left foot elevated into an obtuse crest. Length about 3 inches. It is found in the Indian Ocean.

There are three other species.

Cancellus (Edwards).—This small generic division is but little distant from the *Paguri* properly so called, and is not as yet more than imperfectly known to him, for he had not examined the female of the only species, but the peculiarities offered by the organization of the male prevent him from referring the form to any genus already established. The abdomen, instead of being rolled upon itself and terminating in a sort of shapeless tail, is perfectly symmetrical; the appendages of the penultimate abdominal ring have the same form as in the *Paguri*, but are similar on each side, and there is no other appendage adhering to the abdomen between this segment and the thorax.

C. Typus is the only known species.

Birgus.—This genus, according to M. Milne-Edwards, appears to establish the passage between the *Paguri* (or rather the *Cenobites*) and the *Lithodes*. [HOMOLINÆ.] Their carapace, terminated anteriorly by a horizontal and projecting rostrum, is divided into two portions, as in the *Cenobites*; the anterior portion formed by the stomachal region is narrow, but the posterior portion is very large and oval, the branchial regions being very much developed, and forming on each side a sort of semicircular buckler, which advances above the base of the feet. The ocular peduncles are stout, rounded, and of moderate length. The internal antennae have the same conformation as in the

Cancellus Typus.

Cenobites, except that their basilar joint is still more elongated. The disposition of the external antennae and of the external jaw-feet is also entirely the same as in the last-named Pagurians. The anterior feet are stout, rounded, and of moderate length; the two succeeding pair are terminated by a stout cylindrical joint; and the fourth pair, which are shorter than the preceding, but not elevated above them, are provided with a cheliform hand, the two fingers of which are long and cylindrical; the posterior feet, which are very short and cylindrical, are elevated under the lateral parts of the carapace, and terminated by a very obtuse rudimentary pincer. The abdomen is very large, and covered above by a small horny band, followed by four great corneocalcareous plates, which occupy its whole width, and over-ride each other, as in the Macrurus Crustaceans. On each side of these great segments are to be seen one or two horny pieces, which seem to be the representation of the epimerian piece of the four corresponding abdominal rings. In the female the first three of these segments, that is to say, the second, third, and fourth rings, have on each side a great false foot formed by a small basilar piece and two great narrow and ciliated appendages; those members are wanting on the right side, and in the male no trace of them is perceptible. The whole of the inferior surface of the abdomen is membranous, except that, towards its posterior part, may be seen a small quadrilateral plate, which gives attachment to a second projecting plate, and has on each side an abdominal rudimentary false foot, composed of a basilar piece and two moveable tubercles, which recall the disposition of the appendages of the sixth abdominal ring of the *Paguri*, but which is symmetrical on both sides of the body. The terminal plate is rounded at the end, covers the anus, and represents the seventh abdominal ring.

The respiratory apparatus in *Birgus* presents very remarkable peculiarities of structure. The branchiae are 14 in number on each side of the body, and are fixed by a peduncle situated towards the middle of their internal surface. The respiratory cavity is very large, and the branchiae only fill the tenth part of it; its vault is carpeted below by a delicate and epidermic membrane; but this soon disappears and leaves naked the skin, which is continued with that membrane, and covered by a multitude of vascular vegetations. [BIRGUS.]

PAGURUS. [PAGURIDÆ.]

PAIGLE. [PRIMULA.]

PALÆOMYS, Kaup, an extinct genus of Rodents from the Eppelsheim Sand.

PALÆONISCUS, a remarkable genus of Heterocerac Fossil Fishes, constituted by M. Agassiz, and included by him in the first family (*Lepidostei*) of his great order of Ganoidean Fishes. Its place in this family will appear from the following synopsis of the *Lepidostei* :—

A. Body elongated, fusiform, upper lobe of the tail vertebrated, and longer than the lower lobe.

Acanthodes; *Catopterus*; *Amblypterus*; *Palæoniscus*; *Ostolepis*.

B. Body flat, broad.

1. Upper lobe of the tail vertebrated.

Platysomus; *Gyrolepis*.

2. Tail regular (the lobes nearly equal).

Tetragonolepis; *Dapedius*.

C. Body elongated, fusiform, tail forked or rounded.

Semionotus; *Lepidotus*; *Pholidophorus*; *Microps*; *Notagodus*.

The generic character of *Palæoniscus* is thus given:—

All the fins of moderate size, with small rays on their edges; the dorsal fin opposite the interval of the ventral and anal fins. Scales moderate. In some species the scales are large, and the body is broader and shorter than in the others; there are always large mesial scales in front of the dorsal and anal fins.

The genus comprehends *Palæoniscum* and *Palæothrissum* of De Blainville.

The geological interest of this genus is considerable, inasmuch as the numerous species appear to be very definitely distributed in the strata of the Carboniferous and Saliferous Systems of Europe and America. The following is the series of species examined by Agassiz, with their localities, and the names of the formations in which they occur:—

- | | | |
|------------------------------|-----------------------------------|--|
| 1. <i>Palæoniscus fultus</i> | Coal Formation | Sunderland, Massachussetts; Westwick, Connecticut. |
| 2. <i>P. Duxerney</i> | Coal Formation | Munster Appel. |
| 3. <i>P. minutus</i> | Coal Formation | Munster Appel. |
| 4. <i>P. Blainvillii</i> | Coal Formation | Near Autun. |
| 5. <i>P. Voltzii</i> | Coal Formation | Near Autun. |
| 6. <i>P. angustus</i> | Coal Formation | Munster Appel. |
| 7. <i>P. Vratislavensis</i> | Rotheliegende | Ruppersdorf in Bohemia. |
| 8. <i>P. lepidurus</i> | Rotheliegende | Scharfeneck in Co. Glatz. |
| 9. <i>P. Freieslebeni</i> | Zechstein | Mansfield, Hesse, Eisleben, &c. |
| 10. <i>P. magnus</i> | Zechstein | Mansfield. |
| 11. <i>P. macropomus</i> | Zechstein | Mansfield. |
| 12. <i>P. elegans</i> | Lower part of Magnesian Limestone | East Thickley in Durham. |
| 13. <i>P. Robisoni</i> | Carboniferous Limestone | Burdiehouse, near Edinburgh. |
| 14. <i>P. striolatus</i> | Carboniferous Limestone | Burdiehouse. |
| 15. <i>P. ornatisimus</i> | Carboniferous Limestone | Burntisland, Fifesh. |
| 16. <i>P. comtus</i> | Magnesian Limestone | Durham. |
| 17. <i>P. glaphyrus</i> | Magnesian Limestone | Durham. |
| 18. <i>P. macrophthalmus</i> | Magnesian Limestone | Durham. |
| 19. <i>P. longissimus</i> | Magnesian Limestone | Durham. |
| 20. <i>P. carinatus</i> | Carboniferous Series | Newhaven, near Edinburgh. |

The researches of Agassiz have given a simple and beautiful generalisation of the distribution of these species; the scales of the *Palæonisci*, which abound in the Coal Formation, are almost universally smooth; those of the species which belong to the Magnesian Limestone are almost universally striated or sculptured. We find a few exceptions to this rule, as at Burdiehouse, and at Ardwick near Manchester, but it rests on a considerable number of coincidences. It is an unexpected result of Agassiz's critical inquiry into the forms of fossil fishes, that the *Palæonisci* of the English Magnesian Limestone are not identical with those of the Zechstein of Germany, notwithstanding the supposed contemporaneity of the rocks.

PALÆORNIS. [PSITTACIDÆ.]

PELÆOSAURUS, the name given by Dr. Riley and Mr. Samuel Stutchbury to a genus of fossil Saurians discovered in the magnesian conglomerate on Durdham Down, near Bristol (1834).

The conglomerate wherein the Saurian remains were found rests upon the edge of inclined strata of mountain limestone, filling up the irregularities of their surface, and consists of angular fragments of the limestone cemented by a dolomitic paste. The thickness of the deposit where the remains were discovered does not exceed twenty feet.

Three animals were found, two belonging to the genus *Palæosaurus*, and the other to a genus named by them *Thecodontosaurus*. [THECODONTOSAURUS.]

The following is the generic character of the *Palæosaurus*:—Teeth carinated laterally, and finely serrated at right angles to the axis, differing from those of all the known Saurians.

The two species are *P. cylindricus* and *P. Platyodon*.

PALÆOTHERIUM, Cuvier's name for an extinct genus of Pachydermatous *Herbivora* discovered in the Gypsum Beds at Paris in company with *Anoplotherium*. [ANOPLOTHERIUM.] The following are the generic character of *Palæotherium*:—

Dental Formula:—Incisors, $\frac{6}{6}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{7-7}{7-7} = 44$.

Three toes on each foot. A short fleshy proboscis, for the attachment of the muscles of which the bones of the nose were shortened, leaving below them a deep notch.

The molar teeth bear a considerable resemblance to those of the Rhinoceros; in the structure of that part of the skull destined to support the short proboscis and the feet, the animal closely approached the Tapirs.

The species are numerous, and the following have been named:—*P. magnum* (Gypsum of Montmartre), *P. medium* (Gypsum of Mont-

martre, Osseous Breccia, Sète, &c.), *P. crassum*, *P. latum*, *P. curtum*, *P. minus*, *P. minimum*, *P. indeterminatum* (Gypsum of Montmartre), *P. Aurelianense* (Lacustrine Formation of Orleans, Argenton, &c.), *P. Isselanum* (Tertiary, Issel), *P. Velaunum* (Tertiary, Puyen-Velay).

Skull of *Palæotherium magnum*. (Cuvier.)

Molar teeth of upper jaw of the same, seen from above. (Cuvier.)

External view of part of the lower jaw of the same. (Cuvier.)

Remains of *Palæotheria* have also been found in the Tertiary Formation near Rome, in the department of the Gironde, Provence, &c.

Mr. S. P. Pratt discovered, in the lower and marly beds of the quarries of Binstead in the Isle of Wight, which belong to the lower Fresh-Water Formation, a tooth of an *Anoplotherium* and two teeth of the genus *Palæotherium*, animals characteristic of strata of the same age in the Paris basin. The remains found by Mr. Pratt were accompanied not only by several other fragments of the bones of Pachyderms (chiefly in a rolled and injured state), but also, in his opinion, by the jaw of a new species of Ruminants, apparently closely allied to the genus *Moschus*. From the occurrence of the latter fossil, Mr. Pratt infers that a race of animals existed at this geological epoch whose habits required that the surface of the earth should have been in a very different state from that which it has been supposed to have presented, in consequence of the frequent discovery of the remains of animals which lived almost entirely in marshes. ('Geol. Proc.' 1830.)

In his work on 'British Fossil Mammals and Birds,' Professor Owen describes four species of *Palæotherium* from the Tertiary Beds of Great Britain. They are *P. magnum*, *P. medium*, *P. crassum*, and *P. minus*.

The geological place of the extinct genus *Palæotherium* is in the first great Fresh-Water Formation of the Eocene Period of Lyell, where it is found with its congeners, of which nearly 50 extinct species were discovered by Cuvier.

The zoological position of the genus appears to be intermediate between the Rhinoceros, Horse, and Tapir. Their habits probably approximated to those of the Tapirs. Dr. Buckland supposes that these animals lived and died upon the margins of the then existing lakes and rivers. He is also of opinion that their dead carcasses may have been drifted to the bottom in seasons of flood, and that some perhaps retired into the water to die. The species varied greatly in size, some having been as large as a rhinoceros, and others having ranged from the size of a horse to that of a hog.

We subjoin illustrations which will give an idea of the relative size of two of the British species. The skull of *P. magnum* is the size of that of a large horse; that of *P. minus* is not bigger than the skull of a roe.

a, restored skeleton of *Palæotherium magnum*; b, restored skeleton of *Palæotherium minus*; c, restored outline of *Palæotherium magnum*; d, restored outline of *Palæotherium minus*. (Cuvier.)

PALÆOZAMIA, a genus of Fossil Cycadeous Plants, from the Oolitic and Lias Deposits of Yorkshire, Dorsetshire, and Oxfordshire.

PALÆOZOIC EPOCH, or SERIES, is a term applied to the Lower Secondary Rocks of the earth. These rocks are now generally divided into two series—the Newer Palæozoic and Older Palæozoic Rocks. The Newer include the Permian, Carboniferous, and Devonian Systems; the Older, the Upper Silurian, Lower Silurian, and Cambrian. [GEOLOGY; ORGANIC REMAINS.]

PALAMEDEA. [CARIAMA.]

PALAMEDEA (Linn.), a genus of Birds placed by Mr. Vigors among the *Grallatores*, with its congeners *Parra*, *Chauna*, *Rallus*, and *Fulica*, in the family *Rallidae*. The same author thinks that with *Parra* may be allied *Palamedea* (Linn.) and *Chauna* (Ill.)—the *Parra chavaria* of the 'Systema Naturæ'—both of which seem to approach *Parra* in affinity, although the latter of them is so imperfectly known that its situation cannot be decided with certainty. ('Linu. Trans.,' vol. xiv.)

It has the following generic characters:—Bill shorter than the head, covered at the base with small feathers, conico-convex, slightly vaulted, hooked at the point; forehead armed with a cylindrical horn, which is pointed; nostrils oval, open. Wings spurred, third and fourth quills longest. Anterior toes united at the base by a membrane; hallux touching the ground at the end.

Head of *Palamedea* (Swainson). From the specimen in the British Museum.

P. cornuta, the Kamiehi, or Horned Screamer. It is larger than a common goose; greenish-brown above, except on the middle of the neck, which is variegated with black and white, and a large cinnamon-coloured spot on the shoulders; abdomen whitish. A long spear-shaped horn projects from the forehead. Wings long and pointed; tail wide and square. Tarsi slender and reticulated, as well as the toes, which are long and almost entirely free; claw of the hallux nearly straight and very sharp; two spurs implanted on the edge of the wing.

It is the Anhiwa of the Brazilians, and, according to Cuvier, the Camouch of the people of Cayenne; but M. Lesson thinks that it is the Kotacea of Barrère.

This extraordinary bird lives in the marshy or inundated places in South America (Guiana and Brazil), which it makes resound with its wild and loud cry. Its food consists of grains and aquatic herbs, as its muscular stomach would indicate, though there are not wanting those who state that it hunts reptiles. It pairs, and lives faithfully with its mate.

Horned Screamer (*Palamedea cornuta*).

Chauna, a closely allied genus, has the bill shorter than the head, clothed with small plumes at the base, conico-convex, slightly vaulted, curved at the point; head unarmed; lore naked. Wings spurred. External toes united at the base by a membrane; hallux touching the ground at the end; posterior and intermediate claws nearly straight. Tail graduated.

C. Chavaria has no horn; occiput ornamented with a circle of

feathers capable of elevation; head and upper part of the neck downy; a black collar; the rest of the plumage lead-colour and blackish, with a white spot on the bend of the wing and another on the base of some of the greater quills; hardly any part of the leg naked. Length of adult, 32 inches.

This is the Chaïa or Chaja of the people of Paraguay.

Chaïa (*Chauna Chaararia*).

D'Azara has given us many interesting particulars relating to this bird. Its sharp clarion-like cry is exerted not only during the day, but also in the night, if it hears any noise. The note of the male is expressed by the word Chaja, and that of the female (for they answer each other) by the word Chajali. They are seen sometimes singly, sometimes in pairs, and at other times in numerous flocks. They principally, indeed ordinarily, frequent marshes, and if they are at any time found on the banks of rivers, it is in places where the water is low and runs sluggishly. They do not swim, but enter the water like Herons, but not, like them, in search of fish or frogs, but for the leaves and seeds of aquatic plants on which they live.

D'Azara saw some brought up among the domestic poultry at country-houses, and they were as tame as fowls. Those who kept them told him that the Chaïa ate bits of raw meat, but he saw them picking the grass. They perch on the tops of the highest trees. On the ground they walk with gravity. Some state that the nests are spacious, and formed of small branches on bushes surrounded with water, and others that the bird places it in the rushes in the midst of the water. The eggs are laid in the beginning of August, and the young, which are two in number, follow their parents, though they are only clothed with down.

The Indians of Carthagea rear them among their geese and other poultry, under the idea that they will act as a guard, for the Chaïa is very courageous and will drive away a vulture. D'Azara says that both this bird and the Kamichi are provided with a cottony down at the base of the feathers like swansdown; that the plumage of the neck is a little loose and inclining to downy; and that the skin of the neck is separated from the flesh by an interval of a line and a half, which is filled with cellular integuments, into which the air is introduced. The down at the base of the plumage is evidently calculated to keep up the proper temperature of the bird in its marshy home, and to repel the water when it wades so deep as to immerse the plumage.

It is a native of Paragay, on both banks of the Rio de la Plata, and in Brazil, far from human habitations.

This genus *Chauna* was established by Illiger for the purpose of separating from the Kamichi, the *Parra Chaararia* of Linneus, the Chaïa of D'Azara. Cuvier, as we have seen, did not separate it from *Palamedea*, and M. Temminck, in his 'Analysis,' in mentioning the genus *Chaararia*, expresses his opinion that the Chaïa ought not to form more than a species of Kamichi. The same author has subsequently, in his 'Planches Colorées,' placed it with that genus. Mr. Swainson arranges it as a species of *Palamedea* under the name of *Palamedea cristata*. The general opinion seems to be that the bird should be considered as a species of the genus *Palamedea*, and that the genus *Chauna* should be obliterated.

PALAMEDEIDÆ. [PALAMEDEA.]

PALARUS. [LARRIDÆ.]

PALATE is the partition which separates the cavity of the mouth from that of the nose, forming the roof of the one and the floor of the other. In man it is composed of two portions, which are called respectively the hard and the soft palate: the former is made up of the inferior or palatine processes of each superior maxillary bone and palate bone, which, meeting in the middle line of the body, form a somewhat flattened arch over the mouth; the latter consists of a membranous curtain of muscular and cellular tissue, of which one margin is attached to the posterior border of the hard palate, and the other, with the uvula appended to its middle, hangs loosely backwards into the cavity of the pharynx. Both the hard and the soft palate are covered by a thin layer of vascular mucous membrane, immediately beneath which there are numerous minute glands. On each side, the soft palate is continued downwards in two diverging and arched membranous folds (the arches of the palate), which form the lateral boundaries of the fauces, and between which on each side the tonsil lies. Beneath these folds are muscles passing from the soft palate to the sides of the tongue and pharynx.

The hard palate serves as a firm support against which the food may be pressed by the back of the tongue during mastication; and it is by the various actions of the tongue upon it that we articulate several letters, as *d, g, j, k, q, &c.* The soft palate is capable of such motions by the contractions of its muscles, that it can either be raised so as to close the passage from the pharynx to the nose and Eustachian tube, or be depressed so as (with the assistance of the tongue) to close the passage from the pharynx to the mouth, or even to close both those apertures. By a simultaneous descent of the soft palate and contraction of the lateral arches by which it is connected with the tongue, the food when forced to the back part of the latter organ is impelled into the pharynx, constituting the first part of the act of swallowing. The soft palate is also of great importance in the actions by which substances are expelled from the digestive and respiratory organs through the mouth or nose, directing their passage, according to circumstances, into one or other of those cavities, as in coughing, sneezing, vomiting, &c.

PALEA. [CALATHIDIUM.]

PALECHINUS, a genus of Fossil Echinodermata.

PALEMON. [PALEMONIDÆ.]

PALEMONIDÆ, a family or tribe of Macrurous Decapodous Crustacea. They belong to Milne-Edwards's family of *Salicoides*, or Shrimps, and his tribe Palemoniana. The characters of this tribe are as follows:—Body laterally compressed, but the abdomen never sharp. Thorax large, carapace armed in front with a great sabre-like rostrum, nearly always dentated above. Antennæ placed as in the preceding tribe, but longer, and the first pair often with three terminal filaments. All the feet are slender, and the first two pairs are generally didactylous, whilst the last three pairs are never didactylous. The abdomen is of great size. (Milne-Edwards.)

The genera are, *Gnathophyllum*; *Hippolyte*; *Rhynchocinetes*, *Pandalus*; *Lysemata*; and *Palemon*.

Gnathophyllum (Latreille; *Drino*, Risso).—Rostrum short but compressed, lamellar, and dentilated on its superior edge. Upper antennæ terminated by very short filaments, and blade of the lower antennæ rather large and oval. The external jaw-feet are foliaceous. First two pairs of feet moderate and terminated by a didactylous hand; the last three pairs monodactylous, of moderate length, and terminated by a small dentated tarsus. Abdomen presenting nothing remarkable. (Milne-Edwards.)

G. elegans has the carapace convex, rostrum oblique, and armed above with from six to seven teeth; second pair of feet rather longer and stouter than the first pair; terminal blades of the abdomen oval. Length about 20 lines. It is found at Nice.

Hippolyte (Leach).—General form of the body resembling that of *Palemon*, but their abdomen is incapable of being completely straightened, and appears, in some degree, to be humped; rostrum very large, compressed, and nearly always strongly dentated; internal antennæ small, and terminated only by two multi-articulate filaments nearly of equal length, one of which is very large and strongly ciliated; external antennæ inserted under the preceding, and presenting nothing remarkable; external jaw-feet slender and elongated. Feet formed nearly in the same manner as those of *Lysemata*, only that they offer no appendage at their base; the first pair are short, but rather stout; the second are filiform, terminated by an extremely small didactylous hand, and have a multi-articulate carpus; the last three pairs of feet are rather long, and in general very spiny at the end; the terminal plates of the natatory false-feet are lanceolate, dentilated on their edges, and ciliated all round. Branchiæ 7 on each side. (M.-Edwards.)

The species, which are rather numerous, and all small in size, are divided by M. Milne-Edwards into the following sections:—

1. Species whose rostrum springs from the front and is not continued backwards, with an elevated crest occupying the median line of the carapace.

H. varians. Rostrum passing beyond the peduncle of the internal antennæ, straight, slender, and armed with two teeth above—one situated at its base, and the other near its extremity—and two below,

situated a little behind the last superior tooth; a small spine on each side of the base of the rostrum, above the insertion of the eyes; first joint of the internal antennæ armed externally with a spine of moderate size; lamellar appendages of the external antennæ large, passing a little beyond the rostrum, and oval, or rather truncated obliquely from within outwards, and from before backwards at their extremity. Length 4 or 5 lines. It is found in the British Channel and the coasts of La Vendée. (Milne-Edwards.)

2. Species whose rostrum forms an elevated crest on the anterior part of the stomacal region, but is not prolonged on the posterior part of the carapace.

H. crassicornis has the carapace rounded above; rostrum very small, rather elevated at its base, but taking its origin close to the insertion of the eyes, and not reaching to the extremity of those organs; inflected at first, then straight, bifid at the end, and armed above with two or three dentations; eyes very large; internal antennæ remarkably stout, their basilar joint dilated and lamellar below. Length 4 lines. It is found at St. Malo. (Milne-Edwards.)

3. Species the base of whose rostrum is elevated into a crest and prolonged to the posterior edge of the carapace.

H. gibberosa. Rostrum taking its origin from the posterior third of the carapace, very much bent and armed with four or five teeth at its base, then curving strongly upwards, and only presenting one small spine towards the level of the extremity of the eyes, and two or three dentations at its point; its lower border descending very low at its base and armed with six or seven teeth, the posterior of which are very strong; lateral spine of the internal antennæ very large; lamellar appendage of the external antennæ nearly triangular. Length about 15 lines. It is found on the coasts of Australia. (Milne-Edwards.)

The other British species of *Hippolyte* are *H. spinus*, *H. Cranchii*, *H. Thompsonii*, *H. Prideauxiana*, and *H. pandaliformis*.

Rhynchocinetes (Edwards).—M. Milne-Edwards observes that this genus is closely approximated to *Hippolyte*, but that it is distinguished from all the other macrurous crustaceans by the singular conformation of the rostrum, which, instead of being a simple prolongation from the front, is a distinct lamina of the carapace, and articulated with the front so as to be very moveable, and to possess the power of lowering itself above the antennæ, or of elevating itself vertically; in other respects it much resembles the rostrum of *Hippolyte*. It is very large, sabre-shaped, and denticulated on both edges.

R. Typus. Front armed with three spines, of which the median, placed above the base of the rostrum, is followed by another median spine; rostrum very large, longer than the lamina of the external antennæ, armed above with two spines situated near the base, and with seven or eight dentations situated at its extremity; its inferior border furnished with a score of very large teeth. Length about 2½ inches.

It is a native of the Indian Ocean. (Milne-Edwards.)

Pandalus (Leach).—Closely resembling *Palemon* in the general form of the body, but distinguished from that genus by the conformation of the feet, of which the two anterior are monodactylous. Carapace armed in front with a very long compressed rostrum, which is elevated towards the end, and denticulated both above and below. Eyes large, short, and free. Upper antennæ formed nearly like those of *Palemon*, excepting that they possess only two terminal filaments; external jaw-feet slender and pediform. Feet slender; the first pair shortest, and terminated by a styliform joint; the second pair filiform, and terminated by a very small didactylous hand; their carpus multi-articulate; succeeding feet presenting nothing remarkable. Disposition of the abdomen the same as in *Palemon*. Number of branchiæ, twelve on each side of the body. (Milne-Edwards.)

P. annulicornis. Rostrum of the length of the carapace, armed above with some ten teeth, which occupy the stomacal region and the posterior half of its fore part; a small tooth near the point of the rostrum, separated from the preceding by a rather long smooth space; interior border of the rostrum armed with from seven to eight very large teeth towards its base, and the last of which are placed towards the extremity. Length of the body about two inches.

It is found on the coasts of England and Iceland. (Milne-Edwards.)

Lyngata (Linné).—Resembling very much the *Palemons*, and establishing the passage between them and *Hippolyte*; they have their general form, and their carapace is equally armed with a long, compressed, and denticulated rostrum. Internal antennæ terminating also in three multi-articulate filaments, two of which are long and one very short; the external antennæ are inserted under the first, and present nothing remarkable. The mandibles are deprived of a palpiform appendage.

L. edicordata. Rostrum taking its origin towards the middle of the carapace, a little inflected towards the end, not attaining the extremity of the peduncle of the internal antennæ, and armed with six teeth above and two below; two of the filaments of the superior antennæ as long as the body. Length about two inches. Colour reddish-brown, striped longitudinally with white.

It inhabits the Mediterranean. (Milne-Edwards.)

Palemon (Fabr.).—Body compressed but little, and generally rounded above. Carapace moderate in size, and presenting towards its anterior third a median crest, which is the origin of the rostrum; this last advances above the base of the eyes and antennæ, and pre-

sents nearly always a considerable length; it is very much curved upwards towards the end, and strongly denticulated on its upper and lower borders. Eyes large and projecting. Internal antennæ inserted above the external ones; the first joint of their peduncle very large, depressed, excavated upon its upper surface for the lodgment of the eyes, and armed externally with a strong spine, which occupies its anterior angle; the two succeeding peduncular joints stout and cylindrical. The multi-articulate filaments which terminate these organs are three, two of which are in general extremely long, and one very short and joined by its base to one of the preceding. The external antennæ are inserted below, and rather external to the internal antennæ; the lamellar palp which covers their base is very large, oval, rounded, and ciliated at the end, and armed with a spine at its external border. The mandibles carry a small cylindrical palpiform appendage, and the external jaw-feet are of moderate length, slender, sometimes unguiculated at the end, and sometimes terminated by a small multi-articulate appendage. First pair of feet slender, terminated by a small didactylous hand, and presenting near their base, on the internal side, a small dilatation, which covers the mouth, and acts after the manner of jaw-feet; second pair of feet much longer and stronger, terminated also by a well-formed didactylous hand, and with the carpus entire and formed in the ordinary manner; three succeeding pairs slender and monodactylous, their length diminishing progressively, and without any vestige at their base of flagrum or palp. Abdomen very large, and narrowing gradually towards the end; its upper surface regularly arched, but capable of becoming nearly completely straight, without any hump as in *Hippolyte*. The seventh segment, which forms the median piece of the caudal fin, is triangular and shorter than the lateral blades; it is generally armed with some spines at its extremity, and there are on the upper surface five small spines, the anterior of which is situated on the median line, and the others laterally. The lateral blades of the caudal fin are very large, oval, and nearly of equal size. The abdominal false feet are very large; the first pair carry a large ciliated blade and a second smaller one; the others are provided with two ciliated blades, nearly of the same size, of which the internal one carries towards its base a small cylindrical appendage. (Milne-Edwards.)

M. Milne-Edwards remarks that the nervous system of the *Palemons* presents a much greater concentration than that of the Crawfishes (*Écrevisses*); for all the thoracic ganglions are approximated so that they nearly touch each other. The branchiæ, he observes, are eight in number on each side of the body.

The species of this useful and delicious genus are numerous. M. Milne-Edwards records seventeen, besides the Indian *Palemon brevis* and *P. Coromandelinus* of Fabricius. Those of our own coasts are well known to the epicure; and some of the species which are found in warm climates attain to a considerable size: such are the *P. Carcinus* of the Indian seas and the Ganges, which attains to nearly a foot in length, and the *P. Jamaicensis* of the Antilles, which is from 10 to 12 inches long.

The prawns generally inhabit sandy bottoms near the coasts, but some are found at the mouths of rivers, and far up. They mostly boil red.

M. Milne-Edwards subdivides the species into the following sections:

1. Species having the anterior border of the carapace armed on each side with two spines, situated one above and the other below the insertion of the external antennæ.

P. serratus. Rostrum reaching much beyond the lamellar appendage of the external antennæ; very much elevated towards the end, and bifid at its extremity; its superior border smooth for nearly its anterior half, and armed on the rest of its extent with from seven to eight teeth; the crest which occupies its inferior border very wide at its posterior extremity, and armed with five or six teeth. The small terminal filament of the superior antennæ very short, not attaining the extremity of the rostrum when it is directed forwards, nor the anterior border of the carapace when it is directed backwards. Length from 3 to 4 inches. Colour grayish with small red and brown spots.

It abounds on the coasts of France and England.

This is the *Astacus serratus* of Pennant; *Cancer Squilla* of Herbst; the Prawn of the shops.

There are two other *Prawns* which inhabit our coasts: one, the *Palemon Squilla* and *Astacus Squilla* of Fabricius, with a much shorter rostrum, not reaching beyond the lamellar appendage of the external antennæ, nearly straight, and denticulated to the top, and about 20 lines long altogether; the other, *Palemon varians*, with a very short rostrum armed with from four to six teeth above, and only two or three below, and about one half the size of the last.

2. Species having the anterior border of the carapace armed on each side with a single spine.

- A. A second spine situated behind the preceding, nearly on the same horizontal line.

- A*. Prehensile borders of the pincers nearly straight, and touching each other throughout their length.

P. Carcinus, which inhabits the Indian seas and the Ganges, is an example.

- A**. Prehensile borders of the pincers concave, so as to leave a space between them.

P. spinimanus, which inhabits the Antilles and the coast of Brazil, is an example.

*Palemon serratus.*

44. No second spine situated at the base or behind that with which the anterior border of the carapace is armed on each side.

P. Gaudichaudi, a native of Chili, is an example.

The other tribes of Milne-Edwards's Salicoques are the Alpheans and Penæans (*Alpheidae* and *Penæidae*).

Alpheidae.—The shrimps comprised by M. Milne-Edwards under this tribe are stouter in their forms than those of the preceding division, but they are not depressed as the Crangons are. [CRANGONIDÆ.] The rostrum is very short, and has never the form of a great projecting central blade, as in the Palemonians. The internal antennæ are placed above the external antennæ, and are, in general, very short. One pair of feet is very stout, and generally terminated by a powerful didactylous hand. The two anterior pairs of feet are nearly always didactylous, but the third pair never are; the three last pairs are rather robust, and serve for walking as well as for swimming.

The genera are *Atya*, *Hymenocera*, *Alpheus*, *Pontonia*, *Autonomea*, *Caridina*, *Nika*, and *Athanas*.

Atya (Leach). [ATYA.]

Hymenocera (Latr.). [HYMENOCERA.]

Alpheus (Fabr.).—Carapace advanced above the eyes, forming above each of those organs a small vaulted buckler. Rostrum very small, and sometimes wanting. In other respects the carapace presents nothing particular. The superior antennæ are small, their first joint short, and armed externally with a lamina, which is ordinarily spiniform; the two next joints are cylindrical; and of the terminal filaments, two in number, the upper one is stouter and shorter than the lower, and presents traces of a division near the end. The inferior antennæ are inserted externally to and below the preceding: the lamellar palp is of moderate size, or even sometimes small and pointed, and their terminal filament presents nothing particular excepting that it is often somewhat compressed. The mandibles are provided with a short palpiiform appendage, which is wide and flattened.

They are found in the seas of warm climates. Some species are found in the Mediterranean, but the greater part in the seas of the Antilles or in the Indian Ocean.

M. Milne-Edwards separates the Alpheans into the following sections and subdivisions:—

1. Species with a pointed rostrum.

A. No spine at the outside of the basilar joint of the external antennæ.

Ex. *A. ruber*, from the Mediterranean. (Milne-Edwards.)

B. A great spine fixed on the external border of the basilar joint of the external antennæ, and directed forwards.

Ex. *A. villosus*, from the seas of Australia.

2. Species deprived of a spiniform rostrum.

Ex. *A. frontalis*, from the coasts of Australia.

M. Milne-Edwards records twelve species of *Alpheus*.

Pontonia (Latr.).—Carapace short and convex: the front with a

short but robust and inflected rostrum; the eyes are cylindrical, projecting, and very moveable. The internal antennæ are very short, and formed very nearly like those of the Palemons or Prawns; the first joint of their pedicle is very wide and lamellar externally; the two succeeding joints are small and cylindrical. The terminal filaments, two in number, are very short, and the one between them is bifid at the extremity. The external antennæ are inserted above and external to the preceding; their lamellar appendage is large and oval.

M. Milne-Edwards divides the *Pontonia* into the following sections:—

1. Species with the rostrum very large and depressed, and the external antennæ inserted nearly on the same line as the superior antennæ.

Ex. *P. macrophthalmia*, from Asiatic seas, where it was found by M. Dussumier.

2. Species with the narrow rostrum very much compressed laterally, and inflected towards the point; the external antennæ inserted entirely below the superior antennæ.

Ex. *P. armata*, from New Ireland, where it was found by Messrs Quoy and Gaimard.

Autonomea (Risso).—Antennæ intermediate or superior, terminated by two filaments, one of which is much longer and thicker than the other; external or inferior antennæ longer than the body, and setaceous. Peduncles of the first inarticulate, having their lower portion convex and armed with a spine, the intermediate long and cylindrical, and the last short and bent. Those of the second bi-articulate, without scales, their second portion being hairy at its extremity.

Ex. *A. Olivii*. It occurs in the Adriatic Sea, and rather rarely at the environs of Nice, where it lives solitary in the sea-weed and muddy places; the female carries her reddish eggs about the middle of the summer. (Desm.)

Caridina (Milne-Edwards).—Carapace presenting nothing particular and terminating by a lamellar rostrum varying in length. Eyes projecting. Internal antennæ very long, and terminated by two large multi-articulate filaments, one of which is convex at its base; external antennæ formed like those of the Palemons.

Ex. *C. Typus*.

Nika (Risso).—M. Milne-Edwards observes that this genus is remarkable for the defect of symmetry in the conformation of the first two pairs of feet. In their general form, he remarks, they resemble the Palemons, or rather the genus *Athanas*, for their rostrum is very small. Their internal antennæ are slender, and terminated, as in these last, by two rather long filaments. The external jaw-feet are pediform, long, and stout; the joint which terminates them is pointed at the end. The anterior feet are stronger than those which succeed, but of moderate length; the anterior right limb has a well-formed didactylous hand, whilst that opposed to it is monodactylous and formed after the manner of ambulatory feet. The second pair of feet are filiform, and terminated by a small pincer, which is nearly rudimentary; their carpus is multi-articulate, and their length very different: the left is nearly twice the length of the anterior feet, and the right is nearly twice the length of its opposite. The succeeding feet are monodactylous, and terminated by a styliform tarsus, which is not spiny: the fourth pair are longer than the third. The abdomen has the same form as in the Palemonians.

N. edulis has the rostrum slightly inflected, and nearly of the length of the eyes. A small tooth on each side, on the anterior border of the carapace, below the insertion of the eyes. Length about 2 inches.

It is an inhabitant of the Mediterranean and the English Channel. Mr. Bell regards this species as identical with *Procepa canaliculata* of Leach. He also describes a second British species, *N. Couchii*.

Athanas (Leach).—Carapace not elevating itself into a carina at the base of the rostrum, as in the Palemonians; the rostrum itself not toothed on its edges. Eyes projecting but little, but not covered by the carapace, as in *Alpheus*. Internal antennæ rather large, and terminating by three multi-articulate filaments, disposed as in *Palemon*, as are the external antennæ also. Mandibles robust, with a palpiiform, short, but very large appendage composed of two joints.

A. nitescens has the rostrum sharp, shorter than the peduncle of the internal antennæ; a spine on each side of its base, on the anterior border of the carapace. Hands unequal, convex, and with short and obtuse fingers. Carpus of the second pair of feet divided into five or six joints. Length about an inch.

It is a native of the coasts of France and England.

In the *Penæada*, or Penæans, M. Milne-Edwards comprises those shrimps whose abdomen is in general extremely elongated, and whose feet often carry at their base a palpiiform appendage more or less developed. The rostrum is short, or nearly null, and the lower antennæ, if not both pairs, are nearly always very long. The conformation of the feet varies much; but generally these organs become for the most part so slender and long, that they cannot serve except for swimming, and sometimes the last pairs become rudimentary or disappear.

Genera—*Stenopus*, *Sicyonia*, *Penæus*, *Euphema*, *Ephyra*, *Oplophorus*, *Pasiphaea*, *Sergestes*, and *Acetes*.

Stenopus (Latreille).—Body not compressed laterally, and teguments comparatively soft. Carapace terminated anteriorly by a small rostrum. Eyes short, and disposed in the ordinary manner. Peduncle of the

superior antennæ slender, and not carrying any lamellar appendage, as in the *Penæi*; terminal filaments of those organs long and cylindrical, and two in number. Lower antennæ presenting nothing remarkable. Mandibles strong, and furnished with a palp which is but little enlarged, and resembling that of the *Palemons* rather than that of the *Penæi*. External jaw-feet slender, elongated, and provided with a palp which is nearly rudimentary. First three pairs of feet didactylous, and progressively increasing in length; third pair much stouter than the others, and very spiny. Last two pairs of feet very long also, but filiform, and with their last two joints divided into a multitude of small rings; a disposition which is not seen either in the *Penæi* or the *Sicyonia*, and which recalls the structure observable in the second pair of feet of the species of *Hippolyte*, &c. The feet bear no lamellar appendage as in the *Penæi*. The abdomen is of moderate size, and presents nothing remarkable. (Milne-Edwards.)

Ex. *Stenopus hispidus*; *Palemon hispidus*, Oliv., from the Indian Ocean.

Sicyonia (Edwards).—Tegument harder than in the greater part of the shrimps. Body slightly compressed. Carapace surmounted with a median crest, which is continued forward into a rather large rostrum. On each side of the carapace, about its anterior third, a spine directed forwards. Eyes large, cylindrical, and exposed. Upper antennæ very short, their peduncle very stout, and not presenting, as in the *Penæi*, a lamellar appendage recurved above the eyes; their terminal filaments, two in number, extremely short. External antennæ inserted below the preceding, and offering nothing particular. First two pairs of jaw feet formed nearly the same as in the *Penæi*, excepting that they are deprived of palps. First three pairs of feet terminated by a small didactylous hand, and elongated from before backwards, as in the preceding genus; the last two pairs monodactylous, and the last much longer than the penultimate pair. None of these organs are multi-articulate, as in the *Stenopi*, nor provided with a flabelliform appendage, or a palp, as in the *Penæi*. Abdomen carinated above, and presenting several furrows, which make it appear as if it were sculptured; it carries below five pairs of false feet, each of which is only provided with a single natatory blade; the median blade of the caudal fin is pointed and furrowed above. Branchiæ 11 on each side.

Ex. *Sicyonia sculpta*; *Cancer carinatus*, Oliv., from the Mediterranean.

Penæus (Latreille).—Carapace furnished above with a more or less long median crest, which is continued forwards into a nearly straight, lamellar, and denticulated rostrum; on each side, near the insertion of the superior antennæ, a stout tooth, and a curved longitudinal furrow, which circumscribes laterally the stomachal region; a spine nearly always exists at the point of junction of the stomachal furrow and that of the branchial region, and sometimes a small crest is seen between the first of these furrows and the basillary crest of the rostrum. Eyes stout and rounded. First joint of the superior antennæ very large, and excavated above so as to form a cavity in which the eyes are lodged; its external border armed with a tooth, and its internal border with a small lamellar and ciliated appendage, which curves back upwards and outwards. The last two joints of the peduncle cylindrical and very short; and the terminal filaments of varying length. The external antennæ present nothing remarkable. Mandibles provided with a very large lamellar palp. Last two pairs of jaw feet carrying a very long and multi-articulate foliaceous palp, and provided also with a flabelliform appendage which ascends among the branchiæ; external jaw feet long, slender, and pediform. First four pairs of the thoracic feet provided with a flagrum which ascends into the branchial cavity as in the crawfishes, and at the base of all the feet a small lamellar appendage analogous to the palp of the jaw feet, a mode of conformation which reminds the observer of that of the Stomatopoda. The first three pairs of feet terminated by a small didactylous hand, and augmenting progressively in length from before backwards. Last two pairs of feet monodactylous and of moderate length. Abdomen extremely large and very much compressed; its posterior moiety surmounted with a median crest more or less marked. False feet not encased by the lateral lamina of the abdomen, and terminating by two ciliated laminae of unequal size. Caudal fin large; its median blade triangular, and hollowed below by a median furrow. Branchiæ disposed in bundles as in the lobster, 18 on each side, and between each bundle the flabelliform appendage of the foot situated below. (Milne-Edwards.)

M. Milne-Edwards subdivides the genus into the following sections:—

1. Species having the antennæ terminated by very short filaments.

* A median furrow extending from the base of the rostrum to the posterior border of the carapace.

Ex. *P. Caramote* (*Cancer Kerathurus*, Forsk.; *Palemon sulcatus*, Oliv.). It is found in the Mediterranean.

** No median furrow between the base of the rostrum and the posterior border of the carapace.

Ex. *P. setiferus* (*Palemon setiferus*, Oliv.; *Asiacus fluviatilis* Americanus, Seba). It is very abundant at the mouths of the rivers of Florida.

2. Species having the superior antennæ terminated by filaments longer than the carapace.

Ex. *P. membranaceus*, from the Mediterranean.

M. Milne-Edwards remarks that the genus *Melicertus* of Rafinesque seems to differ but little from *Penæus*.

Euphema (Milne-Edwards).—General form of the body approaching closely to that of *Hippolyte*. Carapace terminating anteriorly by a very long rostrum; abdomen bent towards the middle, its second ring prolonged posteriorly into a long spine, which is directed horizontally backwards, as is the rostrum forwards. Eyes large and short. Disposition of the antennæ presenting nothing remarkable; the first pair have, as usual, their first joint excavated above for the lodgment of the eyes, and terminate by two multi-articulate filaments; the second pair of antennæ are inserted below the preceding. Mandibles short, stout, but slightly denticulated, and provided with a palpiform, short, wide, and biarticulate stem; the valvular appendage of the jaws of the second pair is oval, and only a little prolonged backwards. The last two pairs of jaw-feet are moderate, pediform, and provided with a lamellar palp nearly as long as the internal stem; they also carry at their base an appendage which represents the flagrum, but which is membranous and vesicular, nearly as in the Amphipoda. The first three pairs of thoracic feet are terminated by a small imperfectly didactylous hand; and the last two pairs are monodactylous and strongly ciliated, so as to be rather natatory than ambulatory; all carry at their base a small very short flagrum, as well as a lamellar palp. The appendages of the first five rings of the abdomen are composed of a cylindrical peduncle and of two terminal joints, as in the ordinary Salicoides, only the blades are not ciliated. The caudal fin presents nothing remarkable. Branchiæ lamellar, and fixed in many rows on each side of the thorax.

Ex. *E. armata*, the only species known. It inhabits the Southern Atlantic.

Ephyra (Roux).—Body laterally compressed; carapace smooth; abdomen carinated, and rostrum denticulated. Jaw-feet very much elongated; and the thoracic feet carrying at their base a palpiform appendage, but not appearing to have a point as in the next genus. First two pairs of feet small, shorter than the succeeding ones, and didactylous; carpi simple.

Ex. *E. pelagica*. It is taken in the Mediterranean, at great depths.

Oplophorus (Milne-Edwards).—Body not compressed. Carapace terminated by a styliform rostrum, which is very long and denticulated on its two borders. Peduncle of the superior antennæ very short, and one of the terminal filaments very stout and pyriform at its base, but soon becoming slender and cylindrical like the other; the lamellar appendage of the external antennæ differs much from that of all the other shrimps; it is large, narrows gradually from its base, terminates in a very sharp point, and presents a series of spines on its external edge. External jaw-feet short, and carrying externally an extremely large lamellar palp. First two pairs of feet very short, terminated by a very small hand, and provided at their base with a very large and ciliated lamellar appendage; three succeeding pairs of feet moderate and monodactylous, the appendix fixed at their base small; and the tarsi of the third and fourth pairs styliform and very large, whilst that of the posterior feet is rounded and extremely short; there is also at the base of each foot a small flabelliform appendage, which ascends among the branchiæ, and the number of these last organs is nine. Abdomen differing but little from that of *Hippolyte*.

Ex. *O. Typus*, from New Guinea.

Pasiphaea (Savign; *Alpheus*, Risso).—Body remarkably flat laterally. Rostrum very short, or even rudimentary, and the carapace much narrower forward than behind. Eyes moderate and directed forward. Peduncle of the internal antennæ slender, and terminated by two multi-articulate filaments, one of which is rather long; external antennæ inserted below the preceding, and offering nothing remarkable. Mandibles strongly denticulated, and deprived of a palpiform stem. External jaw-feet very long, slender, and pediform; at their base a lamellar and ciliated palp as in the *Penæi*. The thoracic feet carry also, suspended at the external side of their basillary joint, a rather long lamellar appendage of the same form, but membranous and but little or not at all ciliated. Two first pairs of feet rather stout, nearly of the same length, armed with spines on their third joint, and terminated by a didactylous hand, the pincers of which are slender and furnished with a series of sharp spines on the prehensile border. The next three pairs of feet are very slender, monodactylous, and more or less natatory; in general, if not always, the penultimate pair are much the shortest. Abdomen very long and very much compressed. False feet of the first ring terminating by a single blade, but those of the next four feet carrying each two short natatory and but little ciliated blades. The sixth abdominal ring very long, and the seventh short and triangular. External blades of the caudal fin large and narrowed towards the end.

Ex. *P. Sivado* from the coasts of Nice.

Sergates (Edwards).—Body slender and a little flattened; carapace presenting anteriorly a small spine in lieu of a rostrum. Eyes very much projecting, and the ophthalmic ring on which their peduncles are inserted not completely covered by the carapace. Upper antennæ extremely long, and carrying, besides the principal terminal filament, two rudimentary filaments. External antennæ inserted below the preceding, and also very long. Second pair of jaw-feet nearly pediform and without either palp or flabelliform appendage, long, slender, bent back on themselves, and applied upon the mouth. Appendages which

correspond to the external jaw-feet offering nothing which can distinguish them from the ordinary thoracic feet; they are delicate, very long, ciliated, and terminated by a very slender styliform joint. Next four pairs of feet with the same general form, slender, filiform, furnished with much hair, and presenting at their base neither flabelliform appendage nor vestige of palp; second and third pairs provided at their extremity with a rudimentary joint, which is nevertheless moveable and disposed so as to constitute a microscopic claw. Penultimate pair of feet very short and a little distant from each other; the last pair nearly rudimentary. Abdomen presenting nothing remarkable, except that its lateral laminae do not descend so as to encase the base of the false feet as in the ordinary Salicoques. The first pair of these false feet terminate by a single natatory foliaceous blade, and present in the male a corneous prolongation of an odd form, which is fixed to the peduncle of those appendages, and goes to articulate itself on the median line with that of the opposite side. The next four false feet have two narrow natatory blades, which are ciliated and of unequal size. The median blade of the caudal fin is small and pointed, and the lateral blades are narrow, very nearly oval, and terminated in a point. Branchiae disposed on a single line, seven on each side of the thorax.

Ex. *S. Atlanticus*, the only known species. It inhabits the Atlantic Ocean, at some distance from the Azores.

Acetes (Milne-Edwards).—Analogous to *Sergestes* in its conformation, but placed at a distance from all the animals of the same order by the absence of the last two pairs of feet. Thoracic feet, consequently only three pairs; but, as in the *Sergestes*, the external jaw-feet acquire an excessive length, and perform the same functions as the ordinary feet. Carapace smooth, and presenting at its anterior extremity a longitudinal series of three small teeth, but there is no true rostrum. Eyes spherical and carried on rather long peduncles; the superior antennae, placed above the external ones, have a long peduncle; but its last joint is shorter than the first, and only carries two bristles, one of which is about twice the length of the body. The lower or external antennae present a terminal filament not less elongated, and their basis is covered, as in ordinary, by a great corneous plate. The mandibles, or jaws properly so called, and the two pairs of jaw-feet, do not differ remarkably from those of *Sergestes*; and the same may be said of the ambulatory feet, which are filiform and terminated by a very elongated joint, but the two posterior feet are wanting, as has been observed. Nevertheless a thoracic segment may still be distinguished behind, carrying branchiae like the preceding, but without locomotive appendages. The abdomen presents nothing remarkable; the natatory false feet all terminate by two narrow and pointed blades, which are at first nearly of the same length, but the internal one of which becomes shorter on the last segments. The peduncle of these appendages presents very opposite modifications; for upon the first rings of the abdomen it is long and narrow, whilst upon the last it is stout and short. The caudal-fin resembles that of *Sergestes*.

Ex. *A. Indicus*.

PALICOUREA, a genus of Plants belonging to the natural order *Cinchonaceae*. The limb of the calyx is 5-toothed or 5-lobed, or nearly entire; the corolla tubular and cylindrical, and a little gibbous at the base or curved, 5-cleft, bearded beneath the middle inside. The teeth of the calyx and corolla sometimes rather unequal. The species are American shrubs wholly destitute of pubescence. The leaves often whorled and of considerable size. The flowers are yellow or white in terminal sessile or stalked panicles, thyrses, or cymes.

P. Marcgraavii is a shrub from 5 to 6 feet high, and has smooth quadrangular branches. It is a poisonous plant, used in Brazil to kill rats and mice.

P. crocea has a smooth stem, ovate or oval-lanceolate leaves. It is a native of Porto Rico, Trinidad, Cuba, and Guadaloupe. According to Von Martius this species is emetic.

P. speciosa has smooth round branches, oblong acuminate leaves, acute at the base, membranous, roughish, shining, with smooth stipules. The leaves have by their yellow colour obtained for the plant the name of Gold-Shrub, highly spoken of in Brazil as an antisyphilitic. "The decoction, which in large doses forms a real poison, acts especially by an increased action of the skin and kidneys, and the digestion is not injured by moderate doses." (Martius.)

P. officinalis is a shrub clothed with harsh yellow down in every part. It is a native of Brazil, and is reported to be a powerful diuretic, and is used both in human and veterinary medicine.

Other species of this genus are said to have qualities similar to the last. *P. diuretica*, *P. strepera*, *P. sonana*, and *P. longifolia* are amongst those reported to possess medicinal virtues. *P. tinctoria* forms a fine red dye much valued in Peru.

Lindley, *Flora Medica*; Burnett, *Elements*.)

PALINURUS, the name given by Fabricius to a genus of *Crustacea* which forms the tribe of Langoustiens in the system of M. Milne-Edwards, being the fourth of his family of Cuirassés Macrurians, and characterised by the existence of antennae of the ordinary form and the absence of didactylous pincers. It is also regarded as the type of a family of the *Palinuridae*.

The *Palinuri*, or Sen-Crawfish, as they are popularly called, have the body nearly cylindrical. Their carapace is nearly straight from before backwards, very convex transversely, and presents about its

anterior third part a deep transverse furrow, which is directed forward on each side and separates the stomacal from the cardiac and brachial regions, the only ones which can be well distinguished. The anterior border of the carapace is armed with two stout horns, which advance above the eyes and the base of the antennae. On each side, below the eyes and nearer to the base of the external antennae, there is a more or less strong tooth. A great number of spines also nearly always arm the cephalothoracic buckler, over whose surface they are disposed. The ophthalmic ring is free and exposed; the eyes are large, short, and rounded. The antennular ring is very much developed, and advances between the external antennae, below and in front of the ophthalmic ring; sometimes it is triangular, and much longer than it is wide, and sometimes it is nearly square. The internal antennae, which spring from the lower part of its anterior border, are very long; their first joint is entirely cylindrical, and so are the next two joints; they terminate by two multi-articulate filaments of varying length. The external antennae are very stout and very long; their basilar joint, in which the auditory apparatus is lodged, is very large, and is joined to its conjunger so as to form in front of the mouth a very large epistome; the three succeeding joints are stout, moveable, and thoracic; they constitute the basilar portion of the antennae, and are succeeded by a multi-articulate stem which is very stout and very long. The external jaw-feet are small and pediform; their internal border is only a little or not at all toothed, very obtuse, and furnished with bundles of hairs; their palp is very small or entirely wanting, but they give insertion to a large flabelliform joint. The second pair of jaw-feet are small and vary in the form of their palp; the first pair have a very large palp, which completes the efferent branchial canal forwards, and terminates sometimes by a styliform appendage, sometimes by an oval blade in the form of a spatula. The mandibles are very stout, their edge is trenchant, and their palpi-form stem is very slender. The sternal plastron is of large size and composed of five segments joined together; it is very narrow between the first pair of feet, but is enlarged from before backwards, and presents on reaching the penultimate pair a very considerable width. All the feet are monodactyle; the first pair, which are in general shorter and a little stouter than the others, terminate by a short stout finger, which is not very moveable; sometimes there is at its base a spine, which is the vestige of a thumb, but these organs are never even subcheliform. The third pair of feet are in general longer. The abdomen is very stout and very long; its first ring has no appendages, but each of the four succeeding rings gives insertion to a pair of false feet, composed in the male of a small basilar joint and a large oval terminal lamina, whilst in the female there are two similar laminae, or at least a single lamina and a stemlet which is biarticulate and furnished with hairs. The caudal fin, formed by the seventh abdominal ring and the appendages of that which precedes it, is very large, and each of the laminae of which it is composed remains flexible and half-horny for its two posterior third parts, whilst above it is crustaceous like the rest of the tegumentary skeleton.

Palinurus, under side. (Milne-Edwards.)

The branchiae are composed of cylindrical filaments, which are short and close after the manner of a brush; there are eighteen on each side—two above the second jaw-foot, three above the external jaw-foot, three above the anterior foot, four above each of the succeeding feet

and one above the fifth foot. A large flabelliform appendage elevates itself between each of the bundles of branchiæ. (Milne-Edwards.)

The genus is composed of species of considerable size, remarkable for the hardness of their crusts, and spread over all seas. Rocky coasts are their favourite haunts.

P. vulgaris, the Common Sea Craw-Fish, or Spiny Lobster; Langouste of the French. The lateral horns of the front are smooth above, and armed below with many sharp dentitions; carapace very spiny; suborbital teeth on the border of the carapace very large. Length about 18 inches. Weight sometimes from 12 to 15 lbs.

This appears to be the *Kapdos* of Aristotle and the ancient Greeks, and the *Locusta* of the Roman authors (Suetonius, &c.) and of Belon. In the 'Portraits d'Oyseaux,' &c., 'observez par P. Belon du Mans' (1557), is a cut of the crustacean, and under it the following lines, which allude to its name (*Locusta*), derived probably from its power of springing with the tail or abdomen:—

"On peut nommer Sauterelle de Mer
Ceste Langouste, étant par tout piquante
Dessus le dos. Dieu la fait peu putassante,
Mais il la secut de dure escorce armer."

It inhabits the seas of Europe, and is common on the rocky coasts of Britain, especially in the south, and on the like coasts of France, especially on the south and west.

It is in general use as an article of food when in season, and as wholesome as the lobster; but though M. Milne-Edwards states that the flesh is very much esteemed, the English specimens are certainly far inferior both in tenderness and delicacy of flavour to that of the last-mentioned crustacean.

Common Sea Crawfish (*Palinurus vulgaris*).
a, left outward jaw-foot.

P. fasciatus. Antennular ring armed above with two conical rather large teeth situated near its anterior border. Carapace armed with a small number of spines, and slightly granular, or only dotted on its posterior half; lateral tooth of the anterior border of the carapace small; no spines on the median line of the stomacheal region; median tooth of the anterior border of the epistome very large. Length about a foot.

It is a native of the Indian Ocean.

P. guttatus. Antennular ring armed with two very large conical teeth, sometimes preceded by two rudimentary spines. Carapace very

spiny; two spines on the median line of the stomacheal region near the base of the rostral horns; and on each side of these last, on the anterior border of the carapace, two teeth nearly as large as itself. Length 7 to 8 inches.

Palinurus guttatus.

It is found in the Antilles.

Several fossil species have been referred to the genus *Palinurus*.

PALIURUS (the Greek *Παλιούρος*, and Latin *Palinurus*), a genus of Plants belonging to the natural order *Rhamnaceæ*. It has a spreading 5-cleft calyx, 5 obovate convolute petals, 5 protruding stamens, ovate 2-celled anthers, and a flat pentagonal disc. The fruit is dry and indehiscent, expanding into a membrane round the disc, containing a 3-celled nut. The species are shrubs or trees, with alternate simple leaves.

P. aculeatus, Christ's Thorn, is a very common plant in Palestine, and on the borders of the Mediterranean Sea. It has pubescent

Christ's Thorn (*Palinurus aculeatus*). 1, a ripe fruit of the natural size.

bractless ovate serrated leaves, quite smooth, 3-nerved, and with 2 spines at their base—one erect, the other hooked. The flowers are of a greenish-yellow colour. The fruit has a very singular appearance

resembling a head with a broad-brimmed hat on; the French call the tree 'Porte Chapeau.' This species of *Paliurus* is one of the most common thorns in the hedges of Asia, and its flexible spiny branches form an impassable kind of fence. The seeds are sold in the herb-shops of Constantinople, and the native doctors prescribe them in many complaints under the name of 'Xalle.' They are also used as a dye. It is common in the south-east of Europe and in Asia Minor, and in the districts where it grows there is a tradition that this is the plant from which the Jews platted the crown of thorns for our Saviour. In this country it is not uncommon in shrubberies, where it forms a beautiful hush when in flower, but it does not ripen its fruit. It is supposed to be the third sort of *Palmus* mentioned by Dioscorides, who compares the form of the fruit to that of a vertebra; if so the *Παλιούρος* of this author must have been something else, and perhaps, as Sihthorp conjectures, the modern *Ζίζιφι*, *Ziziphus vulgaris*, or *Jujube*.

PALLADIUM. [PLATINUM.]

PALLAH. [ANTIOPEÆ.]

PALLIOBRANCHIATA, M. De Blainville's name for his first order of his class (the 3rd of the *Malacozoa*) *Acephalophora*.

PALLIUM, the mantle of *Mollusca*. The mark formed by it in hivalve shells is called the Pallial Impression. This mark is normally found near the margin of the shell, and is thence sometimes called the Marginal Impression. In the *Dimyaria*, or hivalves which have two impressions of muscles of attachment, this mark passes from one of those impressions to the other; and if in its passage it bends inwards posteriorly, it is said to be Sinuated, and the part where this occurs is the Siphonal Scar of Dr. Gray.

PALM-OIL. [ELEIS.]

PALM-WINE. [BORASSUS.]

PALMA CHRISTI. [RICINUS.]

PALMACEÆ, *Palme*, a natural order of Endogenous Plants, usually trees, with simple stems, inhabiting the warmer parts of the world and especially tropical countries. They constitute a most important order, on account of the many uses to which the species or their products are applied. They are nearly allied to the Liliaceæ and Juncaceæ or Rushy Plants of northern countries. Linnaeus, who had scarcely any means of judging of the real structure of their fructification, and was therefore uncertain where to station them in his sexual system, placed them in an Appendix by themselves and called them the Princes of Vegetation. It has now however been ascertained that they chiefly belong to *Hexandria*, *Monœcia*, and *Diacia*.

In general they adhere to the soil by clusters of strong simple roots which not uncommonly form a hillock elevated above the surface of the ground. Their trunks are solid, harder on the outside than the centre, and are sometimes, as in the Cane-Palms, coated by a layer of siliceous matter; they are usually quite simple, growing exclusively by a single terminal bud, called in the *Areca* its cabbage, and eaten as a delicacy when boiled; but in the *Hyphæne*, or Doom-Palm, they are regularly forked. In the majority of the order the stem is nearly cylindrical, but in some it is thickest at the base, and in others swollen in the middle; occasionally it is defended by strong hard spines, but is more frequently unarmed, and marked by rings which indicate the places whence the leaves fall off.

The leaves, called fronds by Linnaeus, are alternate, with a very hard epidermis and a distinct petiole, from the base of which a coarse network, called the reticulum, sometimes separates next the trunk; they are usually either pinnated or fan-shaped, but are occasionally nearly split in two; their veins are parallel, the spaces between them plaited, and the whole size sometimes very great, as in the Fan-Palm, in which specimens have been seen as much as 18 or 20 feet in breadth. [CORYPHA.]

The flowers appear in panicle spikes from the inside of hard dry spathes, which are often boat-shaped, and although small, they are sometimes so extremely numerous that each panicle will weigh many pounds. They are generally hermaphrodite, but often monœcious, diœcious, or polygamous. The calyx and corolla consist each of three pieces, which are either distinct or more or less united. The stamens vary in number, from 3 to a large multiple of that number, and bear 2-celled linear anthers which open along their inner face. The ovary consists of 3 carpels, which are sometimes distinct, sometimes consolidated, and occasionally in part abortive, so that the ovary is only 1-celled. The ovaries are almost always solitary, and erect in each cell, but sometimes two are present, which in that case stand side by side; they are orthotropous in some genera and anatropous in others. The styles are very short, the stigmas simple.

The fruit varies extremely in its consistence and appearance. Sometimes it is 3-celled, often 1-celled; in such species as the Cocoa-Nut it is a kind of drupe covered by a coarse fibrous rind; in others it is a soft sweet eatable pericarp, as in the date; in others its surface is broken up into lozenge-shaped spaces, as in the *Sagus*, whose fruit looks as if covered with scale-armour. The seed is single, either solid or hollow, and consists principally of albumen of a fleshy, oily, horny, or cartilaginous texture, within which is lodged a very small cylindrical embryo at some part of the surface distant from the hilum.

Palms appear to prefer a soil in some measure salt, although many species are inhabitants altogether of inland districts and even of high

mountains. Their geographical limits appear to be within 36° N. lat. in America, 44° N. lat. in Europe, 34° N. lat. in Asia, and 38° S. lat. in the southern hemisphere; and according to Von Martius, their powers of migration are extremely small; none of them have been able to cross the ocean without the aid of man. Their favourite stations are said to be the banks of rivers and watercourses, and the sea-shore, some species scattered singly and others collected together into large forests.

There is scarcely a species of this order in which some useful property is not found. The Cocoa-Nut [*Cocos*], the Date [*PHœNIX*], and others are valued for their fruit; the Fan-Palm and many more for their foliage, whose hardness and durability render it an excellent material for thatching; the sweet juice of the *Palmyra* [*BORASSUS*] when fermented yields wine; the centre of the Sago-Palm abounds in nutritive starch; the trunk of the *Iriarteæ* or *Ceroxylon* exudes a valuable vegetable wax [*CEROXYLON*]; oil is expressed in abundance from the Oil-Palm; an astringent matter resembling dragon's blood is produced by *Calamus Draco*; many of the species contain within their leaves so hard a kind of fibrous matter, that it is employed instead of needles, or so tough that it is manufactured into cordage; and finally, their trunks are in some cases valued for their strength and used as timber, or for their elasticity, or their flexibility, as in the Cane-Palm. [*CALANUS*.]

A cluster of fruit of the Date-Palm (*Phoenix dactylifera*), with the spathe from which they spring. 1, a separate flower; 2, the ovary; 3, a section of the fruit, containing a single seed, in the middle of whose back is seen a papilla, which indicates the seat of the embryo.

The number of species is estimated at about 1000, divided into 59 genera, distributed through 5 tribes.

(Martius, *Palmarum Familia ejusque Genera denud illustrata*; also the *Genera and Species Palmarum* of the same author; Endlicher, *Genera Plantarum*; Lindley, *Vegetable Kingdom*.)

PALMACITES, a genus of Fossil Plants, from the Coal Formation. (Sternberg.)

PALMALES. [ENDOGENS.]

PALMELLACEÆ. [ALGÆ.]

PALMINA (Gray), a genus of *Cirripedia*.

PALMITES, Cuvier's name for his sixth order of Birds, which is divided into four families:—The Divers (*Brachyptera*); the *Longipennes*, or Grands Voiliers (*Albatrosses*, &c.); the *Totipalmes* (*Pelicans*, &c.); and the *Lamellirostres* (*Swans*, *Geese*, *Ducks*, &c.) [DUCKS.]

PALMIPES, a genus of Star-Fishes belonging to the tribe *Goniasteriæ* and the family *Asteriadeæ*. The body is thin, flat, and pentagonal, and covered above and beneath with fasciculated spines; avenues bordered by longitudinal fasciculi of spines; suckers visceral. The species of this genus are not numerous.

P. membranaceus, the Bird-Foot-Sea-Star, is a British species. It has broad ample sub-acute lobes. Colour white, with red rays and border. It is the thinnest and flattest of all its class. It ranges from the Arctic seas to the Mediterranean.

(Forbes, *History of British Star-Fishes*.)

PALMITORA, a genus of *Madreporææ*.

PALMS. [PALMACEÆ.]

PALMULARIA, a genus of *Polypiriæ*.

PALMYRA. [BORASSIA.]

PALMYRA, a genus of Dorsibranchiate Annelida.

PALO DE VACA. [COW-TREE.]

PALPEBRA. [EYE.]

PALUDINIDÆ, a family of Prosobranchiate Gastropodous Molluscs. The species are all inhabitants of the fresh water. They embrace Lamarck's family of Peristomians. The genera included in it are *Paludina*, *Valvata*, *Ampullaria*, *Amphibola*, and *Bithinia*. Through *Ampullaria* the family is allied with *Neritidæ*. The animals have broad muzzle-shaped heads, produced tentacula, sessile or sub-sessile eyes, and round or ovate entire-mouthed turbinated shells. They are distributed all over the world, in lakes and streams. All the species are operculated. Some of the *Paludina* are amongst the largest fresh-water shells, whilst others are the smallest. They are mostly dingy; but some are brilliantly coloured. Their fossil forms do not greatly differ from those which are recent, and they are found as far back as the Oolitic period.

Paludina (Lam.).—Animal furnished with a proboscisiform head; mouth toothless, but containing a small lingual bristly mass; tentacles conic, elongated, contractile; eyes at the external base of the tentacles; foot oval, with a marginal furrow at its anterior part; male organ very large, swelling up the right tentacle, whence it comes forth from an orifice situated near its base; anus at the extremity of a small tube in the flooring (plancher) of the respiratory cavity.

Shell furnished with an epidermis, conoid, having the whorls of the spire rounded, and the apex mammillated; aperture rounded, oval, angular at the summit, the borders united and trenchant.

Operculum horny, its elements concentric, with its summit excentric.

Paludina parvula. Animal and shell magnified.
a, side view; b, seen from above. (Goulding.)

Lamarck states that the *Paludina*, many species of which have been confounded with the *Cyclostomata*, *Bulini*, and *Turbinæ*, inhabit fresh-waters almost generally, but some live also in brackish and even in quite salt-waters. They breathe water only, like the *Valvata*, with which they have a great affinity; but their brinchiæ are internal, and they are further distinguished from that genus by the form of their aperture, which is rather longer than it is wide, being modified by the last whorl, which presents an angle at its summit. Their habits he describes as being very nearly those of the *Lymnæa*, like which the *Paludina* may be often seen progressing at the surface of the water, foot uppermost.

This form is widely spread. Species have been found in Europe, Asia, Africa, and America. The European species are the inhabitants of temperate climates.

The number of recent species of *Paludina* given by Woodward is 60 and of fossil species 50.

P. vivipara, the Common River-Snail, has the shell ventricose-conoid, thin, diaphanous, very delicately striated longitudinally, greenish-brown, with brown-red obsolete transverse bands; five turgidly-rounded whorls, the sutures strongly marked. It inhabits the fresh-waters, rivers, and ponds of England, France, Germany, &c.

Paludina vivipara. Female.
a, shell of an adult, with young shells in it; b, operculum; c, young shell before exclusion.

Nematura, Swainson, and *Bithinia*, Gray, are sub-genera of *Paludina*. Forbes and Hanley record two species of *Bithinia* as British, *B. tentaculata* and *B. Leachi*.

Ampullaria (Lamarck).—Animal globular or planorbiform; foot large, delicate, and subquadragular, largely truncated anteriorly. Head flattened terminated anteriorly by a pair of conical buccal ten-

tacula; two great subulate tentacula nearly as long as the foot, supporting at their base oculiferous peduncles, sometimes separated throughout their length. No jaws, but a lingual bristled ribbon. A respiratory canal formed by the mantle, but not leaving any trace on the shell. Branchial cavity of great size, largely open anteriorly, and whose upper wall is doubled so as to form a great aquiferous sac. (Deshayes, principally.)

Shell furnished with an epidermis, generally not stout, but globular, ventricose, and umbilicated; spire very short, the last whorl much larger than all the others put together; aperture oval, rather longer than it is wide, borders united, the right lip trenchant.

Operculum horny or shelly, rarely calcareous, rather delicate, composed of concentric elements, the apex submarginal and inferior.

Ampullaria dubia. Animal in the shell creeping. (Goulding.)
a, operculum; b, the right siphon; c, the left siphon.

Ampullaria dubia, showing the lower side of the foot, &c. (Goulding.) The animal is represented as ascending to the surface of the water to breathe, and with the respiratory siphon exerted. a, the operculum; b, the right siphon; c, the left siphon.

The species of this genus are not found in Europe, but they have been brought to Europe alive. The first was sent to Paris by M. Caillaud from the Nile. That naturalist, during his voyage to Merö, collected several Egyptian Mollusca, which he distributed generously among collectors. One correspondent had been anxious for the fluviatile molluscs found in the Nile. The person employed to collect these, after having gathered a large quantity of river Mollusca, among which were some living *Ampullaria*, put them all into a box of bran (son). This box was delayed on its road by the operation of the quarantine laws for four months, and when it reached M. Caillaud, was in such a state, from the putrefaction of the greater part of its animal contents, that he hastened to throw the whole into the water. To his no small surprise he found, a few hours after, the greater part of the *Ampullaria*, which had been shut up with this mass of putre-

Animal and Shell of *Ceratodes fasciatus*, Guilding; *Ampullaria Cornu-Arietis*, Sowerby. (Guilding.) 1, the animal creeping. 2, the animal in a supine position; a, Operculum; b, the right siphon; c, the respiratory siphon. 3, head, tentacula, eyes at their base, and cervical alae.

faction, quietly creeping about upon the mud. He gave many individuals to M. Deshayes, who kept them alive from four to five months.

M. Deshayes relates that it became an object of inquiry how aquatic animals, unable to respire, except by means of a pectinated branchia, could remain alive so long out of the element apparently necessary to their existence. Nearly all the persons, he remarks, who occupied themselves with this phenomenon, thought that the animal on retiring into its shell carried with it a certain quantity of water, which could not escape owing to the retention of the operculum, which closes the aperture with great exactness. Others thought that the humid air carried upon the branchia was sufficient to keep up the respiratory action. "Wishing to know," continues M. Deshayes, "whether there were anything in the structure of the animal which could explain the singularity, we soon perceived that the upper wall of the branchial cavity was doubled, and formed a great pouch, the aperture of which was placed backwards, above the origin of the branchia. Plunged in the water, the animal has this pouch constantly filled with the ambient liquid, and on retiring into its shell and shutting itself up under its operculum, this bag still remains filled with water, and thus furnishes the necessary materials for the function of respiration. Everything leads us to believe that this is the only cause which permits the *Ampullaria*, pectinibranchiated aquatic animals, to remain a long time out of the water without perishing, and this explains also how it happens that in certain lakes which are annually dry, *Ampullaria* are always to be found. When the great heats approach and they plunge themselves into the mud or sand, they preserve in their

branchial sacs the quantity of water necessary for them during the whole time of drought."

This is one of those beautiful provisions which meet the naturalist everywhere. The tropical torrent and lake may yield to the dry season and burning sun, but the *Ampullaria*, secure in the possession of his water-bag, can afford, like the camel in the desert, to wait till the rains furnish a fresh supply, and again fill the parched channel.

The species are found in the rivers and lakes of warm climates. Species, some of them very large (*A. Guyanensis*, *A. Urceus*, and *A. Gigas*, for example), have been found in Asia, Africa, and America, especially the southern portion of the latter.

A. globosa, Globose Apple-Snail, or Idol-Shell, is a good example of this genus. There are about 50 recent species of this genus. The following sub-genera have been formed out of it:—*Pomus*, *Marisa*, *Asolene*, *Lanistes*, and *Meladonus*.

Ampullaria globosa; the aperture closed by the operculum.

Ampullaria effusa of Swainson. Mr. Guilding is of opinion that this species forms the transition through *Ceratodes* to the *Planorbidae*, and that it is probably more allied to that genus than to *Ampullaria*.

The genus *Ceratodes* of the last-named author is characterised as having a simple lip; a horny operculum; a discoid shell; a very large and deep umbilicus, and an evanescent columella. The sole species given by him is *Ceratodes Cornu-Arietis* above copied.

Mr. Swainson thus defines the genus *Ampullaria*:—Shell globose, rarely discoid, turritate; spire very short; aperture oblong, pointed above, rounded below. The same author characterises the four sub-genera as follows:—

Ampullaria (Lamarck).—Outer lip thin; operculum horny. Ex. *A. fasciata* of Lamarck.

Pachylabra.—Outer lip thickened; operculum shelly. Ex. *P. globosa*, Swainson.

Lanites (Montf).—Shell reversed; the body-whorl ventricose only in the middle; outer lip generally thin. Ex. *L. Guinaiaca*. Sowerby's 'Manual,' f. 319. ('Malacology,' 1840.)

The number of recent species recorded by M. Deshayes in his 'Tables' is 24: in the last edition of Lamarck the numbers given are 27, including *Ampullaria avellana* and *A. fragilis*, of which we shall presently have occasion to speak more at large. Neither Mr. Swainson's *Ampullaria globosa*, Captain King's *A. Cumingii*, nor Mr. Lea's *A. Pealiana* appears among these species. Mr. Swainson gives *Helix ampullacea*, var., Gmelin, as a synonym of his *A. globosa*, but the former stands as a synonym for *A. fasciata*, Lam., in the last edition of the 'Animaux sans Vertèbres.' Mr. Swainson considers it distinct, and quotes the description and figure of Chemnitz, who, like other authors, considered it a variety of *Helix ampullacea*. The rivers of India are given as the locality, by Mr. Swainson.

Some of the *Ampullaria*, or Apple-Snails, are of large size.

Ampullacera, Quoy (*Amphibola*, Schumacher).—Animal spiral, globular, convex; the foot short, quadrilateral, and with a marginal anterior furrow. Head large, flattened, notched into two rounded lobes supporting two sessile eyes, without the appearance of tentacles. Pulmonary cavity limited anteriorly by a collar, and having its aperture at the right border. Mouth membranous. Both sexes united. Shell rather thick, globular, ventricose, deeply umbilicated, aperture round or oblique, with the borders united; spire short, but projecting. Operculum horny, delicate, but little spiral, sometimes with a heel or projection. (Quoy.)

M. Quoy says of this genus, "We have a mollusc breathing air although it lives in pools, possessing the two sexes united, but being, notwithstanding, an insufficient hermaphrodite. It is apathic, and comes but little out of its shell, into which it retires very far upon the slightest touch. We found it sunk in the muddy sand, under some inches of saltish water, with its aperture full of earth. It is found in great abundance in New Zealand, where it is largely eaten by the natives."

M. Deshayes adopts this genus, which he thinks one of the most interesting that has been for a long time discovered. "It offers in fact," says he, "an entirely novel combination of an aquatic animal pulmonated and operculated, and fills up a lacuna. It is, with reference to the aquatic *Pulmonata*, what the *Helicine* are with reference to the terrestrial *Pulmonata*; *Ampullacera*, then, will constitute in

the system not only a genus but a family, which ought to be placed at the end of that of the aquatic *Pulmonata* without an operculum."

The only species known are *Ampullacera arellana*, Quoy (*Ampullaria arellana*, Lam.); and *Ampullacera fragilis*, Quoy (*Ampullaria fragilis*, Lam.), and another.

Valvata (Müller).—Animal with a very distinct head prolonged into a sort of widened proboscis; tentacles very long, subcylindrical, slightly curling outwards, very much approximated at the base, pointed at the extremity; eyes sessile at the posterior side of their base; foot bilobate anteriorly; branchiae long, pectiniform, more or less capable of being exerted out of the cavity, which is largely open, and provided at the right of its inferior edge with a long appendage simulating a third tentacle; male organ retiring within the respiratory cavity. Shell discoid or conoid, umbilicated, the whorls rounded and distinct, the apex mammillated; aperture round or nearly round, its borders united and trenchant. Operculum horny, round; its elements concentric and circular.

Mr. Swainson regards *Valvata* as a sub-genus of *Paludina*.

This genus appears to have been found as yet in Europe and North America only. M. Deshayes, in his 'Tables,' makes the number of living species four, and names *V. piscinolis* as the only species living and fossil (tertiary). In his last edition of Lamarck the number of recent species recorded is six. There are 19 fossil species.

V. piscinolis. Shell conoid, globose, subtrochiform, umbilicated, white; whorls four or five; apex of the spine obtuse.

Valvata piscinolis, with its shell, creeping.
a, natural size; b, enlarged.

Valvata piscinolis.

a, shell, natural size; b, c, magnified; d, operculum enlarged; e, glutinous masses of eggs on a leaf; f, mass of eggs enlarged.

This little shell, which has four complete whorls, without including the apex, inhabits rivulets and ponds in England and France, and is, in all probability, to be found in Europe generally.

PALYTHOA, a genus of *Zoophytes*.

PAMPAS CAT. [FELIZ.]

PANAX (intended to be formed from *pân*, all, and *âkos*, a remedy), a genus of Plants belonging to the natural order *Araliaceae*. The flowers are polygamous, the calyx obsolete and 5-toothed. It has 5 petals, 5 stamens inserted with the petals under the edge of the disc, and alternate with them. The fruit is succulent, compressed, orbicular, from 2- to 3-celled; the cells leathery and 1-seeded. The species are herbs and shrubs and trees, having the leaves and inflorescence variable.

P. quinquefolium, Five-Leaved Panax, or Ginseng, has a fusiform root more or less branched, of a whitish colour, and terminating in fibres. The stem is smooth, round, and green, often with a tinge of red, divided at the top into three petioles with a flower-stalk in their centre. The petioles are round, smooth, and swelling at their base. The leaves ternate, quinate, or septenate. The berries are kidney-shaped, of a bright red colour, and contain 2 semicircular seeds. The flowers are of a yellowish colour. It is a native of Chinese Tartary and North America. In China it has been considered an invaluable drug from time immemorial. In 1709 the Emperor of China commissioned 10,000 Tartars to go in quest of as much of this root as they could find; each one was to give two pounds of the best of it to the emperor, and to sell the rest for its own weight in fine silver. The roots enter into the composition of every Chinese medicine. It is reckoned a stimulant and restorative, and both rich and poor consider it a remedy for every disease. By Europeans and Americans however it is comparatively disregarded, and looked upon as a mere succulent, similar in its qualities to liquorice; hence the question arises, is the Chinese plant the same as the North American? For we cannot regard all that the Chinese say and practise as merely imaginary. The common name of the plant, Gen-seng, Jinehen, or Nindeln, signifies 'wonder of the world,' or the 'dose for immortality;' and the Chinese firmly believe that its powers are almost miraculous. [GINSENG.]

P. fruticosum is also used in China and Cochin-China as a febrifuge, and as an astringent tonic. It has a shrubby unarmed stem, pinnately decomposed leaves; petiolate oval oblong leaflets, coarsely and dentately serrated, the ultimate ones deeply trifid, the panicle corym-

bos, with the branches umbelliferous at the apex. It is a native of the islands of Ternate, Java, and Amboyna.

(Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

PANCRA TIUM, a genus of Plants belonging to the natural order *Amarylhidaceae*. It has a funnel-shaped flower with a long tube. Six superior sepals, and as many stamens, which are inserted on the edge of a 12-cleft membranous cup. Pistil single. The name was applied by the Greeks to some plant allied to *Scilla maritima*, but which has not yet been made out by botanists. The name is now applied to a genus of ornamental plants, found in the equinoctial parts both of the old and of the new world, and of which one species extends to the coasts of the Mediterranean. They are mostly highly ornamental plants with white flowers, many of them fragrant; they are commonly cultivated in stoves, and require a mixture of light loam and rich vegetable mould, with little water when not in a growing state.

PANCREAS is a secreting gland situated behind the stomach and extending from the spleen transversely across the vertebral column to the duodenum. In man it is of an elongated and slightly flattened form, broadest at its right extremity, and gradually diminishing in breadth towards the left. It is of a firm consistence, lobulated, and very similar in structure to the salivary glands, from which circumstance it is often called the salivary gland of the abdomen. It is chiefly composed of the ramifications of the main duct, through which its secretion is poured into the bile-duct, or into the duodenum by a separate aperture close to that of the bile-duct. [LIVER.] The ramifications terminate in little follicles, each cluster of which, with its bloodvessels, lymphatics, nerves, and connecting tissue, forms a lobule. It is in these follicles the pancreatic fluid is formed. This fluid has the following composition:—

Water	986.40
Solids:—	
Fat	0.26
Alcohol Extract	0.15
Albumen	3.09
Alkaline { Chlorides }	8.90
{ Phosphates }	
{ Sulphates }	
Carbonate and Phosphate of Lime and }	1.20
Magnesia	
	13.60
	1000.00

The office of this fluid appears to be the emulsifying and rendering absorbable the oily constituents of the food. On this subject M. Ch. Bernard has performed many experiments, and his conclusions are now very generally admitted as correct. [DIGESTION.]

The pancreas is found in its least developed form in fish, in some of which it consists of simple or slightly branching tubes or sacs, attached to the duodenum very near its commencement, and commonly called Appendices Pyloricæ. In the *Amphibia* and *Birds* it gradually increases in the complexity of its arrangement, and it is most compact and most highly developed in the *Mammalia*.

PANDA, one of the names of the genus *Ailurus* (F. Cuv.), an Animal belonging to the class *Mammalia* and the order *Carnivora*. It has the following generic characters:—Head subglobose, great; face subrotund, cheeks tumid; forehead flat, elongated, broad; tongue rather rough; snout short, conical, very broad; rictus moderate; rhinarium obtuse; nostrils terminal; ears short, acute, distant, villous; eyes approximated to the rhinarium and placed anteriorly; maxilla intumescent; mandible subcondite; a few white vibrissæ. Neck short. Body large, cylindrical, obese, clothed with a very villous under-fur, and long, equal, rather soft hairs, downy at their base. Tail of the length of the body, very large at the base, cylindrical, subattenuated at the tip and clothed with very long spreading hair. Feet plantigrade, 5-toed; the soles thickly clothed with a very fine down; claws falcate, compressed, arcuate, very sharp (retractile).

Dental Formula:—Incisors, $\frac{6}{6}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5}$ = 36.

A. fulgens (F. Cuvier) is the only species of the genus. It was first described by General Hardwicke.

"The peculiarities of our animal," says the General, "on which its rank as a genus depends, are striking and prominent; but its disposition in a natural series is still obscure, as it resembles in several characters the individuals of that subdivision of digitigrade carnassiers, from which it differs essentially both in its teeth and in its plantigrade walk. Among the peculiarities of our animal are to be noticed the great breadth of the rostrum and the singular structure of the teeth: but the most remarkable character, and that on which its distinction principally depends, is the form of the projecting points of the posterior grinders. This character, as far as our observation extends, is peculiar; it does not exist, except in a small degree, in any other genus of carnivorous quadrupeds. The truncation is owing, in our opinion, to original structure, and is not produced by the wearing down of the points. We observe it both in the skull of a young animal and in that of the adult specimen from which the annexed drawing was made; and our description is confirmed by a careful comparison of the relative elevation of the points of the two anterior

Teeth of *Ailurus*.

1, lateral view of the teeth of the upper jaw, as they are seen within. 2, the same as they are seen without. 3, lateral view of the teeth in the lower jaw, as they appear within. 4, the same as they appear without. 5, Front teeth: a, upper jaw; b, lower jaw. (Hardwicke, 'Linn. Transs.')

Feet of *Ailurus*.

1, Anterior foot, left side; 2, posterior foot, right side; 3, sole of one of the posterior feet, to show the hairy covering. (Hardwicke, 'Linn. Transs.')

grinders, in which, although they are equally exposed to attrition, this truncation is not observed. The margins bounding the truncated points, as is shown in the drawing, are circumscribed and perfect, exhibiting no signs of being worn down by attrition. In the disposition and even in the form of the teeth, our animal bears some resemblance to the genera *Nasua* and *Procyon*; but these differ essentially in the lengthened form of the head, and in the extended rostrum, which is terminated by a flexible rhinarium; they also differ

in the number, character, and distribution of the grinders. *Nasua* and *Procyon* have in both jaws six grinders, of which the three anterior are false grinders; and of those which follow, none of the points, even in the adult state, exhibit the truncation above described. Our animal has only one false grinder with a compound crown, and the four posterior grinders are large and highly complicated: the first of these in the upper jaw corresponds with the fourth grinders in *Nasua* and *Procyon*, and the points are attenuated and acute; but the posterior grinders are quite peculiar and characteristic in their structure."

*Ailurus fulgens*. (P. Cuvier.)

General Hardwicke states that this animal's haunts are about rivers and mountain-torrents. It lives much in trees, and feeds on birds and the smaller quadrupeds, and is frequently discovered by its loud cry or call resembling the word Wha, often repeating the same. Hence is derived one of the local names by which it is known. It is also called the Chitwa.

It is found in the Himalaya chain of hills between Nepal and the Snowy Mountains (Hardwicke, 'Linn. Transs.' vol. xv.). It is in Mr. Hodgson's Catalogue of the Animals observed in Nepal ('Zool. Proc.', 1834).

Cuvier declares the *Ailurus* to be one of the most beautiful of quadrupeds. He places *Ailurus* among the Bears, between *Procyon* (Raccoon) and the Benturongs (*Idetes*). J. B. Fischer arranges it between *Gulo* (Glutton) and *Arctictis* (F. Cuv., *Paradoxurus* and *Idetes* of F. Cuv. and Valenciennes).

PANDANA'CEÆ, *Screw-Pines*, a natural order of Endogenous Plants. The species are arborescent or bushy plants, with long rigid sword-shaped leaves, resembling those of the pine-apple, usually arranged in a manner so obviously spiral that they are commonly called Screw-Pines. In a natural arrangement they are classed with Endogens, among which they are, more especially in the genus *Pandanus*, remarkable for their stems forking repeatedly. Their flowers have the sexes separate, and quite covering the spadix on which they grow. The male flowers consist of single stamens with 2-celled anthers; the females of naked 1-celled ovaries, with solitary ascending or numerous parietal ovules. The fruit consists of a mass of ovaries collected into a tuberculated head, and either dry and fibrous or fleshy and succulent.

These plants chiefly abound in the Mascaren Islands and in the Indian Archipelago, of which they form a conspicuous feature. The species of *Pandanus*, *Vaquio*, or *Screw-Pine*, are readily known by their spiral leaves, dichotomous habit, and the long roots emitted by the sides of their trunk for the purpose of holding it down in the loose sand among which they grow, in order to assist in which each root is furnished with a partial exfoliation of the end, which, in the form of a cup, adheres to the root, for the purpose, as is supposed, of holding water during the period that the root is passing through the dry air. The genus *Freyinetia*, on the contrary, is composed of plants with long scrambling or rooting stems, not branching like *Pandanus*, indeed seldom becoming what can be called a tree; and, when in flower, adorned with gaily coloured spathes from which the young inflorescence protrudes. [PANDANUS.] Some of the species yield seeds which are edible. The order contains 7 genera and 74 species.

PA'NDANUS, a genus of Plants, the type of the natural order *Pandanaceæ*. This name is derived from the Malay Pandang, and that of a genus of Plants, from which the natural family of *Pandanaceæ*, or *Screw-Pine* tribe, has derived its name, being so named from their leaves, which resemble those of the pine-apple, and are inserted spirally along the stem. The species are found in the islands of the tropical ocean, in those of Mauritius and Bourbon, as well as in the southern parts of India. One species, *P. odoratissimus*, being highly fragrant, is much esteemed in all Asiatic countries, either where it will grow or where its essence is known. It is constantly referred to by the Sanscrit poets, as may be seen in Wilson's 'Hindu Theatre,' by the name Ketaka, and as the Keora and Ketgee of the Hindoos. The Arabs call it Kazec, and Avicenna describes it under the name of Armak. Oil impregnated with the odour of its flowers and the

distilled water are highly esteemed both for their odour and their medicinal use as stimulants. Dr. Roxburgh states that it is the tender white leaves of the flowers, chiefly those of the male, which yield the very delightful fragrance for which this plant is so celebrated. This species is common in the peninsula of India, where it is called Caldera Bush; in Mauritius it, as well as other species, is known as the Vaquois Plant; in Otaheite, a species is called the Wharra Tree, being in all highly esteemed for its odour, as well as for the useful purposes to which it may be applied. The lower pulpy part of the drupes is sometimes eaten, as is also the terminal bud, like that of the cabbage-palm, and likewise the tender white base of the leaves, either raw or boiled, during times of scarcity. It forms an excellent hedge, but occupies too much space. The roots are composed of tough fibres, which are used by basket-makers to tie their work, and are soft enough to be employed as corks. The leaves are composed of tough longitudinal fibres, white and glossy, a quality which adapts them for covering huts, making matting, as well as for cordage in the South Sea Islands, and in Mauritius for making sacks for their coffee, sugar, and grain.

PANDION. [FALCONIDÆ.]

PANDORA. [PYLORIDÆ.]

PANGIACEÆ, *Pangiads*, a natural order of Diclinous Exogenous Plants. This order embraces three genera, the species of which are trees with alternate stalked entire leaves, polypetalous axillary monœcious flowers, with scales in the throat of those bearing pistils. The stamens are five, the seeds large and oily. Dr. Lindley says, "What the distinction is between these plants and Papayads, except that the last are monopetalous, and have no faucial scales in the ♀ flowers, it is hard to say."

The species are found in the hotter parts of India. They are all poisonous. The natives of India employ extensively in medicine the seeds of *Gynocardia odorata*, which are known by the name of Chaulmoogra and Potarkura. The genus *Hydnocarpus*, formerly referred to *Flacourtiaceæ*, belongs to this order. [FLACOURTIACEÆ.]

(Lindley, *Vegetable Kingdom*.)

PANGOLINS, a name in common use to designate the Scaly Ant-Eaters, said to be derived from the word Pangoeling, which signifies in the Javanese language, according to Seba, an animal which rolls

itself into the form of a ball. The Bengalese name is Badjarkita, or 'reptile of stone.' These animals form the genus *Manis* of Linnæus.

The Pangolins are toothless, and furnished with a very extensible tongue; but their tegumentary covering is very different, for their body, limbs, and tail are clad in a panoply consisting of great treuchant scales overlapping each other like tiles, so as to form a sort of scale-armour when the animal is on its feet. When it is vigorously attacked, and often on the first approach of danger, it rolls itself up in the shape of a ball; and then the trenchant scales are erected, and offer their sharp edges to the enemy.

The species are found in Asia and Africa.

The following are the principal points in their organisation:—The skull is a more or less elongated cone, with the base rounded. Orbita small, round, occupying nearly one-half of its length, and situated towards the lower parts of its sides: they are consequently very much separated from each other. The zygomatic arches are incomplete, and nearly on a level with the palate. The bones of the nose are notched on their inferior border, and enter above into a notch formed in the frontal bones. The articulation of these with the maxillary bones descends obliquely to the orbit, and is continued in the same direction with the palatine bone. The maxillary bone does not enter into the orbit; it terminates at the point where it gives off its zygomatic apophysis, which is short and pointed.

The skull of *Manis tetradaactyla* (Linn.), *Manis macroura* (Erxl.), the Phatagin of Buffon, differs from the description above in being more slender, and also presents the singularity of having, where the lachrymal bone should be, a great oval piece without any hole, which, Cuvier believes, belongs to the ethmoid bone.

In the extremities there is a general resemblance of the skeleton in the Hairy Ant-Eaters [ANT-EATER] and the Pangolins; but there are particular differences, as in the scapula, &c., some of which we shall notice. Both of these groups are remarkable for the great size of the lower part of the humerus, produced especially by the projection of the internal condyle destined for the attachment for the powerful flexors which work the claws. In the Hairy Ant-Eaters the head of the radius is nearly as round as it is in man and the Quadrumanes, having a very complete rotatory power; but it is not so in the Pangolins, which have the articulation of this part by the method termed *ginglymus*. The orbit and radius are both robust, and are constructed

Skull of *Manis pentadactyla*, Linn. (*Manis brachyura*, Erxl.).

a, seen from above; b, seen from below; c, seen from behind; d, profile (Cuvier.)

a, Fore foot of Pangolin; b, hind foot of the same. (Cuvier.)

with proportions and views very different from those to be observed in the Sloths, among which they are so greatly prolonged as to be hardly fit for anything but suspension from trees. [A.] In the Ant-Eaters they have all the strength necessary for tearing down the nests of the Termites, on which they feed; and, as it might be expected, the fore feet of these quadrupeds is, next to their skull, the most remarkable part of their skeleton. The ungual phalanges of their large toes are, like those of the Sloths, so disposed as not to be capable of curvature in any other direction than downwards; and are in effect held in that position, the state of repose, by strong ligaments. In the Pangolins their point is forked, whilst in the Hairy Ant-Eaters it is only furrowed, and has at its base a strong bony sheath for the insertion of the claw. In the Pangolins the general structure of the fore foot is the same as in the Hairy Ant-Eaters; but besides the differences above noticed, the scaphoid and semilunar bones of the carpus are confluent, forming a single piece, as in the Carnassiers. In the Pangolins there is, too, less irregularity in the proportions of the toes, though in them, as well as in the Hairy Ant-Eaters, the middle one is stoutest and longest.

The pelvis in all these animals exhibits the singularity of the ischium uniting with the last vertebra of the sacrum, which is fur-

Pelvis of Pangolin. (Cuvier.)

nished with apophyses for its reception, so that instead of the ischiatic notch there is a hole, which at first sight has the semblance of a second oval hole, a conformation observable in the Sloths and Armadillos. In the Pangolins the os ilii, which is of a prismatic form and termi-

Skeleton of Short-Tailed Pangolin (*Manis pentadactyla*). (Cuvier.)

nates in front by a tuberosity, is articulated also to the last lumbar vertebra; but this is not the case among the Hairy Ant-Eaters, where this bone is besides flatter; in both it is oblong, and not widened as in the Sloth.

The great trochanter is less elevated than the head of the femur. The lower head of the bone is as wide as it is long, and the rotular pulley is wide but not deep. The tibia and fibula are very distinct. The astragalus corresponds to this in the form of its upper head, the lower only corresponds to the scaphoid bone, and is concave, as it is in the Sloths, which is remarkable. The calcaneum is compressed at its posterior apophysis, and is united to the astragalus as in most animals. In the tarsus there is a scaphoid bone, which is convex on the anterior side of its articulation with the astragalus, but curving behind that bone; a cuboid longer than it is wide; three cuneiform bones, the internal of which is double that of the others; and a supernumerary bone articulated on this internal cuneiform bone, and which

in the Tamanoir, Tamandua, and the Pangolins is triangular and very small, but in the Little Ant-Eater is elongated and widened so as to form a sort of heel. This species of calcaneum, it is true, is very short, not going farther backwards than the astragalus itself. It is this supernumerary bone which gives to the sole of the foot of the Little Ant-Eater that concave form which renders it so fit for grasping branches and climbing trees.

The Pangolins are remarkable for the strength of their caudal vertebrae, and for the extended width of their transverse apophyses; there are 47 in the tail of *Manis macroura*, and only 26 in that of the Short-Tailed Pangolin, which has 3 sacral, 6 lumbar, 15 dorsal, and 7 cervical vertebrae; in the Phatagin Cuvier found only 13 dorsal and 5 lumbar vertebrae. The spiny apophyses of the back and loins of these two animals are square, as in the Tamanoir.

The Pangolins have the bones of the ribs flat, eight in number, of which the three penultimate are placed transversely, and the last of all, which is very long, cylindrical, and forked in the Pangolin (flattened in the Short-Tailed Pangolin), terminates in two strong tendons, which in the latter reach to the pelvis, and greatly assist the animals in rolling themselves into a ball.

Manis has the following characters:—Lower jaw very small; tongue very extensible. Body and tail entirely covered above with large triangular trenchant scales disposed quincuncially, and overlapping each other like tiles. Toes five, armed with robust claws. Body endowed with the faculty of rolling itself up more or less into the form of a ball. Dental Formula, 0.

The Pangolins are slow in motion, and live on worms and insects, especially termites and ants, which they seize by means of their extensible and glutinous tongue.

M. pentadactyla (*M. brachyura* of Erxleben, and probably the Phatagin of Aelian, xvi. 6), Indian, Broad-Tailed, or Short-Tailed *Manis*. It has the head small, pointed, and conic; muzzle elongated and narrow. Body rather stout. Tail short and very broad at its base. Dorsal scales disposed in longitudinal rows to the number of eleven; under part of the body, head, and feet naked; some long fair-coloured hairs spring from under the scales. Middle claw of the fore feet far exceeding the others in its proportions.

It is a native of the East Indies, coast of Tranquebar, &c. It feeds much on termites, or white ants, for the destruction of whose conical nests the great middle claw is admirably adapted. Thunberg states that it is found much in Ceylon, especially near Negumbo. The Dutch call it the Negumbo Devil, and the Cingalese, Caballe. Its flesh was given to the sick to eat by way of remedy. Thunberg further informs us that the inhabitants have a method of making a hole in its skin with a knife, and thus of guiding and governing the animal at their pleasure, the point of the knife, which is kept in the hole, goading and irritating him. The cruelty of this proceeding does not however seem to have struck the traveller. The Land-Carp is also an Asiatic name for this species. It is the Kulee Manjar, or Tiled Cat, of the Mahrattas, according to Colonel Sykes, who notices it as very common in Dukhun (Deccan), and living on white ants. Mr. Hodgson, in his catalogue of the quadrupeds of Nepal, mentions a new species of *Manis* allied to *M. javanica* (Desm.), as being of frequent occurrence in the hills of the lower region, and in the mountains of the central tract. ('Zool. Proc.' 1830, 1831, and 1834.)

M. tetradactyla, the Phatagin of Buffon, appears to be the Long-Tailed Pangolin (*M. macroura*, Erxleb). This species is from two to three feet in length, and the tail is twice as long as the body; the scales are pointed.

It is a native of Senegal, Guinea, &c.

M. temminckii (Smuts). Mr. Beunett described this species from a specimen in the collection made by Mr. Steedman in South Africa; and he stated that his object in calling the attention of the Society to it was to point out the external characteristics of a species known to its original describers by its skeleton alone and a few detached scales; and he characterised it as a *Manis* with a rather short head, a rather wide body; the scales large, and in 11 rows; the tail as long as the trunk, rather less than that in width, and hardly narrower at the subtruncate apex. Length 25½ inches; of the tail 12 inches; width of the back 8 inches; of the tail near the apex 5 inches.

Mr. Bennett observes that the most remarkable features of this

animal are the shortness of the head, the breadth of the body, and the breadth of the tail, which is nearly equal to that of the body, and continues throughout the greater part of its extent of nearly the same width, tapering only slightly towards the end, where it is rounded and almost truncate. Mr. Bennett further remarks that a peculiarity in the distribution of the scales of *M. Temminckii* is the cessation of the middle series of them at a short distance anterior to the extremity of the tail, so that the last four transverse rows consist of four scales each, each of the preceding rows having five. ('Zool. Proc.', 1834.)

Dr. Andrew Smith says that only one solitary specimen of this species was obtained by the expedition before reaching 26° S. lat., and but two more between that parallel and the tropic of Capricorn, though others were known to have been captured in the latter tract, while the travellers were actually traversing it. He thinks it very questionable if the animal be so rare in nature as the result of their experience might incline men to believe. He is of opinion that its extreme scarcity probably arises from its having long been zealously sought after by the natives, who cherish a belief that it either has some influence upon cattle, or, at least, that certain observances in respect of it have an effect upon them. Whenever a specimen is secured it is submitted to the fire in some cattle-pen, apparently as a burnt offering, for the increase of the health and fertility of all cattle which may afterwards enter that fold. Dr. Smith states, that not many years ago a specimen was captured in the northern part of the Cape Colony, which renders it probable that the species was at one time scattered over the whole of South Africa, and that its almost total disappearance from the more southern districts had arisen from causes such as are now operating to effect a similar result in the interior. Here we have another cause for the obliteration of a species. Intolerance of their aggression has wrought up the shepherd or the agriculturist to the destruction of some; but in this case a species is probably dying out under the influence of a superstition.

Dr. Smith relates that when *M. Temminckii* is discovered, it never attempts to escape, but instantly rolls itself up into a globular form, taking especial care of its head, which is the only part that is easily injured. Ants constitute its chief and favourite food, and these it secures by extending its projectile tongue into holes which may exist in the habitations of these insects or which it may itself form; and when, by means of the glutinous matter with which its tongue is covered, a full load has been received, a sudden retraction of the retractor muscles carries both into its mouth, after which the ants are immediately swallowed. ('Illustrations of the Zoology of South Africa.')

Manis Temminckii. (From Smith.)

PANICLE. [INFLORESCENCE.]

PA'NICUM, a genus of Grasses the name of which is applied to one of the species (Millet) by the Romans, and which, Pliny states, is so-called from its flowers being in a panicle; though others derive the name from 'panis,' bread, from its uses as such. The genus contains a very large number of species, which abound in the hot parts of the world, though a few extend to higher latitudes and ascend the cool mountains of hot countries. They are chiefly valuable as pasture grasses, and for their seeds, which form a large portion of the food of the poorer classes of many nations, and thus engage a considerable share of the attention of the agriculturists of those countries.

The genus *Panicum* is distinguished by having a 2-flowered spikelet, with the lower flower masculine or neuter, and the upper hermaphrodite. Glumes 2, unequal, concave, blunt. Mase. paleæ 2, stamens 3, sometimes neuter, the upper palea and the stamens abortive. Fertile flowers, paleæ 2, unequal, concave, the lower one embracing the upper; scales 2; stamens 3; style 2, ovary sessile.

P. miliaceum, Millet, is the best known species, being cultivated in the south of Europe as well as in tropical countries. Two varieties are well known, one brown, the other yellow-coloured, imported from the Mediterranean chiefly for feeding poultry, but forming in the south of Europe as well as in India a portion of the food of the inhabitants. In the latter country it is cultivated in the cold weather with wheat and barley, and the only one of the small grains that is so

at that season of the year. It is the Cheena of the Hindoos, Arab Dukhun, Persian Urzun. *P. Miliare* is another species generally cultivated on an elevated rich soil in the peninsula of India: the seed is one of the sorts of dry or small grain which forms an article of diet of the Hindoos who inhabit the higher lands, and cattle are fond of the straw.

P. frumentaceum, the Shama or Samwuk of the natives of India, is a wholesome and nourishing grain, and forms there an article of diet chiefly of the lower classes. There are several varieties of it, which yield from 50 to 60 fold; it delights in a light, tolerably dry, rich soil; the same ground yields two crops between the first of the rains in June, July, and the end of January, in the Circars, but only one crop in the northern provinces. Besides these, which are the most commonly cultivated species, the grains of other species of *Panicum* growing in a wild state are collected, and form articles of diet with the poorer classes of the natives of India, as of *P. floridum* (Burtce), *P. Hlopus* (Koorce), *P. hispidulum* (Dhand).

The uses of this genus are not confined to its grain, for the herbaceous part of several species forms the most valuable pasture grasses of the hot countries both in the Old and New World. Some of the species of *Panicum* of the Brazils are of gigantic stature, and yet tender and delicate in their herbage. The Coapim de Angola of Brazil grows 6 or 7 feet high, and other equally gigantic species constitute the field crops on the banks of the Amazonas; while *P. maximum*, or Guinea Grass, forms the most valuable pasture for cattle in Jamaica. This is said to have been introduced into that island from the coast of Africa, the seeds having been transmitted as food for some birds which were sent to Chief Justice Ellis. The straw of several of the species is esteemed as fodder for cattle in India, but no pasture grass in any country is probably more highly thought of than the Doob of India, which by the Brahmans is held sacred to Ganesha (Janus?) under the name of Doorwal. This is fortunately the most common species throughout India, and forms probably three-fourths of the food of their horses and cows. It is seldom cultivated, but Europeans in the northern parts frequently form lawns by planting small pieces of this grass, which forms excellent hay. The usual mode of obtaining it is to send out the grass-cutters into the uncultivated parts of the country, who scrape off the ground the creeping stems and leaves of this species, which is easily distinguished by its smooth and creeping habit; its spikes being fasciated and digitate, filiform, from 1 to 2 inches long, with the flowers disposed in two rows on the under side. It is the *P. dactylon* of botanists, and occurs also in England.

PANOPEA. [PYLORIDEÆ.]

PANORPA. [NEUROPTERA.]

PANORPES. [BEMEX; CHRYSIDIDEÆ.]

PANSY, a corruption of the French word *Pensee*, is a name now chiefly applied to the garden varieties of *Viola tricolor*, *V. Alata*, and others, which are commonly cultivated under the name of Heart's-Ease. [VIOLA.]

PANTHER. [FELIDEÆ.]

PANTHOLOPS. [ANTILOPEÆ.]

PANTODA'CTYLUS, a genus of Saurian Reptiles.

PAPA'VER, a genus of Plants the type of the natural order *Papaveraceæ*. The history of this, like that of many other cultivated plants, is little known, as well as the time when it began to be cultivated for the sake of its inspissated juice, though it was well known to the Greeks, and cultivated at very early periods on account of its seeds. (Theoph., lib. ix. cap. xiii., ed. Bodæus and Stapel, p. 1097.)

Some authors are of opinion that it is the *Mikwæ* of Dioscorides, and that the kind with black seeds was called 'Aryia, and that with white seeds 'Hæperos; and that it is the juice of this plant which Hippocrates recommends under the name of *ōrds mikwos*, or 'juice of the poppy.' Pliny (xx. c. 18) uses 'opium' to express the inspissated juice of the poppy. Sprengel, in his 'Hist. Rei Herb.', i. p. 176, quotes Diosc., lib. iv. c. 65, as referring to *Papaver somniferum*, and to *P. Rhæas*; but in his edition of that author (ii. p. 600) he mentions only the latter plant; hence we may infer that he conceives the former to have been unknown, as he nowhere else mentions it. We do not in this instance get the same degree of assistance as in many others from Arab authors. Opium is described by them under the name of Afeyoon, while Apaynum is quoted by Dr. Ainslie as its Sanscrit name. The poppy plant is described by the Arabs under the name of Khushkhush, while the Sanscrit is Chosa; and the Persian and Hindoo, Post. The species of *Papaver* are chiefly found in European countries; but a few species extend to the Caucasus and Armenia, and one species grows in the Himalayas, though Egypt is the country where we find the earliest notice of the opium poppy. This species is now common in most parts of Europe, but having been so long cultivated, it may appear indigenous in many countries where it has only escaped from cultivation. It is, as is well known, extensively cultivated in India, but it can nowhere be seen in a wild state, as the climate is too hot to support it except for a few months in the year.

The genus *Papaver* has two convex deciduous sepals; petals 4; stamens numerous; style wanting; stigmas 4 to 20, radiating and sessile upon a disc which crowns the germen; capsule obovate, 1-celled, opening under the crown of the stigmas with short valves; placentæ intervalvular, incomplete; flower-stalks inflexed at the apex before the flowers have expanded; the flowers of all are large and showy, but

last a short time. Herbageous plants abounding in milky juice. The species are numerous.

The English species are distinguished as having a rough and a smooth capsule; of the former, *P. hybridum* has an obovate globose capsule, and *P. Argemone*, an elongated club-shaped capsule; of those with smooth capsules, *P. Rhæas* and *P. dubium*, the former has a globose and the latter an oblong capsule.

P. somniferum, or the White Poppy, is a native probably of Asia Minor, or of some part of the Persian Region of botanists, but having been so long cultivated, it is found wild in many parts of Europe. The species is distinguished by its obovate or globose capsules, smooth as well as the calyx, the stem smooth and glaucous, leaves embracing the stem incised and repand, with subobtuse teeth. There are two distinct varieties, which by some botanists are considered to be distinct species: the dark, the red-flowered, and black-seeded is called by Gmelin *P. somniferum*; and the white-flowered with white seeds, *P. officinale*. The latter is characterised as having an ovate globose capsule; foramina under the stigma either none or obliterated; peduncles solitary. The former (*P. somniferum*) has globose capsules, opening by foramina under the stigma; seeds black; peduncles many. The flowers are usually red of different tints, though sometimes white. Dr. Royle states that he has seen only the white-flowered variety in the plains of India, and the red-flowered in the Himalayas, and both cultivated for the sake of the opium.

The poppy is cultivated in many parts of Europe on account of its seeds, which yield a bland oil much esteemed in France; and in this country chiefly on account of the capsules, which are used medicinally. It is extensively cultivated in Turkey and Asia Minor, Egypt, Persia, and India, on account of its inspissated juice, so well known as opium, though this is occasionally prepared also in Europe.

The cultivation of the poppy is very simple, though the weeding requires care, and the plants must not be crowded too much together. They are carefully watered and manured, the watering being more copious as the period of flowering approaches, and until the capsules are half grown. [OPIMUM, in ARTS AND SC. DIV.]

PAPAVERACEÆ, *Poppyworts*, a natural order of Hypogynous Exogenous Plants. The species are readily known by their deciduous calyx, usually tetramerous flowers, indefinite hypogynous stamens, and parietal placentæ; added to which, they have leaves without stipules, and their stems discharge a turbid white, yellow, or orange-coloured juice when wounded. Their seeds moreover contain a bland oil, lodged in a copious albumen, within which is stationed a minute embryo. They consist for the most part of herbs, which are usually of only annual duration; but a few are shrubby, the most remarkable case of that kind being a genus called *Dendromecon* a native of Cali-

White Poppy (*Papaver somniferum*).

1, the stamens and pistil; 2, a transverse section of the capsule; 3, a seed; 4, the same divided, so as to show the embryo.

ornia, which is a true shrub, with the aspect of a *Cistus*. The greater part of the species inhabit the temperate parts of the Old World; but a few also occur in Australia, at the Cape, and in South America. Their active qualities are usually deleterious, but are for the most part of little moment, except in the case of the *Papaver somniferum*, or Opium Poppy. [PAPAVER.] It is however probable

NAT. HIST. DIV. VOL. IV.

that in most cases the milky juice is narcotic, and the oil of the seeds harmless. An apparent exception to the latter statement occurs in *Argemone Mexicana*, the seeds of which are said to be narcotic, especially when smoked; but it is probable that in this case it is in the coats of the seed that the poisonous principle resides, rather than in the oil itself.

Some *Papaveraceæ* have no petals, as *Bocconia*, thus corresponding with *Thalictrum* and other apetalous *Ranunculaceæ*, with which order they are closely connected through *Platystemon*, a Californian annual with disjointed carpels. They are also related to *Nymphaeaceæ* and *Sarraceniaceæ*. The order embraces 18 genera and 130 species. A description of the British species is given under PAPAVER, GLAUCIUM, MECONOPSIS, ROEMERIA, CHELIDONIUM.

PAPAW. [CARICA.]

PAPAYA'CEÆ, *Papayads*, a small natural order of Exogenous Plants. The species are apparently allied to *Cucurbitaceæ* and *Passifloraceæ*, with the former of which it corresponds in its gourd-like fruit, with parietal placentæ, and in its disunited sexes; while it approaches the latter also in placentation, in its superior succulent fruit, and in the structure of its seeds. The order is remarkable in its fructification for having monopetalous male flowers and polypetalous females, and in its vegetation for its simple unbranched stems, growing only by the gradual development of a terminal bud. The species of most importance in this order is the Papaw-Tree, *Carica Papaya*. [CARICA.] The order as at present constituted contains 8 genera and 25 species.

Papaw-Tree (*Carica Papaya*).

1, a monopetalous male flower; 2, a polypetalous female flower; 3, a transverse section of the ovary; 4, a longitudinal section of a seed.

PAPER-MULBERRY. [BROUSSONETIA.]

PAPER-NAUTILUS. [OCTOPODA.]

PAPILIO, a genus of Lepidopterous Insects, established by Linneus, and divided by subsequent entomologists into many groups and genera. It includes that very natural and beautiful assemblage of insects popularly known as Butterflies. The first section of *Lepidoptera*, named *Rhopalocera* (club-horned) in the arrangement of Boisduval, and *Diurna* in that of Latreille, corresponds with the Linnean genus *Papilio*. The insects composing it have mostly thin and elongated antennæ terminated by a club. They are all day-fliers. Their larvæ, which are variously shaped, have six pectoral, eight abdominal, and two anal feet. The pupæ are usually angulated and, with a few exceptions, naked. The perfect insect varies in size from less than an inch across the wings when expanded, to nearly a foot in breadth. Equally variable are their colouring and outlines. They

are short-lived. Their powers of flight are very great, and the mode of flight varies in the several species. The males are usually more gaily coloured than the females.

The arrangement according to natural relations of the species of butterflies has been attempted by many naturalists. Even in the time of Linnaeus the number and variety of known species was such as to render it necessary to subdivide his great genus *Papilio*. He constituted five principal groups. In the first of these, named *Equites*, he included such butterflies as have the fore wings longer from the posterior angle to the apex than to the base. In the second, the *Heliconii*, the wings are narrow, entire, and almost naked. The *Danai* have also entire wings. The *Nymphales* have dentated wings; and the group of *Plebeii* is composed of small species, whose larvæ are usually short and thick.

Dr. Horsfield has proposed an arrangement of these insects into five groups or stirpes, characterised by the peculiarities of the larvæ. He names the first stirps Vermiform, the second Luliform, the third Scolopendriiform, the fourth Thyasouriform, and the fifth Anopluriform.

Perhaps the most valuable arrangement of the Diurnal *Lepidoptera* is that proposed by M. Boisduval, who divides them into three great sections and fifteen tribes, as follows, founding his classification upon the characters of the larvæ:—

Section I. *Succincti*.

Chrysalis attached by the tail, and also girt.

A. Six feet in both sexes: caterpillars elongated.

Tribe 1. *Papilionides*.

2. *Pierides*.

B. Six feet in both sexes: caterpillars short.

Tribe 3. *Eumenides*.

4. *Lycenides*.

C. The males with four feet, the females with six. Caterpillars short.

Tribe 5. *Erycinides*.

D. Four feet in both sexes: caterpillars elongated.

Tribe 6. *Peridromides*.

Section II. *Suspensi*.

Chrysalis suspended by the tail only.

A. Ungues of tarsi simple. Four feet in both sexes.

Tribe 7. *Danaides*.

8. *Heliconides*.

B. Ungues of tarsi strongly bifid. Four feet in both sexes.

Tribe 9. *Nymphalides*.

10. *Brassolides*.

11. *Morphides*.

12. *Satyrides*.

13. *Biblidides*.

C. The males with four feet, the females with six. Caterpillars elongated.

Tribe 14. *Libythides*.

Section III. *Involuti*.

Chrysalis inclosed in a cocoon.

Tribe 15. *Hesperides*.

(See Boisduval in the *Suites à Buffon* and his other works; Wood, *Index Entomologicus*; Horsfield, *Catalogue of Lepidoptera in the Museum of the East India Company*; and Westwood's *Modern Classification of Insects*, where an enumeration of the principal treatises on butterflies may be found.)

PAPILIONACEÆ, a fanciful name given to the principal division of Leguminous Plants, from an imaginary resemblance between their flowers and a *Papilio*, or Butterfly. [FLOWER; LEGUMINOSÆ.]

PAPPUS. [CALYX.]

PAPYRUS, a genus of Plants belonging to the natural order *Cyperaceæ*. This generic term has been derived from the name of a water plant, whose soft cellular flower-stem afforded the most ancient material from which paper was prepared, and our English word paper is derived from it. It has a stem from 3 to 6 feet high, with 3 acute angles, one of which, according to Bruce, is always opposed to the current of the stream in which it grows, as if to break its force. Its leaves are long and grassy, with a sharp keel. The flowers, which are green, are produced in very large compound umbels, with extremely numerous drooping triangular slender radicle, terminated by very long filiform involucreal leaves, within which are placed the spikes of flowers, each consisting of from 6 to 13 florets. It has been regarded as a species of *Cyperus*, and called *C. Papyrus*. It is also considered a distinct genus, and is named *Papyrus antiquorum*. It is a very common plant in Abyssinia, Egypt, and Syria, and is also met with in Calabria and Sicily; in gardens it is not uncommon. It inhabits both stagnant waters and running streams, and, independently of its ancient employment in the fabrication of paper, has been applied to other uses. The flowering stems and leaves are twisted into ropes; the roots are sweet, and have been employed as food. In Abyssinia boats are constructed from it, according to Bruce. In Syria the plant is called *Labeer*.

PARACENTROSTOMATA. [ECHINIDÆ.]

PARACEPHALOPHORA. [MALACOLOGY.]

PARADISE, GRAINS OF. [AMOMUM.]

PARADISEA. [BIRDS OF PARADISE.]

PARADOXI/DES. [TRILODITES.]

PARAGUAY TEA. [ILEX; TEA, PARAGUAY.]

PARALLEL ROADS OF GLEN ROY. Glen Roy and several other valleys of the Highlands of Scotland exhibit very distinctly a series of parallel and nearly horizontal lines, embracing the sides of the hills and entering many of the lateral glens, at levels from a few to several hundred feet above the general bed of the valley. The nature of these terraces, or roads, has been the subject of much discussion amongst geologists, of which we propose to give an outline.

Glen Roy is a valley in the district of Lochaber, whose headwaters gather on a wild mountain tract near the source of the Spey. The water of Roy runs nearly south, and joins the Spean, which turns westward to enter the Great Valley of Scotland, below the south-western extremity of Loch Lochy. Passing from Fort William to the foot of Glen Roy, we have porphyry, gneiss, mica-schist, primary limestone, and quartz-rock, much disguised by diluvial accumulations. Glen Roy divides, not indeed exactly, the mica-schist and gneiss systems, the former predominating on the western and the latter on the eastern side. About the source of the Spey is a limited tract of granite; and the low summit of drainage between Glen Roy and Glen Spey is formed of this rock. From this flat and hoggy summit the descent is gradual to Loch Spey on the east, and sudden into Glen Roy on the west. Upper Glen Roy, as MacCulloch terms the part near the head, is an oval valley, about four miles in length and one or more in breadth, and bounded on two opposite sides by high mountains, yielding two streams from the north-west and south-east, which meet near the middle of the valley. From their junction the united water of Roy flows in a gradual manner to the south-west for about two miles, when the valley contracts to a low rocky pass, in which the river runs a troubled course, and then emerges into the wide and long and rather sinuous valley of Lower Glen Roy. At the extremity of the rocky gorge which separates the upper from the lower glen, MacCulloch directs attention to a remarkably flat rock; and observes that above this gorge, in Upper Glen Roy, no distinct terrace or shelf was seen, but a line was noticed extending from near the junction of the streams which form the Roy towards Loch Spey; and it was proved by the spirit-level that this line was level with the remarkable flat rock at the gorge which terminates Upper Glen Roy, and also with the uppermost of three such lines, terraces, or shelves in Lower Glen Roy. Passing from Upper to Lower Glen Roy, the single line of Upper Glen Roy ascends from the valley, and girdles the sides of the hills, right and left, with seemingly higher and higher sweeps, and is followed by two other perfectly parallel and equally continuous lower lines, till Glen Roy expands into Glen Spean. Here the two upper lines end; but the lower one appears on the north and south sides of Glen Spean as far towards the source of the river Spean as the singular pass of Muckul, and turns southward a little way up the Gulban River, and still farther along the sides and round the head of Loch Treig. In a westward direction this line continues down Glen Spean on both sides, about half the distance from the Roy to the Lochy, and then ceases; nor has it been noticed in the Great Valley between Fort William and Inverness. Another line however, a few feet higher than the highest in Glen Roy, appears in the upper parts of Glen Gluoy, which, running parallel to Glen Roy, enters Loch Lochy. Mr. Darwin notices a line in another smaller tributary to Loch Lochy, near Kilfinnin; and describes a short terrace which appears on the south side of Loch Spey, about sixty feet above that lake, and higher than the highest terrace of Glen Roy. Sir D. Brewster has also observed shelves resembling those of Glen Roy in a part of the valley of the Spey, several miles below its source.

The elevation of these lines above the sea is known approximately, but not with the exactness demanded by a phenomenon so curious in itself and so fertile of subjects for geological speculation. In the following table we have combined the statements of MacCulloch, Sir T. L. Dick, and Mr. Darwin. The last writer thinks Dr. MacCulloch's measures of the terraces in Glen Roy 100 feet in excess:—

Relative levels of the various lines in Scotland.

	Darwin.	Dick.	MacCulloch.
South of Loch Spey	—	—	—
Kilfinnin	1202	—	1302
Glen Gluoy	—	292	1274
Upper Terrace, Glen Roy	1162	290	1262
Middle Terrace, Glen Roy	—	200	1182
Lower Terrace, Glen Roy	—	0	972
Loch Lochy	82	—	—
The sea at Loch Eil	0	—	0

The lines, shelves, or terraces (for each of these names is locally appropriate) must not be confounded with the more ordinary occurrences of short successive level terraces of gravel, or with the longer declining gravel-banks which margin the sides of many valleys where they pass from the mountains to plain countries or the sea; they should be distinguished also from the similar little terrace-heaps which often appear at the summits of drainage in mountain countries. Such

gravel-terraces are seen both at the summit and at the foot of Glen Roy, and in each case appear intelligible as the result of fluvial action at higher levels than the present water-channel.

The lines of Glen Roy and the other valleys are not short protruding terraces connected with the several lateral affluents, nor declining planes of gravel, but almost perfectly continuous shelves, sloping toward the valley from a level line, and almost perfectly parallel through all the various windings of their linear extent, and round the hollows and projections of the hills, whether these are small or great, sudden or otherwise; and each respective range, on one side of the glens, is exactly on the same level with that corresponding to it on the other side. This almost perfect horizontality and continuity of range is the grand feature of the phenomenon, and though easily admitted on ocular inspection, it is satisfactory to know that Sir T. L. Dick has proved it by careful levelling with Mr. Maclean on each of the shelves in Glen Roy. With such characters it is not wonderful that these mysterious works of nature should be supposed the effect of art, and the term of Parallel Roads is far from inapt, and is certainly very descriptive.

The shelves generally appear distinctly and even sharply defined when viewed from below or from a distance; but when inspected more narrowly, they appear very indistinct, and one may be actually treading on a shelf without being aware of it. This arises in a great measure from the fact that the surface of the shelves is far from level, but being often a little concave above and a little convex below, easily on a near view loses itself in the general slope of the mountain.

Sir T. L. Dick represents the general figure of a section of the shelf thus:—

Dr. MacCulloch gives many representations on a small scale, which show the really sloping character of the shelf or terrace, the angle of declination from the horizon varying from 12° to 30° , while the breadth of the terrace part varies from 10 to 70 feet. Where the slopes of the lines are steepest, their surface is narrowest; and generally where the ground slopes the least the terraces are the broadest. A real profile of one part is given below by the black line.

According to Mr. Darwin's view of the relation between the actual form and the original outline of the fundamental rock, one part will appear to be formed by excavation of the rock, and another part by accumulation of detritus, very slightly projecting beyond the slope of the mountain. MacCulloch's drawings indeed represent the shelves as hardly in any case projecting into a mound. Another part is drawn to represent a valley terrace composed of gravel, to which the shelves, (where they cross valleys) occasionally unite on a level, and thus form broad expansions.

"The shelves entirely disappear when crossing any part of the mountains in which the bare rock is exposed; for loose matter cannot accumulate there, and the rocks themselves, from their laminated structure, do not readily become worn into any regular form. They likewise disappear when crossing any part which is greatly inclined; for their own slope then coincides with that of the alluvial covering, and cannot be distinguished from it." (Darwin.)

The actual surface of the shelves is very irregular: they are composed of the same kind of alluvium with that covering the whole surface of the mountain. (Darwin.) They commonly contain rounded pebbles, and are in many places covered with large masses of stone, some of them many tons in weight, lying for the most part quite detached on the surface, and having their acuter angles rounded off in the greater number of instances; in short, in every respect resembling these fragments generally found strewn on the margin and on the shallow edge of alpine lakes. In some places, where the stones are

large and the shelf narrow, a single block covers its whole breadth. When rock appears anywhere on a shelf, its angles are also rounded. (Sir T. L. Dick, from whom the above description is taken, states that the soil above the highest line of shelf is materially different from that below, which has more gravel, pebbles, and alluvial clay; but Mr. Darwin's subsequent observations do not confirm this.) The cases are few in which the solid rocks are much worn away in this manner; indeed they are not visible on the shelves. Some of the blocks of stone on the shelves have fallen from the heights above; others belong to far-removed sites, and are in fact erratic boulders. Among these latter are large granite blocks.

It must be evident, from the foregoing description, that the Parallel Roads of Glen Roy, and the lines resembling them or connected with them in the neighbouring regions, are marks of the ancient level of water filling the valleys to their summits or nearly so, and extending towards their mouths till within a few miles of the sea, or the great interior valley of Scotland. As many lines as we see, so many successive effects are there of water oscillating about particular levels through all the extent of the lines. This is freely admitted by all writers and all observers on the subject. Sir T. L. Dick, who gives abundance of illustrations of similar shelves being actually formed on the steep sides of modern lakes, adopts the hypothesis which most easily and obviously suggests itself, and ascribes the lines in all the valleys to the operations of a lake whose waters were successively lowered. Dr. MacCulloch discusses very ably two other modes of watery action whereby the lines may be supposed to have been formed; first, by a sort of local deluge filling the valley; secondly, by the excavating power of water in a valley previously filled by alluvial sediments to a particular height; and shows each hypothesis to be unsuitable and untenable.

On the view of the lacustrine origin of the parallel roads it is to be conceived that a lake had existed at the uppermost level of Glen Roy for so long a period as to have accumulated on its margin that alluvium which now forms the uppermost of the lines in question, and that by a subsequent sinking through two successive and similar periods, the two lower ones had been formed in the same manner. (MacCulloch.)

Mr. Darwin explains the phenomenon of these roads on the same principle as Sir Charles Lyell explains the formation of the parallel roads of Coquimbo in South America. Sir Charles says—"The three parallel roads were formed by the waves of the Pacific, and not by the waters of a lake; in other words, they bear testimony to the successive rise of the land, not to the repeated fall of the waters of the lake."

From a series of appearances below the lowest shelf of Glen Roy, continued into Glen Spean—such as the nature and distribution of detritus, the form and position of many short terraces, some related to the shelf or ancient beach, others unconnected with the actions of the streams now running—Mr. Darwin concludes, apparently with reason, that every appearance in the sides of Glen Roy and Glen Spean, below the lowest shelf, will be explained on the supposition of a gradually subsiding sheet of water which received detritus from lateral streamlets. By observations of accumulated sand and pebbles in other valleys, as the sides of Loch Ness, Loch Dochart, &c., Mr. Darwin endeavours to extend this inference to a large portion of the Highland valleys, where no horizontal shelves make it a matter of certainty. Having rejected the hypotheses of separate and connected fresh-water lakes, on account of the difficulties attending them, which even in a single case are great (but if extended to many of the Highland valleys, insurmountable), Mr. Darwin adopts the alternative, that it was the sea-water, in the form of narrow arms or lochs, such as those now deeply penetrating the western coast, which once entered and gradually retired from these several valleys.

That there has been a change of level between the land and sea in Scotland, to the extent of several hundred feet, is proved by Mr. Smith's and Mr. Prestwich's observations at Banff and near Glasgow and other places; and, thus fortified, Mr. Darwin traces in hypothesis the effect of an elevation of the land equally or by intermitting effects, showing that by this means the main phenomena of the Lochaber valleys would certainly be occasioned.

Objections to this speculation easily arise.—Why, for example, are shelves, the marks of intermission in the elevating forces, which affected a large area with extraordinary equality, confined to a few valleys? Why, after encircling in complete belts the upper ends of the valleys, do they cease toward the outlets? Why has Glen Roy three shelves, and the neighbouring Glen Gluoy but one, and that at a different level from any in Glen Roy? Why, if the sea for so long a time laved the mountain sides, are no marine shells found except at comparatively small elevations?

Mr. Darwin answers to these objections: first, that the conservation and even the original formation of heaves (for such the shelves certainly are) might rather be the exception than the rule, requiring particular slopes, loose materials, and freedom from erosive currents; secondly, that the difference of level between the Glen Gluoy shelf and the highest in Glen Roy may be explained as an effect of unequal tidal oscillation; thirdly, that instances of the absence of marine shells from the upper parts of marine deposits occur in Sweden, Scotland, and elsewhere.

Such are the speculations to which the Parallel Roads of Glen Roy have given rise. The progress of modern geology has revealed so many proofs of the instability of the level of land and sea, and so many examples in which this change of level has been occasioned by a real displacement of land, that it is probable Mr. Darwin's explana-

roads being the moraines which are left by the melting of these masses of ice.

(MacCulloch, in *Geological Transactions*, vol. iv.; Sir T. Lauder Dick, in *Transactions of Royal Society of Edinburgh*, vol. ix.; Darwin, in *Philosophical Transactions for 1839*.)

View of the Parallel Roads of Glen Roy. Sketched from nature, in 1826, by Professor Phillips.

Map of the Parallel Roads of Glen Roy.

tions, drawn from the most general consideration, will be preferred to those which are more obviously suggested by the features of any one of the terraced glens.

It has been also suggested more recently that the Parallel Roads of Glen Roy have been formed by the action of glaciers; the parallel

PARAMICIPPA. [MAIDE.]

PARAMITHRAX. [MAIDE.]

PARASITICAL PLANTS are those which grow upon the living parts of other plants, from whose juices they derive their nutriment, a circumstance by which they are immediately distinguished from

false parasites, or Epiphytes, which merely fix themselves upon other plants without deriving food from them.

Parasitical Plants, properly so called, are extremely numerous, and belong to various parts of the vegetable kingdom. Some attack their victims externally, others are insidiously introduced into the interior, where they flourish until they pierce through the skin, place themselves in communication with the open air, and disseminate themselves; hence, physiologists divide them into intestinal and superficial. The former are exclusively fungi, and appear under the forms to which the popular names of mildew, rust, brand, smut, &c. [FUNGI; ENTOPHYTA; MILDEW] are applied; it is among the latter that parasites of so many different kinds are met with. These are again divisible into such as have true leaves, green, and capable of acting, in the manner of ordinary leaves, as organs of respiration and digestion; and such as have scales, brown or some colour not green, in the room of true leaves, without any powers of digestion or assimilation, except in a low degree. The first, or leafy or green parasites, elaborate their food for themselves; the second, or scaly or brown parasites, obtain it in a state of elaboration from other species.

Green leafy parasites belong exclusively, as far as is yet known, to the genera *Viscum* and *Loranthus*. [VISCUM; LORANTHUS.]

Brown scaly parasites always attack the roots of plants, and their underground habits have caused them to be little examined. The most common species in Europe are various kinds of *Orobanchæ*, which attack hemp, clover, lucern, and many other crops; *Monotropa* and *Lathræa*, which infest the roots, the first of the fir, and the second of the ash; in other countries *Rhizantha* abound [RHIZANTHÆ], and probably many others of which we have no sufficient knowledge. To these are usually added *Neottia Nidus Avis* and *Corallorhiza innata*, two Orchidaceous plants, concerning whose real habits we have however no precise information. The best account of the manner of growth of brown parasites is by Mr. Bowman, who studied with care the habits of *Lathræa squamaria*. In that plant he found that the fibres of the roots are each tipped by a tubercle about as large as a pin's head, which tubercle attaches itself to the roots of the ash-tree, and gradually buries itself in the bark until it gets into communication with the wood, from which it derives its nutriment. One of the most remarkable peculiarities of such plants as these is the constant absence of all green colour, although exposed to the brightest light. *Orobanchæ* grow in pastures and open places, and yet their scale-like leaves indicate no visible tendency to any colour except brown or purple; and in *Lathræa* Mr. Bowman has shown that the same thing always happens, although the plants associated with it in its growth are as green as usual. Connected with this is another curious property, that of resisting the attraction of light, towards which all the green parts of plants irresistibly tend; in *Lathræa*, when the flower-stems have acquired their full stature, they are always perpendicular, and in groups of 20 or 30; in the most umbrageous situations the rows of flowers, which have always a unilateral direction, are as frequently turned from the only side on which light is admitted as towards it.

PARASYTES NAGEURS. [SIPHONOSTOMA.]

PARDALOTUS. [PIPIRIDÆ.]

PAIREIRA. [CISSAMPPELOS.]

PARELLA (sometimes written 'Perelle'), the French name of a Crustaceous Lichen, *Lecanora Parella* of botanists, but which is applied to several species similar to it in habit, and employed for the same purpose, that is, for yielding a rich dye known by the name of Litmus. [LITMUS, in ARTS AND SC. DIV.]

PARENCHY'MA is the term which was applied by the old anatomists to an imaginary substance, through which they supposed the blood at the ends of the veins to be strained. It is seldom now used in animal physiology, but it is retained by botanists to distinguish some forms of cellular tissue. [TISSUES OF PLANTS.]

PAREXUS, a genus of Fossil Fishes. [FISIL.]

PARGASITE. [HORNBLÉNDE.]

PARIAS. [CROTALIDÆ.]

PARIDÆ, a natural family of Perching Birds. [INSESSORES.]

Linnaeus, in his last edition of the 'Systema Nature,' placed the genus *Parus* between *Pipra* and *Hirundo*, in his order *Passeres*.

Latham arranges it also at the end of the same order.

Pennant too gives it a place in the *Passerine* section, between the Warblers and the Swallows.

M. De Lacepède places it immediately before the Larks; M. Duméril in the eighth family of the *Passeres* (*Subulirostres*, or *Raphioramphes*), in company with the Manakins, Larks, and Boc-Fins; M. Meyer, in the third sub-order (*Subulata*) of his fifth order (*Oscines*), between *Alauda* and *Regulus*; Illiger, at the head of the *Passerini*, among the *Ambulatores*, immediately before *Alauda*; Cuvier, among the *Conirostres*, directly after the Larks; Vieillot, in the family of *Egithales* in the tribe *Anisodactyli*; Temminck, in the order *Granivores*, between the Larks and Bunting; and Latreille in the family *Conirostres*, also between the Larks and the Bunting. Selby arranges it between the same two forms.

Mr. Vigors places the genus *Parus* among the *Pipridæ*. [DENTIROSTRES; PIPRIDÆ.]

Mr. Swainson ('Classification of Birds') enters among the Titmice by the American genus *Seiurus*, remarkable for the motion of its tail. One species, *Seiurus aquaticus* (Sw.), frequents the sides of streams

and runs upon the ground, whilst another, *S. aurocapillus* (Sw.) is, he observes, confined to damp woods, and runs along the low branches of trees. Here Mr. Swainson sees a change of economy, which, he says, plainly shows that nature has assumed a new form; and as the habit of running along branches of trees is the chief faculty of the Scansorial Birds, or of their representatives, so, he remarks, we may suppose that the group next in succession to the *Motacilline* would possess something of the same characters. These he finds manifested in the genus *Accentor*, and he adverts to an unpublished notice which he heard read at a meeting of the Linnæan Society of London, relating to the habits of an *Accentor* which was killed near one of the public buildings at Oxford, and which was seen to climb so adroitly round the steep abutments of those buildings as to baffle for a considerable time the aim of the person who shot it. He also states that he has seen the common Hedge-Sparrow frequently hop along the whole length of a strong oblique branch, pecking into the crevices of the bark so as to remind the observer of a scansorial creeper, or of a Woodpecker; and he makes the Titmice a sub-family of the *Sylviadæ*. [SYLVIADÆ.]

Mr. Yarrell places the *Paridæ*, or True Tits, between the Warblers, *Sylviadæ*, and the *Ampelidæ*, the latter being represented by the Bohemian Waxwing. [BOMBYCILLÆ.]

Prince Bonaparte ('Birds of Europe and North America,' 1838) arranges the *Parinæ* as the seventh sub-family of the *Turdidæ*, placing it between the *Motacillinæ* (Wagtails), and the *Sylvicolinæ*. The following genera are included by the Prince under the *Parinæ*:—

Regulus, Ray (Wren, including Gold-Crests); *Parus*, Linn.; *Mecistura*, Leach (*Paroides*, Brehm—Long-Tailed Titmouse); *Calamophilus*, Leach (*Mystacinus*, Brehm—Bearded-Titmouse); *Egithalus*, Vigors (*Pendulinus*, Cuvier—Penduline Titmouse).

Mr. G. R. Gray ('List of the Genera of Birds,' 1841) makes the *Parinæ* the fifth sub-family of his *Luscinidæ*, and places it between the *Accentorinæ* and the *Sylvicolinæ*. The *Parinæ*, according to him, consist of the following genera:—*Egithalus*, Vig.; *Melanochlora*, Lesson; *Parus*, Linnæus; *Megistina*, Vieill.; *Tyrannulus*, Vieill.; *Sphenostoma*, Gould; *Calamophilus*, Leach; *Orites*, Mæhr (*Mecistura*, Leach; *Paroides*, Brehm—Long-Tailed Titmouse); *Parisoma*, Swainson; *Psaltia*, Temminck; *Egithina*, Vieill.; *Hylophilus*, Temminck.

In this article we shall confine ourselves to those examples of the family which are more commonly known as Titmice.

The following species are found in Europe:—

The Great Tit, *P. major*; the Sombre Tit, *P. lugubris*; the Siberian Tit, *P. sibericus*; the Toupet Tit, *P. bicolor*; the Azure Tit, *P. cyaneus*; the Blue Tit, *P. caeruleus*; the Coal-Tit, *P. ater*; the Marsh-Tit, *P. palustris*; the Crested Tit, *P. cristatus*; the Long-Tailed Tit, *P. caudatus* of authors (genus *Orites*); the Bearded Tit, *P. biarmicus* (genus *Calamophilus*); the Penduline Tit, *P. pendulinus* of authors (genus *Egithalus*).

The Great Tit, the Blue Tit, the Crested Tit, the Coal-Tit, the Marsh-Tit, the Long-Tailed Tit, and the Bearded Tit, are British.

There is little doubt that the Tits are the *Αἰγθαῖοι* of Aristotle. The Great Tit, the Long-Tailed Tit, and the Blue Tit, are referred by Belon to the *Αἰγθαῖος*, the *Αἰγθαῖος ἔτερος*, and the *τρίτος Αἰγθαῖος* of that author, and we think with good reason.

The Great Tit, the Blue Tit, the Coal-Tit, and the Marsh-Tit, are too well known to require description; but a sketch of their habits may not be unacceptable. White, speaking of the English Tit, says:—"Every species of titmouse winters with us: they have what I call a kind of intermediate bill between the hard and the soft, between the Linnæan genera of *Fringilla* and *Motacilla*. One species alone spends its whole time in the woods and fields, never retreating for succour in the severest seasons to houses and neighbourhoods; and that is the delicate Long-Tailed Titmouse, which is almost as minute as the Golden-Crowned Wren; but the Blue Titmouse, or Nun (*P. caeruleus*), the Coal-Titmouse (*P. ater*), the Great Black-Headed Titmouse (*Fringillago*), and the Marsh-Titmouse (*P. palustris*), all resort at times to buildings, and in hard weather particularly. The Great Titmouse, driven by stress of weather, much frequents houses; and in deep snows I have seen this bird, while it hung with its back downwards (to my no small delight and admiration), draw straws lengthwise from out the eaves of thatched houses, in order to pull out the flies that were concealed between them, and that in such numbers that they quite defaced the thatch, and gave it a ragged appearance. The Blue Titmouse, or Nun, is a great frequenter of houses, and a general devourer. Besides insects, it is very fond of flesh; for it frequently picks bones on dunghills: it is a vast admirer of suet, and haunts butchers' shops. When a boy, I have known twenty in a morning caught with snap mouse-trap baited with tallow or suet. It will also pick holes in apples left on the ground, and be well entertained with the seeds on the head of a sun-flower. The Blue, Marsh, and Great Titmice will, in very severe weather, carry away barley and oat-straws from the sides of ricks." ('Selborne.')

We can confirm, if confirmation were needed, the account of this admirable observer relative to the straw-extracting labours of the Great Tit. The thatch of a root-house in Gloucestershire was nearly destroyed by those fly-seekers. But they have more to answer for than fly-catching: they are small-bird murderers, and frequently kill

their victims by repeated blows on the head with their strong, sharp, and hard beak, for the sake of feasting on the brains.

The Great Tit, without any compass to speak of, is a songster, not unadmired by some for its few but lively notes heralding the spring early in February. The quatrain in the 'Portraits d'Oyseaux' is loud in its praise:—

"Au temps d'Autonne li y a des mesanges
En grand foison, qui hanient par les boys;
Et font des œufs douze ou quinze par fois;
Oyseaux petits, et qui chantent comme anges."

The habits of the Blue Tit are recorded by White with equal truth. This is the bird that fights so stoutly pro aris et focis, hissing like a snake or an angry kitten when her nest in the hollow of some decayed tree is invaded by the school-boy, who, if not deterred by the ominous sounds, often rues his temerity, and draws back his hand with more celerity than he stretched it forth, well pecked by the irritated matron. Hence he calls it 'Billy Biter' by the way, Montagu gives 'Willow Biter' as one of its names. The latter name does not convey much meaning to any one acquainted with the habits of the bird, the former does; may not Montagu have heard it imperfectly?

The gardener who sees this little bird busy about the buds likes it not, and in some parishes a reward has been set upon its head. Mr. Knapp, in his interesting 'Journal of a Naturalist,' notices such a case where the stimulus appears to have operated to some purpose against these innocent little birds, for one item passed in the churchwardens' account was "for seventeen dozen of Tomtits' heads." They may now and then knock off a bud in their busy search for insects, but the great good they do in ridding the plants of these far outweighs any casual harm that may result from their industry.

The song of the Tomtit has but little variety; the vivacity of the bird seems however to have found favour for its song with our neighbours, for the 'Portraits d'Oyseaux' notices it with applause:—

"L'Esté es bôls la mesange bleue est,
Et nous vient voir en Hyver et Autonne,
Le doux chanter d'leelle plaisir donne
A tout esprit, à qui l'escouter plait."

P. caudatus, the Long-Tailed Titmouse. This is the Pendolino, Paronino, Codibugnolo, and Paglia in Culo, of the Italians; Mesange à la Longue Queue and Perd sa Queue of the French; Langschwänzige Meise, Schwanzmeise, and Belzmeise Pfannenstiel, of the Germans; Staartmees of the Netherlanders; Alhtita of the Swedes; Jenaga of the Japanese; Bottle-Tit, Bottle-Tom, Long-Tailed Farmer, Long-Tail Mag, Long-Tail Pie, Poko Pudding, Huckmuck, and Mum-Ruffin, of the English; and Y Benloyn Guyffonhir of the Welsh.

Long-Tailed Titmouse (*Parus caudatus*), male and female. (Gould.)

Male.—Head, neck, throat, and breast, pure white; upper part and centre of the back, rump, and the six middle tail-feathers, deep black; scapulars reddish; belly, sides, and abdomen, reddish-white; quills black; greater wing-coverts bordered with pure white; lateral tail-

feathers white on their external barbs and at their end; tail very long and wedge-shaped. Length, 5 inches 7 or 8 lines.

Female.—A large black band above the eyes, which is prolonged upon the nape, and proceeds to unite itself with the black of the upper part of the back.

Young.—Small black spots on the cheeks and brown spots on the breast; black of the back not so decided. (Temminck.)

This bird is found in Siberia, Russia, and Japan; the whole of Europe; England, Scotland (near Edinburgh at least), and Ireland.

Insects, their larvæ and eggs, form the food of these pretty little birds. When White says that the Long-Tailed Titmouse never retreats for succour in the severest seasons to bouses and their neighbourhood, he must not be supposed to mean that the bird avoids the haunts of men. We have seen in a nursery-garden in Middlesex a whole family of them within a few yards of the nurseryman's cottage, and close to his greenhouse, which visitors were constantly entering; and we have found its exquisitely-wrought nest in a silver fir about eight feet high, in a pleasure-ground in the same county, little more than a hundred yards from the house. Pennant well describes its appearance in flight, when, after stating that the young follow the parents the whole winter, he says, "from the slinness of their bodies, and great length of tail, they appear while flying like so many darts cutting the air. They are often seen passing through our gardens, going progressively from tree to tree, as if on their road to some other place, never making any halt."

Yarrell is equally happy in describing the nest and manners of this interesting little bird. "The nest of this species," says he, "is another example of ingenious construction, combining beauty of appearance with security and warmth. In shape it is nearly oval, with one small hole in the upper part of the side by which the bird enters. I have never seen more than one hole. The outside of this nest sparkles with silver-coloured lichens adhering to a firm texture of moss and wool, the inside profusely lined with soft feathers. The nest is generally placed in the middle of a thick bush, and so firmly fixed, that it is mostly found necessary to cut out the portion of the bush containing it, if desirous of preserving the natural appearance and form of the nest. In this species the female is known to be the nest-maker, and to have been occupied for a fortnight to three weeks in completing her habitation. In this she deposits from ten to twelve eggs, but a larger number are occasionally found; they are small and white, with a few pale red specks, frequently quite plain, measuring seven lines in length and five lines in breadth. The young family of the year keep company with the parent birds during their first autumn and winter, and generally crowd close together on the same branch at roosting-time, looking, when thus huddled up, like a shapeless lump of feathers only. These birds have several notes, on the sound of which they assemble and keep together: one of these call-notes is soft and scarcely audible; a second is a louder chirp or twitter; and a third is of a hoarser kind."

Nest of Long-Tailed Titmouse.

In the 'Portraits d'Oyseaux,' the qualities of this species are thus summed up—

"Ceste mesange est à la longue queue,
Oyseau petit, comme est le Roitelet:
Du demeurant, inconstant, et follet,
Par son hault chant sa voix est bien eogneue."

P. biarmicus, the Bearded Titmouse. This is the Mesange Barbuë ou Moustache of the French; Bartmeise of the Germans; Least Butcher-Bird of Edwards; Reed Pheasant (provincial) of the English; and Y Barfog of the Welsh.

Male.—Black between the bill and the eye, and these black feathers are very long and prolonged on each side on the lateral part of the

neck; head and occiput bluish-ash; throat and front of the neck pure white, which blends on the breast and the middle of the belly into a rosy hue; nape, hack, rump, feathers of the middle of the tail and sides, fine rust colour; great coverts of the wings deep black, bordered with deep rusty on the external barh, and reddish-white on the internal barh; quills bordered with white; feathers of the under part of the tail deep black; lateral tail-feathers bordered and terminated with gray; tail long, much graduated: bill and iris fine yellow. Length, 6 inches and 2 or 3 lines.

Female.—No black moustaches; throat and front of the neck tarnished white; upper parts of the head and body rusty, shaded with brown; on the middle of the back some longitudinal black spots; under tail-coverts bright rusty.

Young at their leaving the nest, and before their first moult, with nearly the whole of the plumage of very bright reddish; a good deal of black on the external barhs of the quills and tail-feathers; on the middle of the hack a very large space of deep black. After the first moult nothing of the deep black of the hack remains but some longitudinal spots.

Varieties.—More or less marked with white or whitish; the colours of the plumage often feebly developed. (Temminck.)

M. Temminck remarks that the *Zahnschäblige Bartmeise* of Brehm is a species or sub-species founded only on individuals which have been long caged, such as may be seen in the Dutch markets, where numbers are sold. Some of these captives come to London, where they may be bought for some four or five shillings a pair. The iris and bill in the living bird are of a delicate orange colour.

It is found in the north of Europe, England, Sweden; Asia, on the shores of the Caspian Sea; nowhere so abundant as in Holland; accidentally, on passage, in France.

Bearded Titmouse (*Parus biarmicus*), male and female. (Gould.)

Dr. Leach had observed the fondness of this species for marshy and reedy spots, the shape of its open cup-shaped nest placed on the ground, and the nature of its food—seeds, insects and their larvae, and small-shelled snails. He had also remarked that the sides of the stomach in this bird were muscular and much thickened, forming a gizzard which the true Tits do not possess; and that this structure of the stomach afforded the power of breaking down the shells of the Testaceous Molluscs—*Succinea amphibia* and *Pupa muscorum*—many of which had been found comminuted therein. Still, from the comparative rarity of this bird in Great Britain, and the impervious nature of its haunts, its habits were comparatively little known. Mr. Hoy and Mr. Dykes have supplied much interesting information on this head.

The former states that the Bearded Tit begins building towards the end of April, and that the nest is composed on the outside of dead leaves of the reed and sedge, intermixed with a few pieces of grass, and lined with the top of the reed. He describes it as generally placed in a tuft of coarse grass or rushes near the ground, on the margin of the dykes, in the fens; and sometimes as fixed among the reeds that are broken down, but never suspended between the stems. Their food, he says, is principally the seed of the reed, and so intent

were they on their search for it, that he had taken them with a bird-limed twig attached to a fishing-rod. When alarmed by any sudden noise, or the passing of a hawk, they uttered their shrill musical notes and coucealed themselves among the thick bottoms of the reeds; but they soon resumed their station, climbing the upright stems with the greatest facility.

Mr. Dykes had an opportunity of examining three specimens, and he found their crops completely filled with the *Succinea amphibia* in a perfect state, the shells unbroken and singularly closely packed together. The crop of one, not larger than a hazel-nut, contained twenty *Succinea*, some of them of a good size, and four *Pupa muscorum*, with the shells also entire. The stomach was full of small fragments of shell in a greater or less degree of decomposition. Numerous sharp angular fragments of quartz which had been swallowed had, with the action of the stomach, effected the comminution of the shells.

Two nests obtained by Mr. Yarrell from the parish of Horsey were sustained only an inch or two above the ground by the strength of the stems of the coarse grass on which they were fixed. Each was composed entirely of dried hents, the finer ones forming the lining; others increasing in substance made up the exterior. Mr. Yarrell states the number of eggs at from four to six, rather smaller than those of the Great Titmouse, and less pointed; $8\frac{1}{2}$ lines long by $6\frac{1}{4}$ lines in breadth; white, and sparingly marked with pale red lines or scratches. ('British Birds.')

P. pendulinus, the Penduline Titmouse. This is the *Rémiz* or *Mésange de Pologne* of the French, and *Beutel Meise* of the Germans.

Male.—Bill black, straight, a little elongated, and pointed; tail short; top of the head and nape pure ash-colour; forehead, space between the eye and the bill, region of the eyes, and feathers of the orifices of the ears, deep black; back and scapulars reddish-gray; rump ash-colour; throat white, the other lower parts whitish with rosy tints; coverts of the wings chestnut, bordered and terminated with whitish-rusty and white; wings and tail blackish, bordered with whitish-rusty; tail-feathers terminated with white; iris yellow. Length 4 inches 3 or 4 lines.

Female.—Rather less than the male; the black on the forehead not so large nor so pure; the band which passes over the eyes and terminates at the ears bluish-black; ash-colour of the head less pure; upper parts more clouded with rusty, but there is a yellowish tint on the middle of the belly.

The Young up to their first moult have the colours brighter; they have not the forehead black.

Penduline Titmouse (*Parus pendulinus*), and nest.*

It is found in the southern and eastern provinces of Europe principally; also in Russia, Poland, Hungary, Austria (along the banks of the Danube, where it breeds), the south of France, and Italy.

M. Temminck has placed this species, together with the Bearded Tit, in his second section of Titmice, the Riverains; and indeed the Penduline Titmouse, both in habits and in the choice of its food, has many points in common with the other species above described. Like the Bearded Tit, the Penduline Titmouse haunts the reedy banks of rivers, or the margins of wide-watered shores; and its food consists not only of the seeds of the reeds, but of aquatic insects and molluscs. It derives its name from its pensile purse-like or flask-like nest, generally suspended at the end of some willow twig or other flexible branch of an aquatic tree. This skillfully-wrought cradle is woven from the cotton-like wool or down of the willow or poplar, with an opening in the side for the ingress and egress of the artificers and their young, and mostly overhangs the water; sometimes however it is interwoven among the reed-stems. The eggs, which are pure white marked with some red spots or blotches, are generally six in number.

P. xanthogenys has the head with a full crest of black feathers; occiput, superciliary stripe, and cheeks, yellow; ear-coverts black; back olive; wings and tail black, the former spotted, and the latter tipped with white; a broad black line passing down the throat, and extending along the middle of the abdomen; sides of the chest and flanks pale-yellow; bill and feet black; size rather less than that of the Greater Tit, *P. major*. (Gould.)

This bird is a native of the Himalaya Mountains.

Parus xanthogenys. (Gould.)

P. atricapillus, the Black-Cap Titmouse. The male has the upper aspect of the head, nape, chin, and throat, velvet-black. A white line from the nostrils through the eye, spreads out on the side of the neck; back lead coloured, glossed with yellowish-gray, quill and tail-feathers blackish-gray, edged with grayish white; under-plumage brownish white, deepening in some specimens to yellowish-gray; bill pitch black; legs bluish; total length 5 inches 6 lines. ('Fauna Borealis-Americana.')

Some ornithologists have considered this bird identical with the Marsh-Titmouse, *P. palustris*, of Europe. M. Temminck in the first part of his 'Manuel' declares that individuals sent to him from North America had absolutely the same distribution of colours on their plumage as those killed in Europe, only the hues of the American individuals were more pure. In the third part, where he notices *P. palustris*, and adds to its synonyms, he says nothing to contradict his original observation; and in the first part he gives *P. atricapillus*, la Mésange à Tête Noire du Canada (Brisson), and the Black-Cap and Canada Titmouse (Lath.), as synonyms of *P. palustris*.

Mr. Swaleson and Sir John Richardson however, after referring to the opinions of those who have considered the European and the American bird as the same, state that the two species appear to them to be sufficiently distinct. According to them this Tit is the *P. atricapillus*, Linn., who by the way gives Canada as its habitat; Mésange à Tête Noire du Canada, Buff.; *P. atricapillus*, Will., Black-Cap Titmouse; *P. atricapillus*, Bonap.; Pécchéhkeeskshes of the Cree Indians; and Mésange of the Canadian voyageurs; and they observe that its loose plumage, like that of the Canadian Jay, is well qualified for its protection in the severe arctic winters. According to Nuttall, 'Chicadee' is the familiar name for this bird.

Supposing this bird to be a distinct species, it is found throughout

the whole width of the American continent, from 65° N. lat. to the southern districts of the United States, throughout the year. It is one of the most common birds in the Fur-Countries, a small family inhabiting almost every thicket. ('Fauna Borealis-Americana.')

In winter it is resident around Hudson's Bay, and has been met with at 62° N. lat. on the north-west coast. It is difficult to say in what part of the United States it is most common, so generally and equally has it colonised the temperate parts. In winter it is abundant in all the forests of the southern states to Florida, and probably extends its visits into Mexico. (Nuttall.)

Black-Cap Titmouse (*Parus atricapillus*).

Nuttall gives a graphic description of the manners of this Titmouse in his 'Manual of the Ornithology of the United States and of Canada.' "In all these countries," he says, "in autumn families of them are seen chattering and roving through the woods, busily engaged in gleaning their multifarious food, along with the preceding species (*Parus bicolor*), Nuthatches, and Creepers, the whole forming a busy, active, and noisy group, whose manners, food, and habits, bring them together in a common pursuit. Their diet varies with the season; for besides insects, their larvæ and eggs, of which they are more particularly fond, in the month of September they leave the woods and assemble familiarly in our orchards and gardens, and even enter the thronging cities in quest of that support which their native forests now deny them. Large seeds of many kinds, particularly those which are oily, as the sun-flower, and pine, and spruce-kernels, are now sought after. These seeds in the usual manner of the genus, are seized in the claws and held against the branch until picked open by the bill to obtain their contents. Fat of various kinds is also greedily eaten, and they regularly watch the retreat of the hog-killers in the country to glean up the fragments of meat which adhere to the places where the carcasses have been suspended. At times they feed upon the wax of the candle-berry myrtle (*Myrica cerifera*), they likewise pick up crumbs near the houses, and search the weather-boards and even the window-sills familiarly for their lurking prey, and are particularly fond of spiders and the eggs of destructive moths, especially those of the canker-worm, which they greedily destroy in all its stages of existence. It is said that they sometimes attack their own species when the individual is sickly, and aim their blows at the skull with a view to eat the brain; but this barbarity I have never witnessed.

"On seeing a cat, or other object of natural antipathy, the Chicadee, like the peevish jay, scolds in a loud, angry, and hoarse note, like 'Tshe, dâigh, dâigh, dâigh.' Among the other notes of this species, I have heard a call like 'Tshe-de-jay, 'tshe-de-jay,' the two first syllables being a slender chirp, with the 'jâj' strongly pronounced. The only note of this bird which may be called a song, is one which is frequently heard at intervals in the depth of the forest, at times of the day usually when other birds are silent. We then may sometimes hear in the midst of this solitude two feeble, drawling, clearly-whistled, and rather melancholy notes, like 'te-derry,' and sometimes 'ye-perrit,' and occasionally, but much more rarely, in the same wiry, whistling, solemn tone, 'plébé.' The young in winter also sometimes drawl out these contemplative strains. In all cases the first syllable is very high and clear, the second word drops low, and ends like a feeble

plaint. This is nearly all the quaint song ever attempted by the Chickadee; and is perhaps the two notes sounding like the whetting of a saw, remarked of this bird in England by Mr. White, in his 'Natural History of Selborne' (vol. i.) On fine days about the commencement of October, I have heard the Chickadee sometimes for half an hour at a time, attempt a lively petulant warble, very different from his ordinary notes. On these occasions he appears to flirt about, still hunting for his prey, but almost in an ecstasy of delight and vigour. But after a while the usual drawling note again occurs. These birds, like many others, are very subject to the attacks of vermin, and they accumulate in great numbers around that part of the head and front which is least accessible to their feet.

"The European bird is supposed to be partial to marshy places. Ours has no such predilection, nor does the American bird, that I can learn, even lay up or hide any store of seeds for provision—a habit reported of the foreign family."

Prince Bonaparte notes *Parus palustris* and *P. atricapillus* as distinct species, in his 'Birds of Europe and North America.'

P. niger, Vieill. (*P. leucopterus*, White-Winged Tit, Sw.), has a deep uniform glossy black with slight bluish reflection in certain lights, except the wings, on which the black is relieved by the snowy white of the lesser and greater coverts and of the quills. Total length nearly six inches. It is abundant in the Kaffir country, South Africa.

Le Vaillant describes the note of this species, his *Mésange Noire*, as the same with that of *P. major*. The nest, he says, is made in the trunks of trees, where the bird also roosts. The pure white eggs, he adds, are from six to eight in number.

White-Winged Tit (*Parus niger*). Le Vaillant.

PARIETARIA, a genus of Plants belonging to the natural order *Urticaceæ*. It has polygamous flowers, surrounded by an involucre, a bell-shaped 4-parted perigone, 4 stamens, and a filiform style.

P. officinalis, Wall-Pellitory, has ovate or oblong-ovate leaves, without lateral ribs at the base, two axillary bifid cymes, the segments of the involucre ovate-obtuse. The leaves are alternate, the flowers small and reddish, the fruit black and shining. It is a Pictetia plant, and is found on old walls and rubbish. It is the *P. crecta* of Koch and Reichenbach.

(Babington, *Manual of British Botany*.)

PARIS, a genus of Plants belonging to the natural order *Asparagaceæ*. It has a patent horizontal perianth, 8-parted to the base, the four inner parts, or corolla, narrower than the others. There are 8 stamens, the anthers fixed to the middle of a subulate filament. The styles are 4 in number, the berry 4-celled, the cells with from 4 to 8 seeds.

P. quadrifolia, Herb-Paris, the only British species, has usually four leaves in a whorl, a stem about a foot high springing from the extremity of a long rhizoma usually with four, occasionally from three to six leaves at its summit. The flowers are solitary and terminal, the sepals

NAT. HIST. DIV. VOL. IV.

lanccolate, the petals subulate. It has no root-leaves, and is found in damp woods in England. It is considered to be a narcotico-acrid poison.

P. polyphylla, a native of Nepal, possesses similar properties.

(Babington, *Manual of British Botany*.)

PARISITE, a Mineral. [YTROCERITE.]

PARKIA, a genus of Plants belonging to the natural order *Leguminosæ* and the tribe *Mimoseæ*. It was named by Mr. Brown in honour of the great African traveller Mungo Park. The genus contains only a few unnamed trees, which are found on the west coast of Africa, the peninsula of India, Silhet, and in the islands to the eastward of the Bay of Bengal. *Parkia* is distinguished among the Mimosa-like *Leguminosæ* by the tubular 5-cleft calyx and the corolla with 5 distinct petals having a more or less imbricate æstivation; stamens 10, hypogynous, monadelphous. Legume many-seeded, 2-valved, with a farinaceous pulp around and between the seeds. Inflorescence an axillary peduncled and club-shaped spike.

P. Africana is the Nitta, or Doura-Tree of Soudan. The farinaceous matter surrounding the seeds is eaten, and also made into a pleasant drink when steeped in water. The seeds are roasted as coffee is with us, then bruised and allowed to ferment in water. When they begin to become putrid, they are well washed and pounded, and the powder is made into cakes resembling chocolate, which form an excellent sauce for all kinds of meat. (Brown, in Denham.) A species of this genus, the *Mimosa pedunculata* of Roxburgh, is said by him to be similarly valued by the Malays, that is, they eat the mealy matter which surrounds the seeds, as well as the seeds themselves, which are said to taste like garlic.

PARKINSONIA, a genus of Plants belonging to the natural order *Leguminosæ*. *P. aculeata*, the Barbadoes Flower-Fence, is a well known West Indian shrub, very generally employed in such climates as an ornamental plant, and especially for the construction of hedges, for which its strong spines render it well adapted. It has long pinnated leaves, with a winged petiole, and grows as much as 12 or 15 feet high. The flowers are large, yellow, very numerous, and a little variegated with red spots, and are succeeded by long narrow knotted pods. When in flower it is said to be one of the most splendid objects in the vegetable kingdom.

PARMACELLA. [LIMAX.]

PARMELIA. [LICHENS.]

PARMOPHORUS. [FISURELLIDÆ.]

PARNASSIA (from the name of Mount Parnassus), a genus of Plants belonging to the natural order *Droseraceæ*. It has a 5-cleft deeply-cut calyx, 5 petals, and 5 stamens, with 5 scales fringed with glandular setæ interposed. The stigmas are sessile and 4 in number, the capsules 1-celled with 4 valves. The species are smooth herbs. The leaves ovate, cordate, cauline ones usually clasping the stem or sessile. The flowers are all white striped with green; the tuft of the glands yellow.

P. palustris, Marsh or Common Grass of Parnassus, has cordate stalked radical leaves, the stem-leaves amplexicaul, the filaments of the petaloid scales from 9 to 13; the petal has a short claw, and is white and veined; the glands of the scales yellow. It is native throughout Europe, in marshy and damp places, and in Britain in mountainous countries.

P. fimbriata is a very elegant species; the leaves are remarkably hollowed out at the base close to the lateral ribs, which are connected with one another by a common base like the divisions of a pedate leaf. It has palmate glandless appendages, obovate petals fringed at the base. It is a native of the western coast of North America.

(Don, *Dichlamydeous Plants*; Babington, *Manual*.)

PARONYCHIACEÆ, Meisner's name for the family of Plants called by Lindley *Knottworts*. Brown named this tribe after *Illecebrum*, *Illecebræ*, which is now most commonly adopted. [ILLECEBRACEÆ.]

PAROTIA. [BIRDS OF PARADISE.]

PAROTID GLAND (from *παρά*, 'near,' and *ὄς*, 'the ear') is the largest of the three principal glands by which the saliva is secreted and poured into the mouth. The parotid glands are situated, one on each side of the face, behind the ascending part of the lower jaw, and below and in front of the ear. The most anterior portion of each lies upon a part of the masseter muscle, immediately beneath the skin of the face, at the most backward part of the cheek; and hence the main duct passes forwards, penetrating obliquely through the fat of the cheek and through the buccinator muscle, to open into the cavity of the mouth nearly opposite to the second molar tooth of the upper jaw. The more posterior part of the gland is placed in an intricate manner among the tissues behind the jaw and beneath the outer part of the base of the skull, fitting into the irregularities that are left between them, and in some parts passing very deeply down beneath the skin.

The structure of the parotid, like that of all the glands secreting saliva, is lobular, being made up of a number of minute cells, the terminations of the branches of the main duct, upon whose walls a net-work of capillary bloodvessels is arranged, and which are collected together in uncertain numbers to form the several lobules of which the whole gland is made up. [DIGESTION; GLAND.]

PARRA. [RAILLIDÆ.]

PARROT. [PITTACIDÆ.]

PARROT-FISH. [LABRIDÆ.]

PARSLEY. [PETROSELINUM.]

PARSLEY, FOOL'S. [ATHUSA.]

PARSLEY PLANT, the common name for *Alchemilla arvensis*.

PARSNIP. [PASTINACA.]

PARTHENIUM. [PYRETHRUM.]

PARTHENOPE. [PARTHENOPIDÆ.]

PARTHENOPIDÆ, or *Parthenopions* of Milne-Edwards. This tribe, in the arrangement of M. Milne-Edwards, corresponds nearly to the genus *Parthenope* as established by Fabricius, but the species are separated by Milne-Edwards into the genera *Eumalonus*, *Eurynome*, *Lambrus*, *Parthenope*, and *Cryptopodia*, forming a natural group which, in the opinion of the last-named zoologist, establishes the passage between the Maiana [MAIDÆ] and the Cyclometopæ.

The following are the characters of this tribe:—Carapace ordinarily triangular, and hardly longer than it is wide; its latero-posterior borders in general nearly transverse, and the latero-anterior borders following the same direction as the edges of the rostrum; but the lateral parts of the carapace are sometimes rounded, and its surface is nearly always bossy and tuberculous. Rostrum in general small and entire, or only notched at the end; the eyes are nearly always perfectly retractile; the basilar joint of the external antennæ sometimes presents the same disposition as in the Maiana, but in the great majority of cases it is quite otherwise; it is short, and is not joined to the neighbouring parts of the shell; its external border does not concur to form the lower orbital wall, and its extremity does not reach to the front; the moveable stem of these antennæ is short, and takes its origin in a gap of the internal orbital angle. The epistome is much wider than it is long, and the form of the external jaw-feet is nearly the same as in the Maiana. The anterior feet are very much developed, and widen so as nearly to make a right angle with the body: in the male they are always more than twice as long as the post-frontal portion of the carapace, and sometimes four times as long; the hand is nearly always triangular, and the claw suddenly curved downwards, so that its axis forms a very marked angle with that of the hand. The succeeding feet are, on the contrary, short; the second pair in general are less than once and a half of the length of the post-frontal portion of the carapace, and the others progressively diminish. The abdomen in the male presents considerable differences in the number of distinct joints, whilst in the female there are always seven.

The tribe is widely distributed, and species are found in the English Channel, the Mediterranean Sea, and the Indian Ocean.

Eumalonus (Edwards).—This genus, in the opinion of the last-named author, establishes in some sort the passage between the Stenorhyncha and the Acheans on one side, and *Eurynome*, *Lambrus*, and *Parthenope*, on the other.

The carapace is nearly pentagonal, as in *Parthenope*, but it scarcely ever goes beyond the level of the third pair of feet. Body depressed; rostrum very wide and very much advanced, and divided at its extremity only; eyes very short, their peduncle entirely filling the orbits, which are circular, a character which again approximates this genus to the Stenorhyncha; internal antennæ bent back very obliquely outwards; external antennæ but little developed; their first joint does not distinctly concur in the formation of the lower wall of the orbit; their moveable stem arises in the slit which the two internal angles of that cavity leave between them nearly as in the *Parthenopes*, and their terminal joint is very short.

E. niger is the only known species. It is remarkable for the great prolongation on each side of the carapace; these points are directed outwards, and their base occupies the whole of the hepatic region. It is a native of the coasts of China.

*Eumalonus niger*.

Eurynome (Leach).—This genus, in the opinion of M. Edwards, establishes the passage between the *Lambrus* and the other Oxyrhyncha. The general form of the body and its aspect approximates these Crustaceans to *Parthenope*, whilst the disposition of their external antennæ is similar to what is seen in *Maia*. The carapace nearly triangular, with a rounded base, very much embossed and covered with asperities. Rostrum horizontal and divided into two triangular horns. Eyes small; orbits deep, their upper border very projecting, and separated from the external angle by a slit. The internal antennæ bent back longitudinally; the first joint of the external ones terminating at the internal angle of the orbit and supporting the succeeding joint at the upper edge of its extremity, so that the moveable stem of

these antennæ, which is prolonged under the rostrum, appears to spring from the internal canthus of the eye.

E. aspera has the carapace with the regions very distinct, rugose, with a great triangular tooth at the external angle of the orbit, and three or four smaller ones along the lateral border on the branchial region; moveable stem of the external antennæ very short, and its two first joints very small.

It is a native of the coasts of Nordinoutier and of the British Channel, at rather considerable depths.

*Eurynome aspera*.

M. Milne-Edwards refers to the *E. scutata* of M. Risso, from the Mediterranean, as having much in common with the species above noticed; but the details are not, in his opinion, sufficient to enable us either to refer it with certainty to this genus or to distinguish it from *E. rugosa*.

Lambrus (Leach).—Carapace nearly as long as it is wide, rounded on the sides and narrowed forwards; branchial regions very much developed, tumid, and separated from the median portion of the carapace by a deep furrow; stomachal region, on the contrary, very narrow; upper surface of the edge of the shell always more or less tuberculous or spiny. Rostrum small, but rather advanced. Eyes perfectly retractile, and orbits nearly circular, the walls of these cavities presenting a fissure above and a wide and deep gap below the internal canthus of the eye. The internal antennæ bend back obliquely, and the fossæ which lodge them are in general continuous with the orbits, for the space which separates the internal angle of the lower orbital border from the front is far from being filled by the peduncle of the external antennæ, whose first joint is extremely small and scarcely longer than it is wide; the second is more elongated, but never reaches to the front, and advances between the basilar joint of the internal antennæ and the internal border of the lower wall of the orbit; the third joint has its origin in the gap which occupies the internal angle of this cavity; and the fourth or terminal filament is very short.

The species are found in the Mediterranean Sea and Indian Ocean, where they live among the rocks at considerable depths.

§ 4. Carapace nearly as long as it is wide.

a. Carapace rugose, covered above with spines or tubercles.

a.* Four first pair of feet having the third joint armed with spines.

Ex. *L. longimanus*. It is found at Pondicherry, Amboyna, &c.

*Lambrus longimanus*.

- a.** Four last pair of feet without spines.
 Ex. *L. angulifrons*. Inhabits the Gulf of Naples and coasts of Sicily.
 aa. Carapace nearly quite smooth above.
 Ex. *L. Messana*. It inhabits the volcanic rocks of the coasts of Sicily.
 § *B.* Carapace much wider than it is long.
 b. Upper surface of the bands rough with spines, which are more or less ramose, and baving their upper and internal borders armed with spines like each other, and neither compressed nor united into a crest.
 Ex. *L. echinatus*. It is found on the coasts of Pondicherry.
 bb. Upper surface of the hands more or less smooth, and never with ramose spines; their upper and external borders armed with teeth, which are compressed, and so disposed as to form a crest.
 Ex. *L. serratus*. It inhabits the Indian Ocean.
Parthenope.—This genus, as limited by modern authors, consists but of one species, distinguished principally by the disposition of the

Parthenope horrida.

external antennæ, whose basilar joint is not soldered to the neighbouring parts, but nearly reaches the front, and whose second joint, more than half as short as the first, is lodged in the gap of the lower orbital angle; the smallness of this gap, which makes the orbit communicate with the antennary fosses; the regularly triangular form of the carapace; and the existence of seven distinct joints in the abdomen of both sexes.

Cryptopodia fornicata.

P. horrida. Carapace pentagonal, wider than it is long, horizontal, strongly embossed, and tuberculous above; rostrum short, triangular, and armed below with a strong interantennary tooth; orbits circular, with a fissure on the upper border; latero-anterior borders of the carapace very oblique, and armed with spines; anterior feet very large, of unequal size, and covered with large spiniferous tubercles; claws less compressed and less inflected than in *Lambrus*. The four succeeding pair of feet armed to the origin of the tarsus with sharp and very large spines, forming one row above and two below.

It is a native of the Indian and Atlantic oceans.

Cryptopodia (Edwards).—M. Milne-Edwards is of opinion that this singular genus establishes in some respects the passage from *Lambrus* to *Ethra* [ETHRA]; and, in fact, he observes, the form of its feet is the same as in the first; while the carapace presents, as in the last, lateral expansions which extend above those organs and bide them. Fabricius therefore placed these Crustaceans among his Partheuopes, Lamarck among the *Ethra*, and Bosc among the *Calappa* and *Maia*.

Ex. *C. fornicata*. Inhabits the Indian Ocean.

PARTRIDGE. [PERDIDÆ.]

PARTRIDGE-WOOD, a kind of Wood much esteemed for cabinet-work on account of its beautiful variegated and hatched appearance, is commonly said to be furnished by *Heisteria coccinea* of botanists, a small inelegant tree, about 20 feet high, found in Martinique by the side of torrents; but this appears to be a mistake which has arisen out of the name given to *Heisteria* in that colony. In the corrupt French of Martinique it is called Bois Perdrix, a name which, as Jacquin tells us, does not signify Partridge-Wood, but Partridge-Pea, bois being used for pois; and the name is given to the plant, not because of the variegated wood resembling a partridge's wing, but because the wild pigeons are fond of the berries. Partridge-Wood is said by Guibourt, who does not however give any authority for the statement, to be really a product of Cayenne, where it forms a tree 60 feet high, and is called Boco. Of this plant, called by Aublet *Bocca provencensis*, an account will be found in that author's 'Plantes de la Guiane Française,' Supp., p. 38, t. 391; but it is now wholly unknown to botanists, its very name being omitted even in the most complete botanical systems. Aublet says it is found in the woods of Caux; and he supposes that its hard heart-wood would be a good material for the blocks or pulleys used in machinery; but he says nothing of its being exported to Europe.

PARTULA, a genus established by Férussac for a form of the family *Colimaça*, Lam. (*Auriculacea* of Férussac).

PARUS. [PARIDÆ.]

PASENG. [CAPRÆ.]

PASIPHÆA. [PALEMONIDÆ.]

PASITHEA (Lea), a genus of Pyramidal Shells allied to *Melania*.

PA'SPALUM (from one of the Greek names for Millet), a genus of Grasses, which, like some species of *Panicum*, forms one of the small grains cultivated in tropical countries as food for the poorer classes of the community. The genus is characterised in babit by having a continuous spiked rachis, on one side of which the spikelets are attached. The glume is 2-valved, 1-flowered, closely pressed to the two plauve converse paleæ. Seed adhering to the paleæ.

P. scrobiculatum, the Koda of the natives of India, is cultivated over almost all parts of India. It delights in a light, dry, loose soil, but will grow in a very barren one. The seed is an article of diet with the Hindoos, particularly with those who inhabit the mountainous parts of the peninsula, as well as in the most northeru parts of the country, or where the soil is barren and unsuited to the cultivation of those grains which are more beneficial. Dr. Roxburgh states that the boiled grain is as palatable as rice. He distinguishes from this another species, which Linnaeus called *Paspalum Kora*, but it appears to be only a variety growing in moist situations. Both species are much relished by cattle either in a green or dry state.

PASQUE FLOWER. [ANEMONE.]

PASSA'LODON, a genus of Fossil Placoid Fishes.

PASSENGER PIGEON. [COLUMBIDÆ.]

PASSER, a genus of Birds belonging to the *Fringillidæ*, a family of Conirostral Insectores. It has the following characters:—Beak strong, conical, longer than deep; the upper mandible slightly curved; the lower mandible compressed, and smaller than the upper. Nostrils lateral, basal, rounded, partly concealed by the short feathers on the base of the mandible. Wings with the second quill-feather rather the longest. Legs with the tarsi nearly as long as the middle toe; claws sharp and curved, that of the hind too rather larger than that of the middle toe. Tail nearly square.

P. domesticus (*Fringilla domestica*, Linn.; *Pyrgita domestica*, Cuv.). This well-known bird, the constant attendant on civilised man wherever it is found, is the Moineau and Passereau of the French, Passero of the Italians, Gorrión of the Spanish, Haus-Sporliug of the Germans, Huis-Musch of the Netherlands, Graspaf of the Swedes, Graeco-Spurre of the Danes, Huus-Kaald of the Norwegians, Common Sparrow and House-Sparrow of the English, and Aderyn and Golfan of the Welsh.

Belon makes it the *Στρούθος* of the Greeks and *Passer* of the Romans, but it is by no means clear that this was the species meant. The Cisalpine Sparrow (*Pyrgita Italica*, Vieill.; *Fringilla Cisalpina*, Temm.; *Passero*, *Passera*, *Passero Commune*, and *Passero Tettajuolo*

of the Italians) is much more abundant at the present day in Italy, where the Common Sparrow is comparatively scarce; and there are two other European species.

It is found in Denmark, Norway, and Sweden, in which last country it is more numerous if possible than with us, the whole of the British Islands, France, Spain, Portugal, Italy (rare), Liguria, and Dalmatia, in small numbers, and a stranger, as it were, in the midst of the numerous flocks of the Alpine Sparrow, according to Temminck; North Africa; the Levant, according to Mr. H. E. Strickland; Trebizond; the Nubian Mountains; the Docean, according to Colonel Sykes, the Himalaya Mountains, and other parts of India.

The bird is everywhere before our eyes, even in our most populous cities, and cannot need description; but a London sparrow requires to be well cleaned before the true colours of his plumage appear. If one of these begrimed soot-collectors be placed near a bright trim sparrow from a barn-door, it is difficult to conclude that the rustic and the citizen are birds of the same feather.

There are many accidental varieties—pure white; yellowish-white, with the colours hardly indicated; rusty-yellow variegated with white; some part of the body white, ash-colour or black-brown more or less deep. The *Pringilla candida* of Sparrmaun, *Passer flarus* of Brisson, and Black Sparrow of Latham, are founded on some of these variegated individuals.

The habits of the Common Sparrow, its amazing fecundity, its strong attachment to its young, the truculent battle-royal in which they will occasionally engage in troops, when excited upon some difference of opinion arising out of questions of love or nest-property, their familiarity, not to say impudence, and their voracity, are familiar to all; but few pause to inquire what service the sparrows do for the unlimited tolls they take. Mr. Knapp gives the following account of this bird:—

"The natural tendency that this sparrow has to increase will often enable one pair of birds to bring up fourteen or more young ones in the season. They build in places of perfect security from the plunder of larger birds and vermin. Their art and ingenuity in commonly attaching their nests beneath that of the rook, high in the chim, a bird whose habits are perfectly dissimilar, and with which they have no association whatever, making use of their structure only for a defence, to which no other bird resorts, manifest their anxiety and contrivance for the safety of their broods. With peculiar perseverance and holdiness, they forage and provide for themselves and their offspring; will filch grain from the trough of the pig, or contend for its food with the gigantic turkey; and if scared away, their fears are those of a moment, as they quickly return to their plunder; and they roost protected from all injuries of weather. These circumstances tend greatly to increase the race, and in some seasons their numbers in our corn-fields towards autumn are prodigious; and did not events counteract the increase of this army of plunderers, the larger portion of our bread-corn would be consumed by them; but their reduction is as rapidly accomplished as their increase, their love of association bringing upon them a destruction which a contrary habit would not tempt. They roost in troops in our ricks, in the ivy on the wall, &c., and are captured by the net: they cluster on the bush, or crowd on the chaff by the barn-door, and are shot by dozens at a time, or will rush in numbers, one following another, into the trap. These and various other engines of destruction so reduce them in the winter season, that the swarms of autumn gradually diminish, till their numbers in spring are in no way remarkable. I have called them plunderers, and they are so; they are benefactors likewise, seeming to be appointed by nature as one of the agents for keeping from undue increase another race of creatures, and by their prolificacy they accomplish it. In spring and the early part of the summer, before the corn becomes ripe, they are insectivorous, and their constantly increasing families require an increasing supply of food. We see them every minute of the day in continual progress, flying from the nest for a supply, and returning, on rapid wing, with a grub, a caterpillar, or some reptile; and the numbers captured by them in the course of these travels are incredibly numerous, keeping under the increase of these races, and making ample restitution for their plunderings and thefts. When the insect race becomes scarce, the corn and seeds of various kinds are ready; their appetite changes, and they feed on these with undiminished enjoyment."

P. montanus (*Pringilla montana*; *Pyrgita montana*), the Tree-Sparrow, or the Mountain-Sparrow; the Bec-Fiu Friquet of the French. This bird is very like the last, but not so numerous. It is smaller than the Common Sparrow, and is found frequenting trees remote from houses, and building in the holes of decayed pollards. It is much more local in England than the last, and is found mostly in Surrey, Suffolk, Norfolk, Cambridgeshire, Rutland, Lincolnshire, Yorkshire, Durham, and Northumberland.

(Yarrell, *British Birds*.)

PASSEIRELLA (Swainson), a sub-genus of *Pringilla*. Ex. *P. itaca*. (Wills, iii. 22, f. 4.)

PASSEIRELLA (Gray), a genus of Serpents.

PASSIFLORA, a genus of Twining Plants, the species of which are called Passion Flowers. This name is derived from a fancied resemblance between the parts of their flower and the emblems of Our Saviour's crucifixion. In the five anthers the Spanish monks

saw his wounds, in the triple style the three nails by which he was fixed to the cross, and in the column on which the ovary is elevated the pillar to which he was bound; a number of fleshy threads which spread from a cup within the flower were finally likened to the crown of thorns. "There are cuts," says Sir James Smith, "to be found in some old books, apparently drawn from description, like the hog in armour upon our signs to represent the rhinoceros, in which the flower is made up of the very things themselves." In reality the flower of *Passiflora* consists of a calyx and corolla, each of five divisions, consolidated into a cup, from within the rim of which spread several rows of filamentous processes, by some regarded as barren stamens; within these, from the sides of the cup, there proceed one or more elevated rings, notched or undivided, and in various degrees of development in different species, and evidently of the same nature as the filamentous processes themselves. In the centre of the flower stands a column, or gynophore, with the sides of which five stamens are united, but spread freely from it beyond its apex, and bear five oblong horizontal anthers. At the apex of the column is the ovary, a 1-celled case, with three parietal polyspermous placentae, and bearing three club-shaped styles at its vertex. Eventually a gourd-like fruit is produced containing many seeds, each having its own fleshy aril, and usually enveloped in a subacid mucilage.

Passion Flower (*Passiflora Horsfieldii*).

1, a flower cut open vertically, so as to show the calyx, corolla, filamentous crown, interior rings, central gynophore, stamens, and ovary.

The genus comprehends a large number of species, chiefly found in a wild state in America, and within or near the tropical parts of that continent. They are all twining plants, often scrambling over trees to a considerable length, and in many cases are most beautiful objects on account of their large gaily- or richly-coloured flowers. This makes them favourites in gardens, where many are cultivated, particularly the *P. alata*, *P. quadrangularis*, *P. edulis*, *P. caerulea*, *P. racemosa*, *P. Loudoni*, *P. onychina*, *P. palmata*, and *P. filamentosa*, all of which are strikingly handsome. It is however chiefly for their fruit that they are valued in the countries where they grow wild, in consequence of the pulp which envelopes the seeds being cool and refreshing, with something of a fragrant bouquet. Under the name of Granadilla the *P. quadrangularis* is well known in Brazil, where its fruit is as large as a child's head; the Water-Lemon of the West Indies is the produce of *P. laurifolia*; *P. maliformis* bears what is called the Sweet Calabash; and the pleasant pulp of *P. edulis* furnishes the confectioner with the most delicate material for the flavouring of ices. Many however are of no value for their fruit, and some are actually fetid.

PASSIFLORACEÆ, *Passion-Worts*, a natural order of Hypogynous Exogenous Plants. This order is included by Lindley in his alliance *Violales*. It is characterised by possessing polypetalous or apetalous corouetted flowers; perigynous imbricated petals; stamens on the stalk of the ovary; simple terminal styles; arillated seeds; and stipulate leaves. The species are herbaceous plants or shrubs, usually climbing, very seldom erect.

Considerable difference of opinion exists among botanists as to the real nature of the floral envelopes of this remarkable order. Jussieu and De Candolle, regarding the parts called petals as a second row of sepals, have made the order apetalous; whilst Lindley and others have regarded the second row of floral envelopes as petals, and made it polypetalous. Lindley makes the affinities of this order with *Samydaceæ*, *Capparidaceæ*, *Malosherbiaceæ*, and *Papayaceæ*.

Most of the useful properties of this order are included in the genus *Passiflora*. [**PASSIFLORA**.] *Murucuja ocellata*, a West Indian Climber, is said to be anthelmintic and diaphoretic. Besides the fruit of several species of *Passiflora*, the fruit of *Tacsonia mollissima*, *T. tripartita*, *T. speciosa*, and *Paropsia edulis* are all of them edible. The species are principally found in South America. There are 10 genera and about 216 species.

(Lindley, *Vegetable Kingdom*.)

PASSION FLOWER. [**PASSIFLORA**.]

PASTINACA (from *Pastinum*, the Latin name for a two-pronged fork), a genus of Plants belonging to the natural order *Umbellifere* and the tribe *Peucedaneæ*. It has a calyx with 5 very small or nearly obsolete teeth; round entire petals, involute, with an acute point. The fruit has a dilated flat margin; the carpels with slender ridges, 3 dorsal equidistant, 2 lateral distant, near the outer edge of the dilated margin; the interstices with single linear vittæ.

P. sativa, the Parsnip, has an angular furrowed stem; pinnate leaves, downy beneath: ovate-oblong leaflets, crenate, serrate, often with a lateral lobe at the base. The stem from two to three feet high. The flowers are yellow. The leaves generally shining above, sometimes downy beneath. It is a native of Great Britain and of Europe, even to the Caucasus, on hillocks and dry banks, in a chalky soil. The root is spindle-shaped, white, aromatic, mucilaginous, and has a sweet taste. A variety of this species, *P. edulis*, is the Common Edible Parsnip, and is much cultivated in our gardens. [**PARSNIP**, in **ARTS AND SC. DIV.**] Another variety, called *P. Coquaine*, has roots from 3 to 4 feet long and upwards of 6 inches in circumference. It is extensively cultivated in Guernsey and Jersey as fodder for cattle. In the north of Ireland parsnips are used in the composition of a kind of beer brewed with hops. Wine and ardent spirits are likewise made from the roots.

P. Sekakul is another edible species of this genus, and is a native of Syria and Egypt. It has a gray root; a terete downy branched stem; pinnate downy leaves; pinnatifid cut leaflets, blunt and unequally toothed. It is cultivated in the Levant, under the name of Sekakul.

(Babington, *Manual of British Botany*; Burnett, *Outlines of Botany*.)

PASTOR. [**STURNIDÆ**.]

PASY'THEA (Lamouroux), a group of *Sertulariæ*.

PATELLIDÆ, a family of Prosobranchiate Gasteropodous Mollusca. The shell is conical with the apex turned forwards; the muscular impression horse-shoe-shaped, open in front. The genera belonging to this family are *Patella*, *Acmæa*, *Gudinia*, and *Siphonaria*. M. De Blainville referred these Molluscs to his order *Cervicobranchiata*, and Cuvier to his order *Cyclobranchiata*.

Patella, Limpet, has the body more or less circular, conical above, flat below, and furnished with a large oval or round foot, which is thick and overpassed on the whole of its circumference by the edges of the mantle, which are more or less fringed. There is a complete series of vertical membranous plaits in the line of junction of the mantle with the foot.

Shell oval or circular, with an upright summit, or more or less curved forwards. The cavity simple, and more or less deep: the border entire and horizontal. Muscular impression narrow, in the form of a horse-shoe, opening forwards.

Animal of *Patella*.

Cuvier thus describes the genus:—"The *Patellæ* have the body entirely covered by a shell made of one entire piece, shaped like a widened cone (en cône évasé). Under the edges of the mantle is a border (cordon) of small branchial leaflets (feuillettes). The vent and the outlet of the generative organs are a little to the right above the head, which is furnished with a large and short proboscis, and two pointed tentacula, carrying the eyes at their external bases. The

mouth is fleshy, and contains a spiny tongue, which goes backwards, and is folded back deeply in the interior of the body. The stomach is membranous, and the intestine is long, delicate, and very much folded. The heart is forwards, above the neck, a little to the right."

G. B. Sowerby ('Genera of Recent and Fossil Shells') says, "there is no canal for the passage of water to the branchiæ, as there is in *Emarginula* and *Siphonaria*, for in this genus the branchiæ are external, surrounding the animal."

Rang follows Cuvier, and his description of the animal differs but little from that given above. The thorax tongue he terms not inaptly "un long ruban lingual épineux." He thus defines the genus:—"Animal furnished with tentacula and eyes at their external bases; branchiæ formed by a cordon of leaflets; shell univalve." He afterwards gives a more detailed description of the shell, and makes the following observation:—"M. De Blainville believes that he has perceived the branchiæ of the *Patellæ* in a vascular network attached to the plafond of a branchial cavity. Not having been able to distinguish this network, we think with Cuvier that the organ of respiration shows itself in these animals in the circle of leaflets which surrounds the body between the foot and the mantle, as in the Phyllidians."

"There is a curious genus named *Patelloida* by Messrs. Quoy and Gaimard. In these molluscs the shell is absolutely like that of the *Patellæ*, and the animal has not only a cervical sac, but moreover a pectinated branchia on the right and anterior side of the body; and, what is remarkable, it is deprived of those vascular leaflets disposed around the foot in the *Patellæ*. The abolition of these leaflets, as soon as a true pectinated branchia is developed, while the cervical sac undergoes no alteration, and remains the same in both genera, affords, by a rational induction, the strongest presumption for believing that the leaflets of the *Patellæ* are in fact respiratory organs. These two methods of induction of which we have spoken would of themselves be sufficient to combat victoriously the opinion of M. De Blainville; but there is a third method still more preferable—that which anatomical investigation furnishes. When by a minute dissection we have traced in the *Patella* the principal branches of the vessels, we find constantly, in the thickness of the muscles of the lateral parts of the foot, two large vessels which reach along the whole circumference, and furnish a strong branch to each membranous leaflet. This disposition is like that which is seen in the Chitons. The vessels which in the *Patellæ* are given off to the cervical sac are very small, and not to be compared with the development of those of the *Helices*, the *Limacæ*, or even of the *Terebratulæ* and *Orbiculæ*, whose respiratory organ, though framed for breathing water only, is formed of a vascular network on a flattened membrane. In the *Patellæ* the cervical vessels are not more developed than in the other molluscs, which, possessing a pectinated branchia, have also a cervical sac. It seems to us that we may conclude from the preceding observations that, in the *Patellæ*, the cervical sac is not branchial; and that the branchiæ consist of the floating lamellæ between the borders of the foot and of the mantle. By a natural consequence then it becomes necessary to reject the opinion of M. De Blainville, and to place the *Patellæ* near the Chitons, forming a small family for each of these genera."

We have only to add that recent observations leave no doubt, if any could have existed after the luminous remarks of Deshayes, that Cuvier and his followers were right, and that M. De Blainville is wrong. The series of simple laminae attached within the circular border of the mantle fulfil the office of branchiæ, and to that end are endowed with cilia, which keep up a perpetual current of sea-water over them. This current flows from the outer to the inner edge over the surface of each branchial lamina.

The following is De Blainville's arrangement of the species:—

- a. Species whose summit is obtuse, vertical, very nearly mesial, and which are conical. Ex. *P. vulgata*. It inhabits the coasts of European seas, and is common in the Channel. Its varieties are almost endless.

Patella vulgata.

- b. Species a little less conical, and whose summit is placed a little anterior to the position of the last, with a slight inclination forwards. Ex. *P. deaurata*. It is found in the Straits of Magelhaens, Falkland Isles, &c.
- γ. Species which are oval, elongated, and compressed at the sides. Ex. *P. compressa*. It inhabits the Indian Seas. Linn.
- δ. Species whose summit is sub-anterior and very little developed, and which are entirely flat or depressed. Ex. *P. scutellaris*.

*Patella decurata.**Patella compressa.**Patella scutellaris.*

- c. Depressed species, whose summit is scarcely indicated, and which are much narrower before than they are behind. Ex. *P. cochlearia* (Cochlear); *Hedion*, De Montfort.

*Patella cochlearia.*

- d. Oval species, with a well marked summit, evidently inclined forward and sub-marginal; border a little convex in the middle. Ex. *P. pectinata*. A native of the Mediterranean Sea.

*Patella pectinata.*

- e. Species which are oval, delicate, nacreous, and with a festooned border; the summit still more marginal and distinct. Ex. *P. eymbularia*.

*Patella eymbularia.*

The other British species are *P. athletica* and *P. pellucida*.

The *Patella* are very widely spread, and few seas are without them. None however appear to have been observed in the Arctic Seas, either by Captain Parry (1819) or Captain Ross. The larger species are found principally in warm climates.

This genus is one of those which has the power of absorbing the shells of other molluscs or rocks, and thus forming cavities or depressions on them. "The *Patella cochlear*," says Dr. Gray ('Phil. Trans.,' 1833), "is often found at the Cape of Good Hope, where it lives almost exclusively, attached to a large species of the same genus, on the surface of which it forms a flat disc, exactly the size of its mouth. To form these flat discs (of which they are so generally two, one on each side of the apex of the larger *Patella*, as almost to form a character of the species), and to assist in the increase of its size, the animal appears also to absorb the coralline or other similar substances with which the larger shells are abundantly covered. The common *Patella* of our own coast, when long adherent to another shell of its own species, to chalk, or to old red-sandstone or limestone, also forms for itself a deep cavity of the same form as its shell, and evidently produced by the dissolution of the surface to which it is affixed." These observations will strike every one who may take an interest in such subjects, and has opportunities of examination.

Patella has been found principally on rocky coasts, stones, and shells, at a depth ranging from the surface to thirty fathoms. Their food is *Fuci* and other sea-weeds, in the separation and comminution of which their rasp-like tongues are probably highly active.

Siphonaria and *Patelloida* differ strongly in their organisation from *Patella*, for instead of having a circle of branchial laminae like that genus, they have a single pectinated branchia on the right side. To these Dr. Gray adds the genus *Lottia* (*Acmaea*, Eschscholtz), which, as he observes, "must be extremely perplexing to those systematists who attend only to the form of the shell without paying any regard to its animal inhabitant. The shells of *Patella* and *Lottia* do not in the least differ in external form, and yet their animals belong to very different orders, the one having the branchia placed round the foot, as in the Chitons, and the other having them placed on the side of the neck, like the *Fissurella*, from which indeed it chiefly differs in having only one branchia." This description, by the way, accords with the genus *Patelloida* of Quoy and Gaimard. [PATELLOIDEA.]

The genus *Scutella*, brought home by Mr. Cuming from the Pacific Ocean, and described by Mr. Broderip in the 'Proceedings of the Zoological Society for 1834,' part 2, should here be mentioned. There is no doubt that the animal is marine; but unfortunately none of the soft parts were found, though the shells were in very fine condition; and, as we have seen, it is difficult in their absence to fix the precise place of the shell. It has the following generic characters:—Shell ancyliiform, shining within. Apex posterior, central, involute. Muscular impressions two, oblong-ovate, lateral. Aperture large, ovate.

Gadinia (Gray) has the shell conical, muscular impression horse-shoe-shaped, the right side shortest, terminating at the siphonal groove. There are eight living species and one fossil.

Fossil Patellæ.—Deshayes, in his Tables, gives 104 living species and 10 fossil (tertiary); one fossil species, *P. equalis*, now living in the European ocean, in the English Crag (Pliocene Period of Lyell), two at Dax, and one at Valognes. Sowerby says that the fossil species are not numerous, and that they occur in the great Oolite, in the Lias, and perhaps in the Oxford Clay and Chalk Marl of the secondary series; in the Calcaire Grossier, and probably in the London Clay of the tertiary series; and also in the Crag of the diluvial formation. De la Bèche gives the following as being found among the organic remains in blue marls of the south of France:—*Patella vulgata* (†), Lam., *P. Bonardii*, Payrandean (analogous to the existing species), also in the Calcaire Moellon; *P. umbella*, Lam. (also an analogue), and also in the Calcaire Moellon; *P. glabra*, Deshayes, Paris. Among the organic remains of the cretaceous group he enumerates *P. ovalis*, Nils., from Bælsberg, Scania; an undetermined species from the Lower Greensand of Sussex, Mantell, and another from the Lower Greensand of Wilts, Lonsdale. In the oolitic group he places *P. latissima*, Sow., Oxford Clay, Yorkshire, and middle and south of England; *P. rugosa*, Sow., Forest Marble, middle and south of England and Normandy; *P. levis*, Sow., Lias, middle and south of England; *P. lata*, Sow., Stonesfield Slate; *P. ancyloides*, Sow., Great Oolite, Ancliff, Wilts; *P. nana*, Sow., same locality; *P. discoides*, Schlot, Lias, Gunderhofen; and *P. papyracea*, Goldf., Lias, Banz. The grauwacke group, according to the same author, affords *P. Neptuni*, Goldf., Eifel, Olpe; *P. primigena*, Goldf., Pfaffrath; *P. (†) conica*, Wahl., Kinnekulle, Westrogothia; *P. (†) pennicostis*, Wahl., Ulanda, Westrogothia; *P. (†) concentrica*, Wahl., Mossberg, &c., Westrogothia; and an undetermined species, Keswick, and near Kirby Lonsdale, Phil. Woodward states the number of fossil species of *Patellidae* to be above 100.

PATELLOIDEA, a genus of *Mollusca* proposed by Messrs. Quoy and Gaimard for certain *Gasteropoda*, which have shells exactly resembling those of limpets, but whose animals are cervicobranchiate. It is synonymous with the genus *Lottia* of Dr. J. E. Gray. The *Patella testudinaria* of Otho Fabricius, a shell not uncommon on the northern coasts of Britain, is the type. Numerous species are known, inhabiting all latitudes and living in various depths of water. Their shells are

gaily coloured, often tessellated, and rayed with purple, orange, or pink. The animals are usually of a uniform tint of white, orange, or pale red.

PATRINIA, a genus of Plants to which the Spikenard of the East was referred, but which has been formed into a new genus, *Nardostachys*. [**NARDOSTACHYS**.]

PAUSSIDÆ, a family of Coleopterous Insects, the precise affinities of which have not yet been satisfactorily determined. By Latreille the *Pausi* are placed between the *Scolytidæ* and the *Bostrichidæ*; but Mr. Westwood (who has devoted much attention to this group of beetles, and has published a monograph on them in the sixteenth volume of the 'Linnean Transactions') is of opinion that the *Paussidæ* possess affinities with the *Trogositari*, and are still more nearly allied to the *Cucujidæ*.

These insects are usually of small size, the largest known species being less than half an inch in length; and their colouring generally consists of various shades of brown, and they are not unfrequently adorned with black markings. The form of the body is generally short, rather broad, and somewhat depressed; the head, in most of the species, is free (that is, not hidden by the thorax), and joined to the thorax by a kind of neck; the thorax is narrower than the elytra, and is almost always divided transversely near the middle by an indentation, in which case the fore part is usually broader than the hinder, produced at the sides so as to form projecting angles; the elytra are rather soft, and in most of the species are of subquadrate form, truncated at the apex, and leaving exposed the terminal segment of the abdomen; the outer posterior angle of the elytra is generally furnished with a small tubercle. The legs are in most species broad and compressed, and of moderate length; the tarsi are five-jointed in some, and apparently in others there are but four. The antennæ are remarkable for their large size and curious forms; in most of the species they consist of a large inflated club, about equal in size to the head and thorax taken together, and varying in form according to the species: the most common form of this knob is that of an oval more or less elongated, and with an angular projection on the outer side at the base; this club is joined by a smaller joint to the head.

Between twenty and thirty species of this family are known, a great portion of which are figured and described by Mr. Westwood in the monograph before alluded to, and in a supplement to this monograph published in the second volume of the 'Transactions of the Entomological Society,' to which works the reader is referred for a more detailed account of these very curious insects. Of their habits little is known; they are confined to the Old World, and almost entirely to the tropical portions. They are said to be nocturnal, and are supposed to live in wood or under the bark of trees: most of the specimens in cabinets have been found in newly-built houses. One species is said, when touched, to make discharges of some volatile fluid, in the same manner as the species of *Brachinus*.

The family *Paussidæ* contains the six following genera—*Paussus*, *Hylotorus*, *Platyrhopalus*, *Cerapterus*, *Pentaplatarthrus*, and *Trochoideus*. In the first three of these genera the antennæ are two-jointed, and the abdomen is of a quadrate form.

The genus *Paussus* is distinguished by the absence of ocelli on the head, and by the ultimate joint of the labial palpi being elongated.

In *Hylotorus* the head is furnished with two ocelli, and this genus moreover differs from *Paussus* in having the head immersed in the thorax; the great club of the antenna is thickest at the base, and somewhat curved and pointed at the opposite extremity.

Platyrhopalus has all the essential characters of *Paussus*, but differs in having the joints of the labial palpi equal.

In the genus *Cerapterus* the antennæ are large, broad, and compressed, and appear to be composed of ten joints, most of which are very distinct; the terminal joint is the largest; the preceding joints (if we except the basal one) are transverse and all of equal width.

In *Pentaplatarthrus* the antennæ gradually increase in size from the base to the apex, and are composed of six joints. The basal joint is longer than broad; the second is transverse; the three following joints are nearly equal in width and length, and the terminal joint is almost spherical.

The genus *Trochoideus* differs from all the preceding genera in having an ovate form of body; the thorax is rather narrower than the elytra; its sides are rounded, the broadest part in front, and there is apparently no transverse indentation. The head is large and rounded, and deeply inserted in the thorax. The antennæ are composed of two small basal joints, which are longer than broad, and terminate in a large oval club. The legs are more slender than in other species of this family, and the tarsi are represented as having only four joints.

[**PAUXI**. [**CRACIDÆ**.]

PAVIA is a small division of the natural order *Asculaceæ*, differing from *Asculus* itself in little except its converging petals and spineless fruit. It consists of small trees or bushes with yellow or red flowers, inhabiting North America, where they are called Buck's-Eye Chestnuts. They are often cultivated in shrubberies under the name of the Yellow or Scarlet Horse-Chestnut. Two species, *P. Indica* and *P. Pundana*, have also been found in the colder parts of India, but they have not yet been introduced into our gardens. With us the American species are usually short-lived and of no value for their timber; the former circumstance is probably owing to their being

grafted upon the Common Horse-Chestnut, a stock that does not suit them. They should always, if possible, be raised from seeds, which are annually imported from the United States.

PAVO. [**PAVONIDÆ**.]

PAVONIA. [**MADREPHYLLIGÆ**.]

PAVONIA (in honour of Don Joseph Pavon, M.D., of Madrid, a traveller in Peru, and one of the authors of 'Flora Peruviana'), a genus of Plants belonging to the natural order *Malvaceæ*. It has a 5-cleft persistent calyx, surrounded by an involucre from 5- to 15-leaved. The ovary has 5, and rarely 4, 1-ovuled cells. It has 10 stigmas, 5 carpels, capsular, 2-valved, and 1-seeded.

P. diuretica has cordate acuminate serrated leaves, velvety on both sides, and full of pellucid dots. The flowers are axillary, solitary, and sulphur-coloured. It is a native of Brazil, in the province of Minas Geraes. A decoction of this plant is used in Brazil as a diuretic. This is the only species of *Pavonia* used in medicine; many others are however worth cultivation for the beauty of their blossoms.

(Lindley, *Flora Medica*.)

PAVO'NIDÆ, a family of Rasorial Birds, to which the Peacock belongs.

The genus *Pavo* of Linnaeus stands next to *Didus* (Dodo) in the 'Systema Naturæ,' and is immediately succeeded by *Meleagris*, which is followed by *Crax*, *Phasianus*, *Numida*, and *Tetrao*.

Cuvier makes his *Paons* consist of the true Peacocks (*Pavo*, Linn.) and *Lophophorus*. This group is followed by the Dindons (*Meleagris*, Linn.); the Peintades (*Numida*, Linn.); and the Faisans (*Phasianus*, Linn.), including the Cocks and Hens—*Gallus*, Briss.; the true Pheasants (*Phasianus Colchicus*, &c., including *Argus*, Temm.); the Crested Pheasants (*Houppifères*, Temm., *Phasianus ignitus*, &c.); the Tragopans (*Tragopan Satyrus*, &c.); and *Cryptonyx*. The *Tetraonidæ* immediately follow.

Mr. Swainson makes the *Pavonidæ*, the first family of the order *Rasores*, according to his arrangement, consist of the genus *Pavo*, with the sub-genera *Argus*, *Polyplectron*, and *Meleagris*; the genus *Phasianus*, with the sub-genera *Phasianus*, *Nycthemerus*, and *Cerionis* (*Tragopan*); the genus *Gallus*; the genus *Lophophorus*; and the genus *Numida*.

In this work, *Phasianus*, with its sub-genera, *Tragopan*, *Gallus*, and *Euplocamus*, are treated of under the title *PHASIANIDÆ*.

Pavo (Linn.) has the following generic characters:—Bill convex, rather stout, curved towards the end, smooth at the base; cheeks partially naked; nostrils basal and open; head plumed and surmounted with an aigrette-like crest; sixth quill longest; tail-feathers 18; tail-coverts very long, large, and extensible in the male.

Two species only of this magnificent genus are recorded, *P. cristatus* and *P. Japonensis*.

P. cristatus, the Common Peacock. This is the *Taōs* and *Taōs* of the Greeks; *Pavus* and *Pavo* of the Romans; Pavon and Pavone of the Italians; Pavon of the Spanish; Paon of the French; and Pfau of the Germans. The head is surmounted by an aigrette of 24 upright feathers. In the male the tail-coverts consist of feathers with loose barbs and of unequal size, the upper one shortest, each terminated by numerous eyes or circlets of a metallic iridescent brilliancy: these the bird has the power of erecting into a circle or wheel, which presents, when the sun shines on it, an object of dazzling splendour which sets all description at defiance. The female has the aigrette, but has not the splendid ornament with which the male is gifted: her colours generally are sombre.

People usually talk of the peacock spreading its tail, but the rich display is composed principally of the tail-coverts. White soon saw the distinction. "Having to make a visit to my neighbour's peacocks, I could not," says he, "help observing that the trains of those magnificent birds appear by no means to be their tails, those long feathers growing not from the uropygium, but all up their backs. A range of short brown stiff feathers, about six inches long, fixed in the uropygium, is the real tail, and serves as the fulcrum to prop the train which is long and top-heavy when set an end. When the train is up, nothing appears of the bird before but its head and neck; but this would not be the case were those long feathers fixed only in the rump, as may be seen by the turkey-cock when in a strutting attitude. By a strong muscular vibration these birds can make the shafts of their long feathers clatter like the swords of a sword-dancer; they then trample very quick with their feet, and run backwards towards the females."

This species is spread over the north of India and the islands of Malaisia in its natural state. It is the Mohr of the Maharratas, according to Colonel Skyes, who describes the wild bird as abundant in the dense woods of the Ghauts; it is readily domesticated, and many Hindoo temples in the Dukhun (Deccan) have, he tells us, considerable flocks of them. On a comparison with the bird as domesticated in Europe, the latter, both male and female, was found by the Colonel to be identical with the wild bird of India.

Colonel Williamson, in his account of peacock-shooting, states that he had seen about the passes in the Jungletary district surprising quantities of wild pea-fowls. Whole woods were covered with their beautiful plumage, to which the rising sun imparted additional brilliancy. Small patches of plain among the long grass, most of them cultivated, and with mustard, then in bloom, which induced the birds to feed, increased the beauty of the scene. "I speak within bounds,"

continues Colonel Williamson, "when I assert that there could not be less than twelve or fifteen hundred pea-fowls, of various sizes, within sight of the spot where I stood for near an hour."

Buffon and others say that the bird was introduced into Greece, whence it has been spread throughout Europe, in the time of Alexander the Great. Others again, with greater show of reason, assert that it was brought to Greece before the time of Pericles. Certain it is that the peacock is mentioned in two plays of Aristophanes, the 'Acharnians' and the 'Birds,' the first of which was represented in the third year of the 88th Olympiad, and the last in the second year of the 91st Olympiad. Now Alexander was not born till the second year of the 98th Olympiad. Athenæus quotes from other old poets—Eupolis, for instance; nor does Aristotle speak of the bird in any other terms than those which would indicate that it had become very well known when he wrote: "Some are jealous and vain like the peacock," says Aristotle, when speaking of the qualities exhibited by certain animals. ('Hist. Anim.,' i, l.)

Although not often eaten in this country, the peacock when young is said to be juicy and sapid. In ancient times no great feast was complete, even in this country, without this bird, which was presented by the sewer well cooked, but in all its gorgeous plumage; and the adventurous knight made his solemn vow before the peacock and the ladies.

P. Japonensis, Aldrov. (*P. Javanicus*, Horsfield). Mr. Bennett, who had an opportunity of examining two living birds in the garden of the Zoological Society of London, in addition to stuffed specimens, gives the following accurate description of this species. Prevailing tints blue and green, varying in intensity and mutually changing into each other according as the light falls more or less directly upon them. In size and proportions the two species are nearly similar, but the crest of *P. Javanicus* is twice as long as that of *P. cristatus*, and the feathers of which it is composed are regularly barbed from the base upwards in the adult bird, and of equal breadth throughout. Head and crest interchangeably blue and green. A naked space on the cheeks, including the eyes and ears, is coloured of a light yellow behind, and bluish-green towards its fore part. The feathers of the neck and breast, which are broad, short, rounded, and imbricated like the scales of a fish, are at their base of the same brilliant hue as the head, and have a broad, lighter, somewhat metallic margin; those of the back have still more of the metallic lustre. The wing-coverts are of the general hue, with a deeper tinge of blue; the primary quill-feathers are light chestnut. The tail-feathers and their coverts (train) are of a splendid metallic brown, changing into green; their barbs are extremely long, loose, silky, and somewhat decomposed; and the latter are almost all terminated by ocellated spots similar to those which mark the tail (train) of the common species, and of nearly the same size. As in it, they are of beautiful deep purple in the centre, which is about the size of a shilling; this is surrounded by a band of green, becoming narrow behind, but widening in front and filling up a kind of notch that occurs in the blue; then comes a broad brownish band; and, lastly, a narrow black ring, edged with chestnut, all beautifully metallic, or rather representing the hues of various precious stones when viewed in certain lights. Bill of a grayish horn-colour, rather longer and more slender than in the common species; iris deep hazel. Legs strong, naked, reticulated, dusky black; spurs large, and of the same hue. ('Gardens and Menagerie of the Zoological Society.')

The bird above described is the *Paro muticus* of Linneus, who, as the name implies, described it as being devoid of spurs, relying probably on Aldrovandus, whom he quotes, and who figures it without spurs, describing it under the name of *Paro Japonensis*. It is the Japan Peacock of Latham, the *Paro spiciferus* of Vieillot, the *Paro Aldrovandi* of Wilson, and *Paro Javanicus* of Dr. Horsfield, who saw it in Java. Of these names, that of Aldrovandus has the priority; then comes that of Linneus, which may mislead; then that of Horsfield; then that of Vieillot. We do not see anything objectionable in the name given by Aldrovandus, and therefore we have retained it.

Meleagris (Linn.).—The *Meleagris* of the ancients was not a turkey, but a guinea-fowl (*Nemida*). Linneus however having given this as the generic name for the Turkeys, which were not known to the ancients, ornithologists have continued it. Nor is this now of much consequence, certainly not of sufficient importance to change the name; for notwithstanding the confusion and doubt thrown over the subject by the learned discussions of the earlier modern ornithologists, it is generally known and satisfactorily proved that the Turkeys were only known to Europeans after the discovery of America, from which one species has been spread in a domesticated state over the greatest part of the civilised globe. It has the following generic characters:—The bill rather short, strong, curved, convex, vaulted, its base furnished with a naked skin; a fleshy caruncle surmounting the bill of an erectile nature and conical form. Head and neck surrounded with a wrinkled mammillated skin, hanging loose like a dewlap as far as the upper part of the breast. Hind toe touching the ground.

Two species are known: one, *M. Gallopardo*, the original stock from which the domesticated turkey is derived; the other, *M. ocellata*, a much more beautifully plumaged bird, did not exhibit in the only known specimen any trace of the tuft of hair on the breast. That

character therefore is omitted above; but it is not certain that the last-mentioned species is entirely without this tuft, for the plumage of the specimen was damaged.

M. Gallopardo. This is the *M. occidentalis* of Bartram; *M. fera* of Vieillot; Gallo d'India, Gallinaccio (male), Gallina d'India (female), of the Italians; Coq d'Inde and Dindon, Dinde (female), of the French; Indialisches Huhn of the Germans; Wild Turkey and Domestic Turkey of the British and Anglo-Americans. In its wild state it has the following characters:—

Male.—Head small in proportion to the body, covered with a naked bluish skin, continued over the upper half of the neck and uneven with warty elevations, changeable red on the upper portion and whitish below, interspersed with a few scattered black hairs. The flaccid and membranous naked skin, also changeable on the lower part of the neck, extends downwards into large wattles. A wrinkled conical fleshy protuberance, capable of elongation and with a pencil of hairs at the tip, takes its rise from the base of the bill, where the latter joins the front. When this excrescence is elongated under excitement, it covers the bill and depends several inches below it. A tuft of long rigid black hair springs from the lower part of the neck at its junction with the breast, shooting out from among the plumage to the length of 9 inches. The base of the feathers of the body, which are long and truncated, consists of a light fuliginous down; this part of the feather is succeeded by a dusky portion, which is again followed by a broad shining metallic band, varying from copper-colour or bronze to violet or purple, according to the play of the light, and the tip is a broad velvety band; but this last is absent in the feathers of the neck and breast. The general plumage presents a glancing metallic lustre, which is however least glossy on the lower part of the back and tail-coverts. The wings are concave and rounded, not extending much if at all beyond the base of the tail. Quills 23; primaries blackish banded with white, secondaries whitish banded with blackish, tinged towards the hack particularly with brownish-yellow. Tail 15 inches in length at least, rounded at the extremity, the feathers 18, broad, and capable of expansion and elevation into a fan-shape. The general colour of these feathers is brown mottled with black, crossed by numerous narrow undulating lines of the same. There is a broad black band near the tip, then a short mottled portion, and lastly a broad dingy yellowish band. The bird stands rather high on its robust red legs, the scales of which have blackish margins, and the blunt spurs are about an inch long: the claws are dusky. Bill reddish, but horn-coloured at the tip. Irides dark-brown. Length nearly four feet; expanse of wings more than five.

Female.—Irides similar to those of the male. Bill and spurless legs less stout. Head and neck with less of naked skin, being partially covered with dirty gray feathers. Those on the back of the neck have brownish tips, and so produce a longitudinal band there. The short caruncle on the front is incapable of elongation; and though the tuft on the breast is not present in young hens, it is highly developed in the older ones, as may be seen in Mr. Audubon's celebrated plate. Prevailing hue of plumage dusky gray, each feather having a metallic band duller than in the male, then a blackish band, and lastly a grayish fringe. The blackish band is almost obliterated on the neck feathers and under surface. The whole plumage is more sombrous than that of the male; there is less white on the primaries, and there are no bands on the secondaries. The colour of the tail is much as it is in the male. Length not exceeding 3½ feet.

Young.—The sexes are not easily distinguished till the skin of the head and neck begins to be tinged with red; but a tubercle on the breast of the young males at the approach of the first winter shows where the tuft is to be; during the second year the tuft becomes some three inches long; and during the third the bird is adult. It continues however to grow in dimensions and beauty for several years. The females attain their full size and colouring at the end of four years, when they have the breast tuft, which is not so full as it is in the male, and seldom exceeds the length of 4 or 5 inches.

The weight of these birds must either be now greatly diminished or the older writers must have been given to exaggeration, which last is the probable case. From 50 lbs. to 60 lbs. has been mentioned, and a modern ornithologist of some celebrity, relying on old authorities, goes beyond the latter weight, as the maximum, putting however the minimum at 20 lbs. Prince Bonaparte states that birds of 30 lbs. weight are not uncommon, and that he had ascertained the existence of some which weighed 40 lbs. Mr. Audubon gives the average at from 15 lbs. to 18 lbs., and mentions a single instance, in the market at Louisville, where the weight was 36 lbs.

Prince Bonaparte, in his continuation of Wilson's 'North American Ornithology,' informs us that the males, usually termed Gobblers, associate in parties of from ten to a hundred, and seek their food apart from the females, which either go about singly with their young, at that time about two-thirds grown, or form troops with other females and their families, sometimes to the amount of 70 or 80. These all avoid the old males, who attack and destroy the young, whenever they can, by reiterated blows on the skull. But all parties travel in the same direction and on foot, unless the dog of the hunter or a river in their line of march compel them to take wing. When about to cross a river, they select the highest eminences, that their flight may be more sure, and in such positions they sometimes stay for a day or more, as

if in consultation. The males upon such occasions gobble obstreperously, strutting with extraordinary importance, as if to animate their companions; and the females and young assume much of the pompous air of the males, and spread their tails as they move silently around. Having mounted at length to the tops of the highest trees, the assembled multitude, at the signal note of their leader, wing their way to the opposite shore. The old and fat birds, contrary to what might be expected, cross without difficulty even when the river is a mile in width; but the wings of the young and meagre, and of course those of the weak, frequently fail them before they have completed their passage, when in they drop, and are forced to swim for their lives, which they do cleverly enough, spreading their tails for a support, closing their wings, stretching out their neck, and striking out quickly and strongly with their feet. All do not succeed in such attempts, and the weaker often perish.

The wild turkeys, according to the same interesting author, feed on maize, all sorts of berries, fruits, grasses, and beetles; tadpoles, young frogs, and lizards, are occasionally found in their crops. The pecan-nut is a favourite food, and so is the acorn, on which last they fatten rapidly. About the beginning of October, whilst the mast still hangs on the trees, they gather together in flocks, directing their course to the rich bottom-lands, and are then seen in great numbers on the Ohio and Mississippi. This is the Turkey-Month of the Indians. When the turkeys have arrived at the land of abundance, they disperse in small promiscuous flocks of every sex and age, devouring all the mast as they advance. Thus they pass the autumn and winter, becoming comparatively familiar after their journeys, and then venturing near plantations and farm-houses. They have been known on these occasions to enter stables and corn-cribs in search of food. Numbers are killed in the winter, and are preserved in a frozen state for distant markets. The beginning of March is the pairing time, for a short time previous to which the females separate from their mates, and shun them, though the latter pertinaciously follow them, gobbling loudly. "The sexes," continues the Prince, "roost apart, but at no great distance, so that when the female utters a call, every male within hearing responds, rolling note after note in the most rapid succession; not as when spreading the tail and strutting near the hen, but in a voice resembling that of the tame turkey when he hears any unusual or frequently repeated noise. Where the turkeys are numerous, the woods, from one end to the other, sometimes for hundreds of miles, resound with this remarkable voice of their wooing, uttered responsively from their roosting places. This is continued for about an hour; and, on the rising of the sun, they silently descend from their perches, and the males begin to strut for the purpose of winning the admiration of their mates. If the call be given from the ground, the males in the vicinity fly towards the individual, and, whether they perceive her or not, erect and spread their tails, throw the head backwards, distend the comb and wattles, strut pompously, and rustle their wings and body-feathers, at the same moment ejecting a puff of air from the lungs. Whilst thus occupied, they occasionally halt to look out for the female, and then resume their strutting and puffing, moving with as much rapidity as the nature of their gait will admit. During this ceremonious approach, the males often encounter each other, and desperate battles ensue, when the conflict is only terminated by the flight or death of the vanquished." The usual fruits of such victories are reaped by the conqueror, who is followed by one or more females, which roost near him, if not upon the same tree, until they begin to lay, when their habits are altered with the view of saving their eggs, which the male breaks if he can get at them. They are usually from 9 to 15 in number, sometimes 20, whitish and spotted with brown like those of the domestic bird. The nest consists of a few dried leaves placed on the ground, sometimes on a dry ridge, sometimes in the fallen top of a dead leafy tree, under a thicket of shrub or briars, or by the side of a log. The females are particularly attentive to their young.

The range of the wild turkey appears to extend from the North-Western Territory of the United States to the Isthmus of Darien; the birds which have been taken for it to the south of the Isthmus were probably Curassows [CRACIDÆ]; and the improbability of its extension beyond the Rocky Mountains, or even so far, is shown not only by the absence of notice of it by the travellers in those parts, but from more positive evidence.

The time of the first appearance of the turkey in Europe is doubtful. The French writers attribute its introduction to the Jesuits somewhat hastily, for there is evidence that turkeys were known in Europe about 1530, if not before that year; whereas it was not before 1534 that Ignatius Loyola, being at Paris, entered into a solemn compact with six of his friends and fellow-students to promote his great object, the foundation of that religious order. The probability is that the Spaniards were the first to bring this bird to Europe, whence it has spread over the whole civilised world; but it is not impossible that it may have been brought to England by Cabot, or some of the subsequent expeditions.

In a domesticated state the plumage varies as much or more than it does in the common poultry. White is far from uncommon; buff is more rare. But the most curious variety is that mentioned by M. Temminck, which was in Madame Backer's aviary at the Hague. This bird had a topknot springing from the crown of the head; and a flock

of a pale reddish tint, with an ample crest of pure white, were reared by the same lady.

The royal forests of this country would afford ample shelter to these fine birds, and there, with little trouble, they might be kept in a state of nature. They would soon return to their wild habits, even if it should be thought too much trouble to import some of the true wild breed; and a noble addition they would make to the game in such royal preserves as Windsor and the New Forest. Formerly many were thus kept in Richmond Park, and Windsor Forest was much frequented by them.

M. ocellata. Cuvier first described this beautiful bird from the specimen formerly in Mr. Bullock's museum, and now in that of Paris, for which it was bought at the breaking up of Mr. Bullock's collection, and lost to this country.

The crew of a vessel were cutting wood in the Bay of Honduras, when they saw three individuals, and captured one alive, which was sent to Sir H. Halford, and met with an accident after its arrival in the Thames, and before it reached Sir Henry, which caused its death. Sir Henry presented it to Mr. Bullock, who then exhibited his museum in the Egyptian Hall, Piccadilly, of which it was one of the most distinguished ornaments.

Its size is nearly that of the common turkey; but the tail is not so much developed, nor is it known whether the bird can spread it or not: the probability is that it can. Bill of the same form with that of the common turkey, having a caruncle at its base, apparently capable of elongation and contraction like that of the common sort. Head and two-thirds of the neck naked, and, apparently, livid, but without fleshy tubercles on the lower part. There are five or six above each eye, five upon the centre of the crown, and six or seven in a line one above the other at nearly equal distances on the sides of the neck. No trace of a tuft on the breast could be perceived; but the plumage was rather damaged. Feathers rounded at the ends; those of the lower part of the neck, upper part of the back, scapulars, and all the lower part of the body, bronze-green, with two terminal bands, the first black, and the last, or that next to the tip, of a golden-bronze hue. The tints on the other parts of the back are the same, but near the tail-coverts they are more vivid, the bronze becoming of a rich blue or emerald-green, according to the incidence of the light, whilst the outer band becomes broader and more golden. Red mingles with the tints on the rump, where the plumage almost assumes the brilliant character of that of some humming-birds, and the bright border is separated from the blue by a band of velvety black. The hidden part of each feather is gray, mottled with black; and indeed upon the tail and upper coverts this gray is shown, forming bars, one of which, immediately succeeding the blue band, surrounds it, and gives each feather an ocellated appearance. The tail-coverts and lower feathers of the rump are so disposed that there are four rows with these ocellated tips. The tail, consisting of 14 feathers only, is rounded. Lower parts of the body banded with bronze, black, and green, but wanting the lustre of the upper parts. Quills and bastard wing black, edged obliquely with white, which occupies the external margin of the first almost entirely. Outer webs of the secondaries pure white, not showing the bands in the centre when the wings are closed; the uppermost blotched in the centre with black shot with green, which as the feathers shorten extends more over their surface, so as to leave only a white edge. Greater coverts chestnut. Feet and legs lake-red. (Cuvier; Temminck.)

*Meleagris ocellata.*

Polyplectron (Temm.).—Bill moderate, slender, straight, compressed, the base covered with feathers, convex above, where it is rather thick; orbits and part of the cheeks naked; nostrils lateral, placed towards the middle of the bill, and half-closed by a membrane. Two spurs on the feet; tarsi long and slender, the hind toe not touching the ground. Tail-feathers long and rounded, the fifth and sixth longest.

This beautiful form was raised to the rank of a genus by M. Temminck, who established it upon the bird which was named *Paro Tibetanus* by Brisson, the Chinese Peacock-Pheasant by Edwards, *Paro bicalcaratus* by Linnaeus, and L'Eperronier by Buffon. Cuvier placed it among the Peacocks, properly so called, but other species have been since discovered, which, throwing further light upon the modifications of form, well justify its genuine separation. It is the *Diplectron* of Vieillot.

P. Emphanum. Male. Length about 10 inches. Forehead and crown ornamented with a crest of long, narrow, loose feathers, which, together with the plumage of the neck and breast, are rich bluish-black with metallic reflections. Above the eyes a large pure white shining stripe, and a patch of the same colour upon the ear-feathers. Back and rump brown, with irregular paler waved bands. Belly and vent deep black. Wing-coverts and secondaries brilliant blue, each feather tipped with velvety-black. Tail rather long, much rounded, brown, thickly spotted with ochraceous-white, and distinguished by large ocellated oval spots of a brilliant metallic-green. Towards the end of each feather there is a blackish bar. This beautiful and ample tail is supposed not to be erectile, but to be capable of very wide expansion. This is the Eperronier à Toupet of M. Temminck; the Crested *Polyplectron*. Probably inhabits Sunda and the Molucca Isles.

Crested *Polyplectron* (*Polyplectron Emphanum*).

P. Tibetanum. This is the *Paro Tibetanus* of Brisson and Gmelin, the Chinquis of Buffon, the Thibet Peacock of Latham, the Peacock

Thibet Peacock (*Polyplectron Tibetanum*).

Pheasant of Edwards, and the Eperronier Chinquis, *Polyplectron Chinquis* of Temminck.

It is supposed to be a native of the mountain chain which separates Hindustan from Tibet.

In the *Polyplectron Chalcurem* the plumage is comparatively sombre. The ocellated spots on the wings and tail are absent, and the latter, instead of being rounded, has a more elongated pheasant-like form, approaching to that of *Argus*.

The beautiful birds above briefly noticed, and inhabiting the Indian Islands or China, are described as being almost as hardy as the Peacock, and there is little doubt that they might be domesticated in this country. The Tibetan *Polyplectron* is procured for the aviaries of the wealthy Chinese, and M. Temminck's drawing was taken from a bird that had lived for five or six years in an aviary at the Hague.

Dr. J. E. Gray ('Illustrations of Indian Zoology') has figured two other species, *Polyplectron Hardwickii*, nearly allied to *P. bicalcaratus*, and *P. lineatum*, which appears to Sir W. Jardine to be the young of some other species; there are, he observes, no spurs on the tarsi. Dr. Gray's figures were taken from General Hardwicke's drawings by native artists.

Argus (Temm.).—Bill compressed, straight except at the extremity, where it is curved, vaulted, and naked at its base; nostrils placed in the middle of the upper mandible, half-closed; head, cheeks, and neck, naked. Tarsi long, slender, spurless. Two middle tail-feathers longest, secondary quills much more developed than the primaries.

Head of *Argus*.

The only species known is *Argus giganteus*.

This bird is remarkable for the beauty of its plumage. The wings, the secondaries of which are three times as long as the primary quills, are painted and ocellated in a manner that defies description. A very faint idea of the pattern of one of these secondaries may be derived from the accompanying cut.

Secondary quill of *Argus giganteus*.

This bird is the beautiful Chinese Pheasant described in 'Phil. Trans,' vol. 55, p. 88; L'Argus ou Luen of Buffon; *Argus* Pheasant, *Phasianus Argus* of Latham; L'Argus, *Argus giganteus* of Temminck.

The unwieldy size of the secondaries forms an impediment to the bird in its progress through the air, but they assist its pace when running, which it does swiftly with their aid. Its flight, when it does rise on the wing, is heavy and short. When the bird is at rest or unexcited, the beauty spots on the secondaries are hardly visible; but when showing himself off in the presence of his females, the wings of the *Argus* are expanded, and trailed upon the ground to display their beauties; and at this time the tail is comparatively spread, and is raised erect; when at rest it is carried in a line with the body, and

with the two long feathers folded together. The rest of its habits are not known, but it is said not to thrive well in confinement.

It is a native of Sumatra, and probably other Indian Islands, but principally of Malacca. No proof appears of its having been brought from China and Chinese Tartary, although ornithological writers name those countries as the places of its habitation. The feathers and drawing of the bird described in the 'Phil. Trans.' by G. Edwards were sent from Canton to Dr. Forbergill, and are stated to have come from one of the most northern provinces of China.

Argus Pheasant (*Argus giganteus*), full-grown male.

Lophophorus, Temm. (*Monaulus*, Vieill.).—Bill strong, long, very much curved, wide at its base, rather thick, convex above; the upper mandible longer than the lower and overlapping it, large, and trenchant at its extremity; nostrils half closed by a membrane covered with small scattered plumes. Tarsus furnished with a long and sharp spur; hind toe elevated and not touching the ground except at its end. Tail-feathers 14, straight and rounded; fourth and fifth quills longest.

L. Impeyanus (*L. refulgens*, Temm.; Impeyan Pheasant, *Phasianus Impeyanus*, Lath.). We must refer our readers to the bird itself, or to the excellent figure in Mr. Gould's 'Century of Birds from the Himalaya Mountains,' for anything like an adequate idea of the beauty of its tints; for the greater proportion of the plumage is dazzling with changing hues of green, steel-blue, violet, and golden-bronze. The bird looks as if it were principally clothed in a scale-armour of iridescent metal; but the plumage is soft and velvety to the touch. The crest on the head consists of naked-shafted feathers, with an oval or

Head of Impeyan Pheasant (*Lophophorus Impeyanus*), male.

battledore tip of the same quality as the rest of the plumage, and of a metallic green; the centre of the back is pure white; the tail is rounded and bright chestnut. Size of a hen turkey.

The principal food of this species consists of bulbous roots, for scooping out which its bill is well adapted. Nothing certain seems to be known of the rest of its habits.

It is a native of the mountain ranges of Nepaul and the Himalayas.

Impeyan Pheasant (*Lophophorus Impeyanus*), male and female; upper figure, male. (Gould.)

Numida (Linn.).—Bill short, strong, vaulted, stout, furnished with a warty membrane at the base; from the lower mandible hang two carunculated wattles; head naked or feathered; forehead surmounted with a bony casque or feathered crest; nostrils pierced in the cere, and divided by a cartilage. Tail short; fourth quill longest.

Head of Guinea Fowl (*Numida Meleagris*).

The birds known to the ancients under the name of *Meleagrides* and *Gallina Numidica* belonged to this genus. They are all natives of Africa, living principally on berries, small slugs, &c.

N. Meleagris (the Gallina di Numidia of the Italians; Poulle de la Guinée and Pintade Meleagride of the French; Pintado of the Spanish; Perl Huhn of the Germans; and Pearl-Hen, Guinea Hen, and Common Guinea Fowl of the English) is too well known to need description.

The bird has been spread very widely, and few poultry-yards are without it. In Jamaica, where they do much mischief to some of the crops, they have resumed their wild habits, and are shot like other game.

N. cristata is the Peintade à Crête and Peintade liuppé of the French, and Crested Pintada of Latham; it is the genus *Guttera* of Wagler. It is less than the Common Guinea Fowl. Head and neck bare, of a dull or leaden blue shading into red on the head, which is ornamented with a crest of loose hair-like feathers of a bluish-black, instead of the hard casque of the common species; this crest advances forward as far as the nostrils, but the feathers mostly turn backwards. General plumage bluish-black spotted with gray; there are from four to six spots on each feather; quills pale yellowish-brown; edges of the secondaries pure white, showing well in contrast with the rest of the dark colouring.

It is a native of Africa, in Great Namaqua Country.

Crested Pintada (*Numida cristata*).

Mr. Swainson is of opinion that the Spotted-Winged Pintada is a distinct species, which he names *N. maculipennis*.

 PE'CURA, the name given by Linnaeus to his fifth order of *Mammalia*. [MAMMALIA; MAMMALIOT.]
 PECTEN. [PECTINIDÆ.]
 PECTINARIA (Lamarck), a genus of *Amphitritida*, Cuvier's fourth family of his Annelidæ Tubicoles, the first order of his Annelidæ. [ANNELIDA.]
 PECTINIBRANCHIATA, Cuvier's sixth order of *Gastropoda*. [MALACOLOG.]
 PECTINIDÆ, or OSTREIDÆ, a family of Conchiferous *Mollusca*, to which the common Oyster belongs. It has the following characters:—Shell inequivalve, slightly inequilateral, free or adherent, resting on one valve; beaks central, straight; ligament internal; epidermis thin; adductor impression single, behind the centre; pallial line obscure; hinge usually edentulous. Animal marine; mantle quite open, very slightly adherent to the edge of the shell; foot small and byssiferous, or obsolete; gills croceat-shaped, two on each side; adductor muscle composed of two elements, but

representing only the posterior shell-muscle of other bivalves. (Woodward.)

The principal genera referred to this order are—*Pecten*, *Ostrea*, *Lima*, *Placuna*, *Anomia*, *Placunomia*, *Hinnites*, *Spondylus*, and *Plicatula*.

Pecten (Lamarck).—Animal subrotund, not thick; lobes of the mantle very delicate, disunited throughout, thickened on the borders, and furnished with many rows of fleshy cilia, between which are regularly disposed a series of smooth oculiform tubercles; branchiæ large, decomposed into detached filaments; the small foot dilated at its extremity; mouth rather large, oval, surrounded with projecting and deeply-cut lips, and furnished on each side with a pair of triangular palps, truncated at their extremity. (Deshayes.) Shell free, regular, inequivalve, auriculated; lower margin transverse, straight; umbones contiguous; hinge toothless; cardinal pit entirely internal, trigonal, and receiving the ligament. (Lamarck.)

The Pectens are widely diffused, and species are to be found in the seas of most climates. Though there is a general similitude in the shells of all the numerous species which at once shows to what genus the animal belongs, the varieties of form and colour are infinite, and the species are in many instances very difficult to be defined, though the eye of an acute observer will at once determine differences which the pen cannot convey without some difficulty, if it succeed in making the differences understood at all. The colours of some are most vivid and beautifully variegated, whilst those of others again are sombre. The shells of some are stout and heavy, of others light, and some are nearly as transparent as glass (*P. vitreus*, Gray, and *P. vitreus*, King, for example). The depths at which they have been hitherto found range from the surface to 20 fathoms. *P. vitreus* (King), which occurred everywhere in the Strait of Magalhaens, was found attached to the leaves of *Fucus giganteus*, and formed, with other molluscs, the food of the Steamer or Race-Horse Duck (*Micropterus brachypterus* and *M. Patachonicus*). The bottoms haunted by the Pectens have been found to be sands, sandy-mud, and mud.

As an article of food, the species of this genus are generally useful. On our own southern coasts, where the sea is prodigal of its contributions to the table, Pectens are considered a delicacy, and when well treated by a good cook make a rich and sapid dish, as might be expected from the name of them when so prepared, 'Quins.' The St. James's Cockle-Shell (*P. Jacobæus*) was formerly the badge of the pilgrim who had been to the Holy Land.

Linnaeus separated this extensive genus, that is, the Pectens properly so called, into three sections:—1. The Auriculated Equilateral Pectens. 2. The Pectens with one auricle ciliato-spinous within. 3. (Including *Lima*) Pectens with their valves more gibbous on one side than on the other. Of the first of these, *P. Jacobæus* and *P. Pleuronectes* are examples; of the second, *P. Pallium*, the well-known Ducal Mantle of collectors; and of the third, *P. flavicans* and *P. fasciata* (Linu.).

Lamarck divided the genus into two sections only: the first containing the species with the auricles equal or nearly equal; the second consisting of those which have the auricles unequal. The species cited as examples of the first and second divisions of Linnaeus will serve as illustrations of this arrangement.

M. De Blainville separates the Pectens into four subdivisions:—1. (Les Pelerines) Those species which are very inequivalve, the left valve being very flat (*P. Jacobæus*, &c.). 2. (Les Soles) Equivalve species which do not gape (*P. Pleuronectes*). 3. Species whose two valves are nearly equally concave, but the right rather the least, and having its inferior auricle less wide than that of the left, so as to produce a sort of notch, for the passage of the byssus, as he thinks (*P. gibbus* and *P. glaber*). 4. Species with striae parallel to their border (*P. orbicularis*, fossil).

Mr. G. B. Sowerby makes the divisions five:—1. Both valves convex, equal or nearly in size (*P. turgidus*). 2. One valve flat, the other deep or convex (*P. Jacobæus*). 3. Both valves rather convex, not meeting all round (*P. Pleuronectes*). 4. Both valves convex, but unequal in size (*P. bifrons* and *P. aurantiacus*). 5. Irregular, apparently adherent by the outside, but only taking the form of whatever it is attached to in consequence of being close pressed to it (*P. Pusio*, *Hinnites*).

The same author states his belief that all the Pectens are attached by a byssus, although it is seldom observed, even in the living specimens.

The following sub-genera have been formed from this genus:—*Neithea* (Drouet), *Pallium* (Schum.), *Hinnites* (Defr.), and *Hemiacetus* (Adams). Woodward gives the number of recent species of *Pecten* as 120, and the fossil species as 450.

P. Jacobæus. Shell inequivalve, rather flattened above, with from 14 to 16 angulated rays; those of the lower valve longitudinally sulcated. Often agreeably variegated.

It is a native of the seas of Europe, but not of the British Islands. It is fossil in Italy.

P. Pleuronectes. Shell sub-equivalve, rather thin, smooth externally, somewhat convex on both sides. This species has the upper valve always coloured, generally reddish or rich reddish-brown, and the lower one white, whence its name. In the inside of the valves are projecting radiated somewhat distant ribs.

It is found in the East Indian seas, and fossil in France, at St. Paul-Trois-Châteaux, in the department of Drôme.

*Pecten Jacobæus.**Pecten Pleuronectes.*

P. gibbus. Shell sub-equivalve, ventricose, turgid, red, with from 20 to 22 convex rays, which are somewhat rugose at their sides and interstices.

It is found in the Atlantic and American oceans.

*Pecten gibbus.*

P. orbicularis. Shell suborbicular, depressed, rather convex, with transverse concentric striae on one valve, the other valve smooth; no

rays. It has been found fossil in England—Wiltshire, Devizes; Sussex, chalk formation; France—Coullaines, near Mans. It approaches *P. Pleuronectes*.

*Pecten orbicularis.*

The following species of *Pecten* are British:—*P. varius*, *P. niveus*, *P. Pusio*, *P. striatus*, *P. tigrinus*, *P. Danicus*, *P. similis*, *P. maximus*, *P. opercularis*.

The sub-genus *Hinnites* has the shell oval, irregular, adhering by the right valve, inequivalve, subequilateral, perfectly closed; its upper part terminated on each side by auricles similar to those of *Pectens*; cardinal border straight, toothless, prolonged with age into a small heel (talon); ligament thick, contained in a narrow and very deep gutter (gouttière).

A small number of species only belonging to the genus is as yet known, and a single living species (*H. sinuosus*, Desh.; *Pecten sinuosus*, Lam.; *P. Pusio*, Pennant, Sow.; *Ostrea sinuosa*, Gmel., Matou, and Rackett) has been recorded.

The fossil species, four or five in number, come from the tertiary beds of France and Italy.

H. sinuosus, *Pecten Pusio* of authors, has the shell ovate, unequally sinuous, variegated with brownish orange and white, and marked with numerous very narrow, striaform, and scabrous rays.

*Hinnites sinuosus. a, outside of under valve.*

Lima (Brug.).—Animal oval, having the lobes of the mantle separated nearly throughout their extent, larger than the valves of the shell, and turned inwards (se renversant en dedans); this part of the border is wide, and furnished throughout its extent with numerous tentacular, elongated, and annulated cirrhi. Branchiae rather large, equal, and separated (écartées); foot cylindrical, vermiform, rather club-shaped, and terminating in a small sucker (ventouse), by means of which the animal can fix itself to submarine bodies; no byssus; buccal aperture oval, furnished with large foliaceous lips, terminated on each side by triangular and obliquely-truncated labial palps, (Deshayes.)

Shell longitudinal, subequivalve, auriculated, rather gaping on one side of the valves; umbones distant (écartées), their internal facets inclined inwards; hinge toothless; cardinal pit partly external, receiving the ligament.

M. Deshayes, in his edition of Lamarck, states his opinion that *Lima* is a genus which well deserved to be separated from its congeners in the family of *Pectinida*. Not only, says M. Deshayes, has it no byssus, but its mantle, like the shell, gapes much; and the large re-entering edge of the former is furnished with a great number of vermiform flexible tentacula, which seem formed, like the antennae of insects, of gradually decreasing articulations. Between these tentacles there are no tubercles with smooth surfaces similar to those of the *Pectens*, the *Spondyli*, and the *Peda*. The foot has a particular form, recalling to the observer that of *Lucina* or *Loripes*; it is elongated, narrow, cylindrical, and rather thickened at its free extremity, where it terminates in a sort of sucker, which, according to the observations of M. Quoy, serves to fix the animal upon solid bodies even of the most smooth surface. The mouth is placed between two lips comparable to those of *Pinna*; they are foliaceous, descend upon the lateral parts of the body, and terminate on each side in a pair of labial palps, which are truncated and triangular. The branchiae are rather large and equal. Those on one side are separated from those on the other by a rather wide space, in which may be easily perceived the adductor muscle, on the posterior face of which the anus terminates. This muscle seems more extensible

than in the greater part of the molluscs of the same class. When it is not contracted the valves are widely opened, and the animal has the power of impressing on it frequent and sudden contractions, the rapidity of which is facilitated by the extreme elasticity of the ligament of the valve. By means of these reiterated contractions the animal can flutter in the water, to use the happy expression of M. Quoy, and one must run after it to catch it among the corals or in the shallows where it dwells. M. Deshayes concludes that, from this remarkable union of characters, it might be possible for zoologists to decide upon forming of this genus a small family distinct from the Pectens, but placed in their neighbourhood.

The power of flitting through the water is possessed by the Pectens. [CONCHIFERA.]

The species of *Lima* are widely distributed, and is generally found in the seas of warm and temperate climates, where it has been taken at depths ranging from the surface to thirty fathoms.

Mr. Garner remarks that in the heart of *Lima* there are two ventricles, the rectum passing between them.

Limatula (S. Wood) and *Limca* (Brown) are sub-genera. Woodward computes the recent species at 20, and the fossil at 200.

L. squamosa. Shell oval, depressed, clipped as it were anteriorly, white; ribs squamous, rough as a file; hinge oblique, margin crenated. It is a native of the seas of America. There is a variety which has the scales less numerous.

Lima squamosa.

The British species of *Lima* are—*L. subauriculata*, *L. Loscombii*, and *L. hians*.

Spondylus.—Animal oval, oblong; the borders of the mantle disunited, thick, and furnished with many rows of tentacular cirrhi, many of which are truncated, and terminated by a smooth and convex surface. Mouth oval, furnished with great cut (decoupées) lips, and on each side with a pair of oblong and pointed labial palps. Branchiæ in form of a crescent, and formed of detached filaments. Foot rudimentary, on the disc of which a club-shaped pedicle raises itself. Anus floating behind the adductor muscle of the valves. (Deshayes.)

Shell inequivalve, adherent, auriculated, beset with spines or rough; the umbones unequal; the lower valve offering an external cardinal facet which is flattened and divided by a furrow, and which increases with age. Hinge with two strong teeth in each valve, and an intermediate fosset for the ligament, communicating by its base with the external furrow. Ligament internal, the ancient remains of which show themselves externally in the furrow. (Lamarck.)

Spondylus dorsalis; internal view of valves, showing hinge, ligament, muscular impression, &c. a, upper valve; b, lower valve.

The spines with which the *Spondyli* are armed, in some instances very long, must have struck everybody, and also that they bristle out on every side from the upper valve. The lower valve is attached, and adheres to submerged bodies by means of foliations. If the whole lower surface adheres, as it often does, not a spine is given out from the lower valve; but where the adhesion takes effect towards the anterior part of the lower valve only, as is very frequently the case,

especially when the shell is affixed among the branches of corals, a favourite locality with some species, the foliations are confined merely to that part where adhesion is required, and the rest, or free part of the valve, is as profuse of spines as the upper valve itself. There are two points to be gained, support or adhesion, and defence; the first is of primary importance, but as soon as that is safe, all the resources of the animal seem to be turned towards its defensive and offensive armour. Those fishes which browse among the corals are thus deterred from injuring the living fixture which has there taken up its abode. A very fine series of specimens was collected with a view to this habit, and they showed not only the power which the animal had of secreting the proper process of shell according to the circumstances required, but of modifying the secretion according to the exigencies of the occasion.

Spondylus Americanus, with the valves closed; the umbones towards the spectator.

But there is another, and more interesting phenomenon, well displayed in one of the species of this genus. Professor Owen, having been led to reflect, while considering the uses of the camerated part of the shell of *Nautilus*, upon the degree or extent of that structure as possibly dependent upon the mode of growth of the animal and its shell, and how far it was a necessary physical consequence of the increase and change of position of the animal, independently of any special purpose served by the forsaken parts or chambers of the shell, had paid attention to all the cases that had come under his observation of the formation of chambers in shells, by the secretion, on the part of the animal, of a nacreous layer, forming a new basis of support to the soft parts, and cutting off the deserted portion of the shell from the chamber of occupation. In a paper on the 'Structure of the Water-Clam' (*Spondylus varius*, Brod.), read before a meeting of the Zoological Society of London, he observes that it is well known that the process above adverted to is not the only mode adopted to suit the shell to the changing form and bulk, or other exigencies of its occupant. Taking the genus *Magilus*, for one example, the Professor remarks that the part of the shell from which the body gradually recedes is filled up by the continuous compact accretion of calcareous matter, and a solid massive elongated shell is thus produced, which would be a great incumbrance to a locomotive mollusc, but is of no inconvenience to a univalve destined by nature to live buried in a mass of lithophytous coral.

Other instances were observed in *Helix decollata* and in the chambers formed in *Septaria*. Among the bivalves the *Ostrea* not unfrequently present shallow and irregular chambers in the substance of the shell, and the *Etheria* have vesicular cavities interposed between the testaceous laminae; but the most constant and remarkable example of the camerated structure of the shell is presented by the large *Spondylus*, or Water-Clam, above named, so called from the fluid which (until lost by slow evaporation) occupies the chambers, and which is visible in the last-formed chamber through the thin semi-transparent exposed septum.

In order to examine this camerated structure, and more especially to see how it was modified by the presence and progressive change of place of the adductor muscle, he had a fine specimen sawn through vertically and lengthwise; it measured 8 inches in length; the substance of the concave valve, which was 2½ inches in thickness at the thickest part, included 14 chambers separated from each other by very regularly formed and stout partitions, composed, as in other chambered shells, of the nacreous portion or constituent of the shell. The septa were slightly undulating in their course, but presented a general concavity towards the outlet of the shell. Not any of these partitions were however continued freely across the shell, but each became continuous at the muscular impression, which is near the middle of the shell, with the contiguous septa. In general also the septa commenced singly from the cardinal or upper wall of the valve, and divided into two when about one-fourth of the way towards the opposite or lower wall, the thickness of the undivided part of the septum being equal to, or greater than, that of the two divisions of layers into which it splits.

"The secreting power of the lower lobe of the mantle in the *Spondylus*," says Professor Owen in continuation, "is greater than in the upper; and the layers of nacre which are successively deposited on the cardinal margin push forward in a corresponding degree the upper valve, leaving a heel or umbo behind the hinge of the lower valve, which, from the inactivity of the secreting surface of the upper lobe of the mantle, is not opposed by a corresponding umbo in the upper valve.

"The laminae, which are deposited in a continuous series of superimposed layers at the hinge of the lower valve, are not continued in a like state of superposition throughout; they soon separate from each other, and do not again unite, except at the space corresponding to the adductor muscle, and at the circumference of the valve.

"The interspaces of these successive layers of the growing *Spondylus* cannot, from the absence of a medium of intercommunication, serve any purpose hydrostatically with reference to locomotion; it is a singular fact indeed that the *Spondylus*, in which the chambered structure is constant, and the *Ostrea* and other bivalves, in which it is occasional, are cemented to extraneous bodies by the outer surface of the shell, generally by the concave valve; so that the septa must be regarded as mere dermal exuviae still left adhering to the animal, to which, as a motionless bivalve, they are no incumbrance. It is highly probable that all the chambers are originally filled with fluid, as more or less is found in the outer ones of the specimens brought to this country.

"In the Testaceous Cephalopods a new structure is added, namely, the siphon, whereby the exuvial layers of the old shell and the deserted chambers are converted into a hydrostatic instrument, subservient to the locomotion of the animal. The operation of the siphon and chambers has been ably explained by Dr. Buckland in the *Nautilus*, where the calcareous inflexible tube protecting the membranous siphon is not continuous. The working of the siphon is however less intelligible in those species in which the outer calcareous tube is continued from chamber to chamber, as in the *Spirula*, *Orthoceratites*, &c.; and it is with respect to camerated shells of this kind that I would ask how far the reasoning suggested by the chambers in the Water-Spondylus may be applicable in their case, and whether a final intention can be clearly traced beyond the diminution of specific gravity occasioned by a large proportion of the shell being converted into receptacles of gas; if indeed we have sufficient evidence to assume that they do not contain denser fluid, like the *Spondylus*."

The cut represents a section of a very old individual of this species, in which the upper valve was very convex, and furnished with a great number of septa.

Section of Water-Spondylus cut longitudinally through both valves, which are represented as closed.

The species of *Spondylus* have been found attached to rocks, corals, other shells, &c., at depths varying from the surface to 100 fathoms, in the seas of warm and temperate climates, as the West Indies, the Canaries, the Mediterranean, India, Torres Straits, the Pacific, and West America. The finest and most beautiful species are natives of tropical and intertropical localities.

The number of recent species is about 30, and fossil 45. The latter are found in the Inferior Oolite and Neocomian Beds.

Pedum, Lamarck, (sub-genus).—Animal oval, oblong, flattened, having the lobes of the mantle open throughout their circumference, thickened on their edges, and furnished on this part with many rows of tentacular cirrhi, and, at regular distances, tubercles with smooth surfaces. A pair of large branchiæ descending on each side to the edge of the lower border of the mantle; abdominal mass small, having anteriorly and high up a small vermiform foot, and at its base a silky bysuss of some size; mouth oval, having on each side a pair of labial triangular palps. (Dehayes.)

Shell inequivalve, subauriculate, lower valve gaping; umbones unequal and distant. Hinge toothless; ligament partly external, inserted in an elongated canaliform pit, which is hollowed out in the internal wall of the umbones. Lower valve notched near its posterior base. (Lamarck.)

P. Spondyloideum is the only species. The shell is ovato-cuneiform, planulate; whitish tinged with red or purplish, especially near the umbones; the upper valve flat and striated longitudinally; the lower valve largest, with the lateral edges turned up and raised above those of the upper valve.

Shell of *Pedum Spondyloideum*.

There is a smaller variety, much more round, and generally more delicate.

It is a native of the East Indian Seas (Isle of France, &c.), where it is found half-imbedded in coral-reefs.

Plicatula.—Shell inequivalve, inauriculate, narrowed towards its base; the upper border rounded, subpublicated; with unequal umbones, and without external facets. Hinge with two strong teeth in each valve. A fosset between the cardinal teeth, receiving the ligament, which is entirely internal. (Lamarck.)

The species inhabit the seas of warm climates, where they are found adhering to stones, shells, and other submarine bodies, at depths varying from four to eleven fathoms.

Woodward makes the number of recent species six, and fossil forty.

Shell of *Plicatula*. a, hinge of upper valve.

Ostrea (*Gryphæa* (Lam.), fossil principally; *Exogyra* (Say), fossil only). The two latter genera are so generally established in fossil catalogues, that it may be convenient to retain their names; but we agree with Mr. G. B. Sowerby and M. Deshayes, that, physiologically considered, they ought to be abandoned. Mr. Sowerby, in his 'Genera,' remarks that the particular points upon which Lamarck depends for his distinction between the Oysters and *Gryphææ* are, 1st, the apparent regularity of the latter; 2nd, their being scarcely if at all attached; and 3rd, the generally large, involute, spiral umbo of the lower valve. To the first Mr. Sowerby answers, that though the *Gryphææ* are in general apparently more regular than the *Ostrea*, they cannot be considered as regular shells, and that they are moreover very variable; secondly, the *Gryphææ*, as well as all other *Ostrea*, are attached by the umbo of the larger and concave valve, and this particularly in the young state (in which state in fact it is impossible to distinguish between one and the other); moreover both become free as they advance in size; and if the *Gryphææ* are then apparently more regular, it is because in their young state they have lived in situations where they could only become attached to small regular objects, while the *Ostrea*, having lived in more rugged and irregular situations, and necessarily remaining attached for a longer time, have partaken more of the regularity of their native situation. "Indeed," adds Mr. Sowerby, "there is sufficient evidence that an oyster, when by any chance it becomes attached to a small smooth object, where it is comparatively free, becomes also regular in the same degree: thirdly, we cannot approve of the term spiral as at any time applicable to the umbo of the lower valve of the *Gryphææ*; when young, it is not involute; and though Lamarck mentions the size of this as one important distinguishing mark of his genus, he gives the characters of several species in which this part is small. Another circumstance in which the *Gryphææ* is thought to differ from *Ostrea* has been dwelt upon by some, an obscure lobe or sulcus observable on the right side, particularly

of the lower valve; but this is far from being distinct in some species."

But if the generic claims of *Gryphæa* be untenable, those of *Ecyrga*, established by Say for the reception of the *Gryphæa*, whose umbo, instead of rising above the valves, take a lateral direction, have still less foundation. There is not, says Deshayes in conclusion, a single character which is not to be found in the oysters, and sometimes in the varieties of the same species.

The species of *Gryphæa* are found in almost all the strata down to the lias inclusive, and consist of about thirty-five species.

G. angulata is recent.

Gryphæa incurva (Lias).

Ecyrga is included in the species of *Gryphæa* noticed in the last edition of Lamarck. Von Buch has recently published a fine species under the name of *E. polygona*, from Montan (South America), where it was found in company with *Pectens* by M. Alexandre de Humboldt.

Ecyrga conica (Upper Greensand, Gault, Lower Greensand, Blackdown).

The generic characters of *Ostrea* are as follows:—Animal oval, oblong, flattened, often irregular; lobes of the mantle thick and fringed on the borders, separated throughout their extent; no foot; mouth moderately furnished with two pair of elongated lanceolate palps; branchie large, curved, nearly equal. The non-symmetrical heart not having its basis upon the intestine, which last terminates behind the adductor muscle by an anus which floats between the lobes of the mantle. (Deshayes.)

Shell adherent, inequivalve, irregular; umbones distant, and becoming very irregular as the animal advances in age; upper valve smallest, gradually displacing itself, and advancing forwards as the animal grows older. Hinge toothless; ligament demi-internal, inserted in the cardinal pit of the valves; the pit of the lower valve increasing with the age of the animal, as well as the umbo, and acquiring sometimes a great length.

The species of this genus are distributed very widely, and principally in the seas of temperate and warm climates: no species appear to have been met with in the Polar Expeditions very far north. Oysters have been taken on gravel and sand, in estuaries, and on the sea-coast, sometimes attached to rocks, trees, &c., at depths varying from the surface to 17 fathoms. In the British Museum there is a good-sized crab, on the back and claws of which are many oysters. [CAR.]

The True Oysters have been divided into two groups, which may be satisfactorily used by zoologists and geologists as subdivisions of this numerous genus.

A. True Oysters with simple or undulated, but not plaited valves.

This considerable group, which consists of between 30 and 40 recorded species (recent), may be illustrated by the well-known *Ostrea edulis*, or Common Edible Oyster of the European seas.

The Edible Oyster is the *Ostrea* and *Ostreum* of the Romans; *Ostrica* of the Italians; *Ostra* of the Spaniards; *Auster* of the Germans; and *Heltre* of the French.

"The *Ostrea edulis*," says Professor E. Forbes, in the 'History of British Mollusca,' "may be said to have its capital in Britain, for though found elsewhere on the coasts of Europe, both northward and southward, in no part of them does it attain such perfection as in our seas, through which it is generally distributed, sparingly in some places, abundantly and in gregarious assemblages in others, chiefly inhabiting the laminarian and coralline zones. The ancient Romans

valued our native oysters even as we do now, and must have held them in higher estimation than those of Italian shores, or they would not have brought them so far for their luxurious feasts. Juvenal records the exquisite taste of the epicure:—

"'Who,

At the first bite, each oyster's birthplace knew;
Whether a Lucrine or Circæan he'd bitten,
Or one from Rutupinian deeps in Britain.'

"'Circæis nata forent, an

Lucrinum ad saxum, Rutupinovæ edita fundo
Ostrea, collebat primo deprendere morsu.'

(Juvenal, 'Sat.' I., iv. 140.)

Property necessarily exposed, as these valuable oyster-beds must be, required the protection of the legislature. (Stat. 31 George III., c. 51; 48 George III., c. 144; and 7 and 8 George IV., c. 29.) By the last-named statute (which repeals 31 George III., c. 51), sec. 36, stealing of oysters or oyster-brood from any oyster-bed, laying, or fishery, is larceny, and the offender upon conviction shall be punished accordingly. Moreover, if any person shall unlawfully and wilfully use any dredge, net, &c. for the purpose of taking oysters or oyster-brood, within the limits of any oyster-bed or fishery, every such person shall be deemed guilty of a misdemeanour, and upon being convicted thereof, shall be punished by fine or imprisonment, or both, such fine not to exceed 20*l.*, and such imprisonment not to exceed three calendar months. The statute contains a provision that the catching floating fish with any net, instrument, or engine adapted for catching such fish, within the limits of any oyster-fishery, shall not bring the fisher within the penalties of the Act. [OYSTER, in ARTS AND SC. DIV.]

The bill for the protection of the oyster-fisheries in Scotland provides that any person in Scotland knowingly stealing oysters from a bed, laying, or fishery, which is sufficiently marked as the property of other persons, shall be deemed guilty of theft, and punished accordingly; and that any person using any net, dredge, or other instrument, within the limits of such oyster-fishery, for the purpose of taking oysters, although none be actually taken, shall be deemed guilty of an attempt to commit theft, and be liable to fine or imprisonment, the fine not to exceed 20*l.*, and the imprisonment not three months, with a clause that nothing in the act shall prevent persons from catching floating-fish in an oyster-fishery with instruments adapted for taking floating-fish only.

B. True Oysters, with the borders of their valves distinctly plaited.

Of this group, consisting of more than 30 recorded species (recent), *O. Crista Galli*, the Cockscomb Oyster, will serve as an example. It has a shell varying in form according to the bodies to which it adheres, but generally somewhat rounded, very much plaited, the plaits

Cockscomb Oyster (*Ostrea Crista Galli*).

longitudinal and angulated; internal border rough; externally violet, purplish, or reddish-white. The shell externally has subgranulous striae, and subtabular scales. It is found in the East Indian Seas.

The number of recent species of *Ostrea* is 60, and of fossil 200. (Woodward.)

Placuna (Brng.).—Animal very much compressed. Shell free, irregular, very much flattened; valves delicate and almost translucent, quite translucent in some species, nearly equal, and subequilateral; hinge internal, offering on one valve two longitudinal, trenchant, rib-like elevations, converging at the summit, and on the other two furrows, corresponding to those ribs, and giving attachment to the ligament; muscular impression subcentral and rather small. (Rang.)

The species now known are from the East Indian and Red Seas, and have been taken on sandy bottoms.

M. Deshayes remarks that the animal is not known, but that he is convinced that it has a great analogy to that of *Anomia*.

The number of species recorded in the list of M. Deshayes is three living and one fossil (tertiary). Of the living species, *P. papyracea* is noted as both living and fossil (tertiary). Four species are enumerated in the last edition of Lamarck as they were in the first; but the fourth, *P. pectinoides* (fossil), is considered to have all the characters of *Plicatula*, and is therefore removed by M. Deshayes to that genus. Mr. G. B. Sowerby had previously given a similar opinion. The species best known are, *P. Placenta*, vulgarly known as the Chinese Window-Oyster, the valves of which are sufficiently delicate to transmit light; and *P. Sella*, known to collectors as the Saddle-Oyster (from Tranquebar, &c.).

P. Placenta has the shell suborbicular, flat, pellucid, white, with longitudinal subdecussate striae. It is found in the East Indian Seas.

Pl. cuna Placenta.

Anomia (Brug.).—Animal very much compressed, having the borders of the mantle delicate, and furnished externally with a row of tentacular filaments. Foot rudimentary; adductor muscle divided into three branches, the largest of which passes by a notch in the lower valve in order to attach itself to an opercular stony or corneous piece fixed to marine bodies. Shell adherent by its opercular piece, inequivalve, inequilateral, irregular, delicate, and often translucent; the fixed valve most flattened, having a round or oblong notch near the umbo for the reception of the opercular piece; the other larger and more concave; both joined by a short and thick ligament; muscular impression separated into three portions. (Rang.)

NAT. HIST. DIV. VOL. IV.

The recorded species are generally quoted as coming from the European seas and the Atlantic Ocean. The depths at which they have been taken are stated to vary from the surface to 100 fathoms, adhering to oysters, and other shells, rocks, &c.

The species are not very numerous; and perhaps more are recorded than actually exist; for the shell will take upon itself the regularities or irregularities of the body to which it is attached. Thus, on a Pecten, an individual will become striated like that Pecten through both valves, when another of the same species is smooth if adherent to a comparatively smooth body. M. Rang observed this frequently on the shores of the Mediterranean; and both Mr. G. B. Sowerby and M. Deshayes make the same observation.

There are 20 recent and 30 fossil species. The fossils are found in the Crag and London Clay, in the marine formations above the Chalk in France, and as low down as the Oolite.

A. Ephippium. Shell suborbicular, rugoso-plicate, waved, planulate, with an oval foramen, whitish or yellowish, often reddish-yellow, below. One of the largest species. It is found in the British Channel, the Mediterranean Sea, and Atlantic Ocean.

Anomia Ephippium.

a, valve closed; *b*, open to show the hinge; *c*, hinge of attached valve without the bony appendage.

Bony appendage of *Anomia Ephippium* adhering to the rock.

a, the bony part that goes through the opening of the shell; *b*, the surface which is attached to external objects.

M. De Blainville records a species, *Anomia squamata*, which has not this bony appendage, and which he says is affixed by the valve itself. This so-called species, however, which should be *Squamula*, is in Mr. G. B. Sowerby's opinion nothing more than *A. Ephippium* in a very young state before the appendage is ossified.

Anomia squamata.

Placunanomia of Broderip has the following generic character:—Animal probably intermediate between that of *Placuna* and *Anomia*. Shell adherent, subequivalve, irregular, flattened, plaited towards the margin, vitreous internally. Hinge internal, with two elongated, thick, subcurved, divaricated teeth converging at the base in the lower valve, and two ligamentiferous furrows opposite in the upper valve. Lower valve superficially fissured externally towards the hinge, the subosseous organ of adhesion inserted between the laminae of the shell, and filling the fissure externally. Muscular impression in each valve subcentral. In the upper valve the impression of the organ of adhesion is superadded.

This sub-genus partakes of the characters of the genera *Ostrea*, *Plicatula*, *Placuna*, and *Anomia*. It may be regarded as the connecting link between the two latter. With an arrangement of the hinge approaching very nearly to that of *Placuna*, it has the distinguishing organisation of *Anomia*, while the external appearance of the shell, especially if viewed in situ, bears the strongest resemblance to *Plicatula*, or some of the plicated Oysters. The organ of adhesion, which in its bony character (for it is more bony than shelly) resembles that of *Anomia*, does not perforate the lower valve directly, but is inserted between the laminae of the internal surface of the lower valve above the muscular impression and below the hinge, and passes

out into an external, irregular, somewhat longitudinal superficial fissure, or cleatrix, which is narrowest at the hinge margin, and which it entirely fills to a level with the surrounding surface of the shell. (Broderip, 'Zool. Proc.', February 1832.)

The species of this genus are widely diffused, and inhabit the seas of warm climates in both hemispheres. Mr. Broderip has described four ('Zool. Proc.' and Müller's 'Synopsis') brought to this country by Mr. Cuming from the West Indies, Central America, and other western localities. They were dredged from sandy mud and muddy bottoms, adhering to bivalve shells, dead and living, and dead coral, at depths of 6, 11, and 17 fathoms; of these *Placuna echinata* wears something of the appearance of the short-spined *Spondyli*. Besides the species above alluded to, Mr. Broderip states that Mr. Sowerby furnished him with an odd valve of a large species from Luçon, which was beautifully iridescent internally; but as it was believed that this was identical with the fine shell sold by him to the British Museum, Mr. Broderip left the description of it to the officers of that establishment. Mr. Sowerby had some other odd valves, which Mr. Broderip thought might prove new, and the latter possessed two or three specimens adhering to *Spondyli*, from an unknown locality; but they appeared to be young.

M. Deshayes remarks that this genus establishes the passage between *Placuna* and *Anomia*, and that it shows that the V-shaped tooth of *Placuna* is only an extreme modification of the large callosity of the *Anomia*; he adds that a fossil shell found in Egypt, and which has been taken for a *Placuna*, is a new step, as regards the hinge, between the *Anomia* and *Placuna*.

P. Cumingii (Brod.) has the shell subround, obscurely silvered, white, flattened; margin plaited, the plaits very large; length 2½ inches, breadth 7-10ths of an inch; height 2½ inches.

It inhabits the shores of Central America (Gulf of Dulce, Province of Costa Rica); dredged from a muddy bottom, at the depth of 11 fathoms, attached to dead bivalve shells and dead coral.

Placunanomia Cumingii.

a, internal appearance of the organ of adhesion; b, the same seen externally.

PECTUNCULUS. [POLYODONTA.]

PEDALIACEÆ, a natural order of Monopetalous Exogenous Plants, very nearly related to *Verbenaceæ*, having like it irregular and usually

Pedaliaceæ.

A shoot of *Josephinia imperatrix* in flower. 1, the corolla laid open; 2, the pistil; 3, the ripe fruit; 4, a transverse section of the latter.

didynamous flowers and a few-seeded 2- or 4-celled fruit; but differing in having the radicle directed towards the base instead of the apex of the fruit. From *Bignoniaceæ*, with which they are more generally compared, their wingless seeds offer the principal distinction. They are all exotic tropical herbaceous plants, with opposite leaves and axillary flowers, and are of little known use, with the exception of the genus *Sesamum*, whose seeds afford a bland oil not inferior, when fresh, to that of the olive. [SESAMUM.]

Uncaria procumbens, the Grapple Plant of the Cape of Good Hope, has the fruit covered with curved spines, which lay hold of the clothes of travellers. The horns of *Martynia proboscidea* do the same, and are called in Italy the Testa di Quaglia (Quail's Head). The order contains 14 genera and about 25 species.

PEDETES. [MURIDÆ.]

PEDIASTRUM. [DESMIDIEÆ.]

PEDICEL. [PEDUNCLE.]

PEDICELLARIA, the name given by Müller to little pincer-shaped bodies found on the surface of many species of star-fishes and sea-urchins. When seen on the surface of the dried specimens they appear like little cleft spines. In *Uraster rubens*, according to Dr. Sharpey, they cover the surface generally, and are more numerous round the spines. Each one of those little bodies consists of a soft stem, which bears on its summit a little forceps of calcareous matter. If anything is introduced between the blades of these forceps when the animal is alive, it is instantly grasped with considerable force. Those on the body and upper spines differ in shape from those on the spines immediately bordering the avenues. When the star-fish is living the blades of the forceps are in continual activity, but when cut off they seem to lose that power. These bodies have been observed by Sars in *Echinus sphæra*, and he describes three species—*P. tridens*, *P. triphylla*, and *P. globifera*.

The question of the nature of these bodies has been often agitated. Whilst Müller and others have considered them to be parasitic animals, Oken, Sharpey, and Sars regard them as organs of the animal. Sars assigns the following reasons for his belief:—

1. The *Pedicellariæ* are found in the same species of *Echinodermata* under all circumstances, which would not be the case if they were parasitical animals.

2. The structure of the calcareous forceps and stems to which they are attached, bear structurally a greater resemblance to the spines of the *Echinodermata* than to other structures.

3. The *Pedicellariæ* have a vital connection with the skin and shell of the *Echinus*. The stem of the *Pedicellaria* is attached to a knob of the shell of the *Echinus*, on which it moves.

4. Sars states that when a single *Pedicellaria* is irritated, the rest are inclined towards it.

Although Professor E. Forbes states that he was not able to confirm Sars's observation on the two last points, he was nevertheless inclined to adopt the opinion that they were peculiar organs of the *Echinodermata*, rather than parasitic animals.

(E. Forbes, *British Star-Fishes*.)

PEDICULARIS (from the Latin word *Pediculus*, a louse, from its supposed quality of making sheep that feed upon it lousy), a genus of Plants belonging to the natural order *Scrophularaceæ*. It has an inflated 5-toothed calyx, a ringent corolla, with the upper lip laterally compressed, the lower plane, 3-lobed; the capsules are acute and compressed; the seeds numerous and angular. The species are usually simple herbs. The flowers sessile, disposed in dense terminal interrupted spikes.

P. palustris, Marsh Louse-Wort, has a solitary erect stem, branched throughout, pinnatifid leaves, with oblong blunt-lobed segments; an ovate pubescent 2-lobed calyx, the lobes incise, dentate, crisped. The upper lip of the corolla has a short truncate beak, with a triangular tooth on each side. The flower is large and crimson, varying to white. It is found in marshes and wet meadows, particularly in the north of England, and is said to be injurious and disagreeable to cattle. This is the *Pedicularis Herba* of Columella, vi. 30, and of Scribonius Largus.

P. sylvatica, Wood Louse-Wort, has a stem branched at the base, erect, the branches long, spreading, and prostrate; the leaves pinnatifid, leaflets ovate and deeply toothed. The upper lip of the corolla as in the last species, the flower large and rose-coloured. It is found on wet, heathy, and rather hilly grounds in Siberia, Europe, and Great Britain. The expressed juice of the herb, or a decoction, has been used with advantage as an injection in serous ulcers. It is injurious to the sheep that feed on it. There are 75 other species of *Pedicularis* enumerated, none of which are British, or applicable to any useful purpose. They are found chiefly in Europe and Northern Asia.

(Babington, *Manual of British Botany*.)

PEDICULUS (Linnaeus), a genus of Insects belonging to the order *Aptera*. These insects, commonly called Lice, form the order *Anoplura* of Dr. Leach, and *Parasita* of Latreille. [ANOPLURA.] Latreille thus characterises this order of Insects:—Their body is flattened, nearly diaphanous, and divided into 11 or 12 distinct segments, of which three belong to the trunk (or thorax), each bearing one pair of legs. The first of these segments frequently forms a sort of thorax (or rather prothorax). The stigmata are very distinct. The antennæ are short, equal, composed of five joints, and frequently inserted in a

notch. There are one or two small ocelli on each side of the head. The legs are short, and terminated by stout claws, or two opposing hooks, which enable these animals to cling with great facility to the hairs of quadrupeds or the feathers of birds, whose blood they suck, and on whose body they propagate and pass their lives. They attach their ova to these cutaneous appendages, and multiply excessively, one generation succeeding another with great rapidity. Particular and unknown causes facilitate their increase to an astonishing degree, the *P. humanus*, under such circumstances, producing in man what is termed the 'morbus pediculosus.' Their movements are slow.

Three species of Lice are said to infest the human subject—the *P. humanus*, which inhabits the bodies and garments, and is known by the name of the Body-Louse; the *P. cervicalis*, or *P. humanus capitis* of De Geer, which inhabits the head of man, and particularly children; and lastly, the *P. pubis* of Linnæus, which constitutes Leach's genus *Phthirus*. This species inhabits the eyebrows, &c., and is commonly known by the name Crab-Louse.

The following are the principal genera into which the Pediculi are divided:—

In *Pediculus* proper the mouth, which is in the form of a snout, consists of a very small tubular mammilla situated at the anterior extremity of the head; the tarsi are composed each of a joint almost equal in size to the tibia, and terminated by a strong claw, which folds over a projection, and fulfils the function of a forceps; the thorax is composed of three distinct equal segments. The *P. humanus* and *P. cervicalis* belong to this genus.

The genus *Phthirus* differs from *Pediculus* in having the body wide and rounded, the thorax very short and confounded with the body: the anterior feet are simple, and the two hinder pairs are didactyle.

The *Pediculus* of the Hog has the thorax narrow and distinct from the abdomen, which is very broad; it constitutes, according to Leach, the genus *Hæmatopinus*.

The *Nirni* (*Nirmus* of Hermann, Leach, &c., and *Ricinus* of De Geer) have the mouth situated beneath the head, and composed of two lips and two hook-like mandibles; their tarsi are very distinct, and terminated each by two equal hooks. Latreille says that the species of this group, with one exception, that of the dog, are exclusively confined to birds.

PEDILANTHUS, a genus of Plants belonging to the natural order *Euphorbiaceæ*. It has a common slipper-shaped involucre. The male flowers several in the circumference. Pedicels bracteolate, each articulated with a naked anther. Female flowers one in the centre. Calyx wanting; style 1; stigmas 3; capsules 3-coccus.

P. tithymaloides, Jew-Bush, is found in various parts of the West Indies in stony hushy places, near the coast. It is a shrub throwing out runners, erect, about six feet high, abounding in white bitter milk. The stems are numerous, weak, soft, as thick as the finger; when old cinereous, when young green. The leaves are ovate, obtuse, or acute; coriaceous, entire, alternate, stalked, distichous, when young downy on each side, and wavy at the edges, becoming at last quite smooth and flat. Peduncles 1-flowered, short, clustered about the extremities of the branches. Involucre slipper-shaped, bright-red with a green back. The practitioners of Curaçoa give a decoction of the whole plant, especially of the stem, as the ordinary beverage, and in large doses in some diseases. The root is emetic.

(Lindley, *Vegetable Kingdom*; Lindley, *Flora Medica*.)

PEDIPES (Adanson), the name for a genus of Turbinate *Mollusca* belonging to the family *Auriculacea* of M. De Blainville and *Colimacea* of Lamarck.

PEDUM. [PECTINIDÆ.]

PEDUNCLE, the stalk of the flower in Plants. The secondary stalks are called Pedicels. [INFLORESCENCE; FLOWER.]

PEEWIT. [CHARADRIADÆ.]

PEGANUM, from Πήγανον, the Greek name of Rue, of which three kinds are described by Dioscorides—the Garden, the Mountain, and the Wild. The last is said to be called Moly in Cappadocia and Galatia, and by some Harmala. It is remarkable that even in the present day a plant is found in the north of India, the Punjab, and Cabul, which is called Hoormul by the natives of the above countries, and sometimes distinguished in India by the name of Lahoovee-Hoormul, indicating that it was introduced from the direction of Lahore. The Persian works on *Materia Medica* in use in India give Molee as its Greek name, according to Dr. Royle ('Illustr.' p. 155). It is interesting to find that the plant to which these names are assigned by the natives of the country is the *Peganum Harmala* of botanists, a fact which shows that the investigations of the West had arrived at the same conclusion as those in the East respecting the plant alluded to by Grecian authors; and this enables us to put more faith in the results of such investigations than is sometimes done. The plant, which is called Syrian Rue in gardens, belongs to the natural family of *Rutaceæ*, and is of easy culture in any light soil. The seeds, which were formerly in use in medicine in Europe, still are so in the East, but are not possessed of any peculiar or very active properties.

PEKKA, a genus of Plants inhabiting Guyana, and furnishing the Saouari or Sawarra Nuts of the shops, a very different fruit from that to which the name of Saouari is given in Guyana. *Pekea* comprehends two species, the *P. butyrosa* and *P. tuberculosa*: the former is unknown

in this country; the latter, which yields the fruit in question, is a very large tree inhabiting the woods of Guyana, where it is called Tata-youha by the Garipou Indians. It has opposite digitate leaves, whose leaflets are oval, smooth on the upper side, but white with down beneath; the terminal leaflet is said to be 8 inches long by 3½ inches in breadth, while those at the sides are much smaller. The flowers are unknown. The fruit consists of greenish compressed drupes, which adhere around a common centre, and contain a single seed of large size, covered with a brownish rugged woody shell, and containing a kernel of a soft consistence, and of the most delicate buttery quality. It is by far the best of the South American nuts that are brought to England, and much superior to our own walnuts, almonds, and filberts; but it is scarce and dear in most seasons.

Pekea tuberculosa.

PEKTOLITE, a Mineral occurring in spheroidal masses which have a radiating fibrous structure. Its colour is grayish. Hardness 4·0 to 5·0. Lustre pearly. It is nearly opaque. Specific gravity 2·69. It is found in large masses on Monte Baldo in the Southern Tyrol, and at Monzoni in the Fassa-thal. Its analysis by Von Kobell afforded—

Silica	51·30
Lime	33·77
Soda	8·26
Potash	1·57
Alumina and Oxide of Iron	0·90
Water	3·89

—99·69

PELAGIA. [MILLEPORIDÆ; PULMOORADA.]

PE'LAGUS, De Montfort, a genus of *Ammonites*.

PE'LAMYS. [HYDRIDÆ.]

PELARGONIUM is the name given by botanists to the gaily painted flowers which are usually called Geraniums in our greenhouse. The latter differ obviously from *Pelargonium* in having regular flowers, and in being herbaceous plants, while the genus in question consists almost entirely of shrubs with flowers as irregular as those of the Pansy. There is a large number of genuine species of this genus, chiefly inhabiting the Cape of Good Hope; and as these intermix very readily, producing in great abundance shrubs which are capable of being perpetuated by cuttings, a prodigious number of spurious species, as well as acknowledged varieties, have found their way into the writings of systematic botanists. For example, De Candolle enumerates 369 supposed species, of which at least one-half are of artificial origin. While however science has been embarrassed by this facility of cross-breeding, the gardens have been enriched by crowds of the most beautiful objects, in which the features of their savage progenitors

can no longer be recognised; and it is probable that of all the flowers which have been acted upon by the hand of man, the *Pelargonium* is that in which the result has been most striking.

By care and attention to a few simple points of practice these plants may be cultivated and multiplied by any one who has a greenhouse, and hence they have become universal favourites. These points are the following, namely:—1, water; 2, warmth; 3, a gentle bottom heat; 4, abundance of air; 5, as much light as the leaves will bear; and 6, a rich soil during the season of growth; and a cool atmosphere, less water, abundance of light, and close pruning afterwards.

PELEA. [ANTILOPEÆ.]

PELECA'NIDÆ, a family of *Natatores*, or Swimming Birds.

The genus *Pelecanus* of Linnæus, placed in the 'Systema Naturæ' between *Diomedea* and *Plotus*, contains the True Pelicans (*Pelecanus Onocrotalus*), the Frigate Bird or Man-of-War Bird (*Trachypetes*), under the designation of *P. aquilus*, the Cormorants (*P. Carbo* and *P. Graculus*), and the Solan Goose and Boobies.

The Totipalmes of Cuvier (comprising those Palmipeds which have the hind toe united with the others in a single membrane, perch on trees, are good fliers, and have short legs), consist of the Pelicans (*Pelecanus*, Linn.), comprehending all those which have the base of the bill denuded of feathers. Their nostrils are slits, the aperture of which is scarcely perceptible. The skin of the throat is more or less extensible, and their tongue very small. Their delicate gizzard, if gizzard it may be called, forms one large sac with their other stomachs. Their cæca are only moderate or small. The following are the genera comprehended under the Pelicans:—The Pelicans properly so called (*Onocrotalus* of Brisson, *Pelecanus* of Illiger); the Cormorants (*Phalacrocorax* of Brisson, *Carbo* of Meyer, *Halicus* of Illiger); the Frigates (*Pelecanus Aquilus*, Linn., *Tachypetes*, Vieill.); the Boobies (*Sula* of Brisson, *Dysporus* of Illiger). The Pelicans are succeeded by the Anhingas (*Plotus*, Linn.), and the Tropic Bird (*Phaeton*, Linn.).

Mr. G. R. Gray, of the British Museum, in his 'List of the Genera of Birds, with an Indication of the Typical Species of each Genus' (London, 1840), makes the *Pelecanidæ* the sixth and last family of the Palmipeds, and separates it into the sub-families *Plotinæ*, *Phaetoninæ*, and *Pelecaninæ*. The last sub-family consists of the genera *Sula*, *Onocrotalus*, *Pelecanus*, *Phalacrocorax*, and *Fregata*.

Pelecanus (Linn.).—Bill long, straight, wide, very much depressed; upper mandible flattened, terminated by a very strong hook or nail, which is compressed and very much bent; lower mandible formed by two osseous branches, which are depressed, flexible, and united at the point, and from which a naked skin in the form of a bag is suspended.

Head of Pelican.

Foot of Pelican.

Face and throat naked. Nostrils basal, in the shape of longitudinal slit. Feet strong and short; three anterior toes; the hind toe is articulated anteriorly, but on the same plane with the others, and all are united by a membrane; middle claw without dentulations. Wings moderate; first quill shorter than the second, which is the longest; greater wing-coverts and secondaries nearest to the body as long as the quills. (Temm.)

The true Pelicans are large and heavy birds, with a great extent of

wing, and are excellent swimmers. The expansive pouch, whose elasticity is well known to all who have witnessed the shapes into which it is stretched and formed by the itinerant showman, will hold a considerable number of fish, and thus enables the bird to dispose of the superfluous quantity which may be taken during fishing expeditions, either for its own consumption or for the nourishment of its young. In feeding the nestlings—and the male is said to supply the wants of the female when sitting in the same manner—the under mandible is pressed against the neck and breast, to assist the bird in disgorging the contents of the capacious pouch; and during this action the red nail of the upper mandible would appear to come in contact with the breast, thus laying the foundation, in all probability, for the fable that the Pelican nourishes her young with her blood, and for the attitude in which the imagination of painters has placed the bird in books of emblems, &c., with the blood spiring from the wounds made by the terminating nail of the upper mandible into the gaping mouths of her offspring.

The neighbourhood of rivers, lakes, and the sea-coasts, are the haunts of the Pelicans, and they are rarely seen farther than twenty leagues from the land. They appear to be to a certain extent gregarious. Le Vaillant, upon visiting Dassen-Eyland, where was the tomb of a Danish captain, at the entrance of Saldanha Bay, beheld, as he says, after wading through the surf and clambering up the rocks, such a spectacle as never perhaps appeared to the eye of mortal. "All of a sudden there arose from the whole surface of the island an impenetrable cloud, which formed, at the distance of forty feet above our heads, an immense canopy, or rather a sky, composed of birds of every species, and of all colours—cormorants, sea-gulls, sea-swallows, pelicans, and I believe the whole winged tribe of this part of Africa, were here assembled. All their voices, mixed together and modified according to their different kinds, formed such a horrid music that I was every moment obliged to cover my head to give a little relief to my ears. The alarm which we spread was so much the more general among these innumerable legions of birds, as we principally disturbed the females which were then sitting. They had nests, eggs, and young to defend. They were like furious harpies let loose against us, and their cries rendered us almost deaf. They often flew so near us that they flapped their wings in our faces, and though we fired our pieces repeatedly we were not able to frighten them; it seemed almost impossible to disperse this cloud. We could not move one step without crushing either their eggs or their young ones; the earth was entirely strewn with them." The same traveller found on the Klein-Brak River, whilst waiting for the ebb tide, thousands of pelicans and flamingoes, the deep rose-colour of the one strongly contrasting with the white of the other.

The species of *Pelecanus* are widely spread (Europe, Asia, Africa, and America), though not numerous: two are European, *P. Onocrotalus*, and *P. crispus*. We select the former as an example.

P. Onocrotalus, the Common European Pelican. The plumage generally of a fine white tinted with light rose- or salmon-colour, which is brightest in the breeding season, except the primaries and spurious wing, which are black, and the depending occipital crest and a few pendulous feathers on the lower part of the neck, which are light-yellow; naked space round the eyes and at the base of the bill, where the frontal feathers form a point, flesh-colour; the upper mandible bluish, with a crimson line running along the top, reddish at the base, yellowish at the tip, and the terminal nail red; gular pouch yellow; irides bright reddish-brown or hazel; feet livid; tail short. Length from five to six feet; expanse of wings twelve or thirteen feet. Sexes similar.

The young of the year and those of a year old are whitish-ash throughout; belly whitish; wings and back very deep ash; all the feathers bordered with brighter ash; quills blackish-ash; bill and naked parts livid; iris brown. The first white feathers appear on the neck and belly. (Temm.)

Fish is the food of the Pelican, which it captures with great adroitness, generally in shallow inlets. It is no diver, but it will occasionally dash from a great height on the wing upon a fish with such velocity that it becomes submerged, though its buoyancy brings it instantly to the surface again. Although it perches on trees, it seems to prefer rocky shores. The nest, generally formed of coarse reedy grass, with a lining of grass of a softer quality, is large (about a foot and a half in diameter), and made upon the ground. Two, three, four, and sometimes five pure white eggs, but mostly two, of nearly the same size at both ends, are laid in it.

Sonnerat found five under a female of this genus. She would not rise to let him pass, but kept her seat. She struck at him with her bill, and screamed when he attempted to drive her from her eggs. Labat fastened two young pelicans to a stake. The mother daily brought them food, and remained with her young ones constantly until the evening, when she flew up to roost in a tree immediately above them. The trio became very familiar, suffering Labat to touch them; and the young ones gratefully accepted the little fish which he offered to them, and which they first put into their pouches. These Pelicans were, in all probability, not of the species under consideration.

This bird is found in the Oriental countries of Europe; common on the rivers and lakes of Hungary and Russia; tolerably abundant

on the Danube; rare and accidental on the sea-coast. An adult specimen, sent to M. Temminck, who gives the above habitata, from Egypt, and another from the Cape of Good Hope, differed in nothing from those of Europe, except in their greater dimensions. That the species exists in Asia there is no doubt. Belon, who refers to Leviticus (xi. 18), where the bird is noted as unclean, says that it is frequent on the lakes of Egypt and Judæa. When he was passing the plain of Roma, which is only half a day's journey from Jerusalem, he saw them flying in pairs like swans above his head, rather low; and adds that they are seen flying in a large flock like those birds. Hasselquist saw it at Damietta in Egypt. He also adds that it comes to Egypt in the middle of September, in his chapter on the arrival there of migrating birds. "In flying," says Hasselquist, "they form an acute angle, like the common wild geese when they migrate. In the summer they inhabit the Black Sea and coasts of Greece; and in their migration remain for a few days near Smyrna and other parts of the coasts of Natolia, but never stray far from the continent: they fly very high. Some of them remain at Damietta, and in the islands of the delta in the Mediterranean, but the greater part go to Egypt." They appear in some of the Egyptian drawings. (Rossellini.)

Common European Pelican (*Pelecanus Onocrotalus*).

Dr. Von Siebold and M. Bürger saw it in Japan, and their observation is confirmed by M. Temminck. Mr. Gould states that though the tropical climates of Africa and India constitute its natural habitat, nevertheless the eastern rivers of Europe, such as the Danube and Volga, the extensive lakes of Hungary and Russia, and the shores of the Mediterranean, are places where it dwells in abundance. The same author says that it is a species strictly confined to the Old World, over a great part of which it is distributed. Prince Bonaparte quotes it as being rare and adventitious at Philadelphia and Rome. Sir John Richardson quotes it, or rather a variety of it, killed on the Mississippi, 56° N. lat.

In the 'Proceedings of the Zoological Society' for 1835, is an account of the dissection of a Pelican by Professor Owen, and the dissection of a male of the same species, by Mr. Marten, is given in the same volume.

Phalacrocorax (Brisson).—Bill moderate or long, straight, compressed; upper mandible very much curved towards the point, and hooked; lower mandible compressed; base inserted in a small membrane, which extends under the throat. Sides of the face and throat naked. Nostrils basal, linear, hidden. Feet strong, short; three toes before, the hind-toe articulated interiorly, all united by a membrane; nail of the middle toe serrated. Wings moderate, the first quill longer than the second, which is longest.

This is the genus *Haliæus* of Illiger, *Carbo* of Meyer, and *Hydrocorax* of Vieillot.

Mr. Yarrell, who observes ('Zool. Journ.,' vol. iv.) that most of those authors who have written on the comparative anatomy of birds agree in describing an additional bone as peculiar to the back part of the head of the Cormorant, or Corvorant, as he writes it (*Pelecanus Carbo*), adds that the muscles attached to this bone, and the services they are destined to render the animal, have been either overlooked or misconceived. He describes the additional bone as about one inch in length, triangular in shape, somewhat grooved on its surfaces, and from its articulation with the occiput, tapering gradually to a point. The mode by which this bone is articulated to the occiput is considered by Mr. Yarrell to be similar to that observed in the ribs of serpents, in which the condyle is situated upon each vertebra, and the cavity is at the end of the rib: so in the Cormorant, the condyle is upon the occipital bone, the cavity at the triangular end of the

xiphoid bone; the joint is therefore hemispherical, admitting great extent of motion. Mr. Yarrell then notices the great length of the os quadratum (c) from above downwards, in this and other birds which feed on fishes. The articulation of this bone, he observes, both with the cranium itself, as well as with the lower mandible, admits great latitude of motion. It moves with facility backwards, forwards, outwards, and inwards, by the action of the numerous muscles attached to it, thus increasing the capacity of the pharynx for the more easy passage of any unusually large fish. The rami of the lower mandibles are comparatively slender, weak, and elastic, and hence the value of the additional pair of muscles described by Mr. Yarrell, muscles which are not, he states, possessed by any of the species of *Colymbus*, *Alca*, *Uria*, and *Larus*, all of which have the rami of the lower mandibles much deeper and thicker in proportion.

The xiphoid or sword-shaped bone is described by Mr. Yarrell as having three surfaces, each slightly concave, forming together an isosceles triangle, the base of which is downwards.

1, Cranium of Cormorant, reduced in size. *a*, the occipital crest; *b*, the xiphoid bone; *c*, the os quadratum.

2, Cranium of Cormorant, with the muscles moving the lower mandible. *a* and *b*, muscles answering to the masseter and temporal; *c*, the muscle arising from the xiphoid bone.

The xiphoid bone exists in the other European species of *Phalacrocorax*, and probably in the whole of that genus; but it is absent in the true Pelicans, and, we believe, in the Frigate Bird and *Plotus*. The recorded species are not numerous; five are noted as European.

P. Carbo, the Common Cormorant. (Old.) Under the throat a large white or whitish collar, the upper extremities of which reach to just below the eyes. Summit of the head, neck, breast, all the lower parts and the rump, lustrous greenish-black; on the neck small whitish traits, which are nearly imperceptible; feathers of the upper part of the back and wings ashy-brown, or bronzed in the middle, bordered by a large band of glossy greenish-black; quills and tail-feathers black; bill blackish-ash; naked region of the eyes greenish-yellow; small guttural pouch yellowish; iris green; feet black. Length 27 to 29 inches (both sexes)—winter plumage. Temm.)

M. Temminck remarks that individuals in this state of plumage have been most frequently described as females of this species.

Spring or Nuptial Plumage.—On the occiput and a part of the nape are long feathers, which form a crest of deep lustrous green; the large collar on the throat is pure white; on the summit of the head, on a great part of the neck, and on the thighs, appear very long, loose, and silky feathers of a pure white. These plumes are more or less long, according to the age of the individual. Rest of the plumage as in winter. (Temm.)

Young of the Year.—Summit of the head, nape, and back, deep brown, with slight green reflections; the large collar whitish-gray; front of the neck and all the lower parts gray-brown, varied with whitish, particularly on the breast and the middle of the belly, where these spots are numerous; feathers of the upper part of the back, scapulars, and coverts of the wings, gray-ash in the middle, bordered by a band of deep brown; bill bright brown; iris brown. It is not till the age of one year that the young assume the perfect winter livery.

The Cormorants on the south coasts of England are very large. Pennant relates that he weighed a bird of this species that exceeded seven pounds; the length was 3 feet 4 inches: the extent 4 feet 2 inches.

There is little or no doubt that this is the *Kópaξ* of Aristotle ('Hist. Anim.,' viii. 3), whose description of the bird and of its habits agrees well with that now before us. It is the Corvo Marino, Corvo Aquatico, Marangone, Merangone, and Mergona, of the Italians; Cormorant (Belon) and Cormoran of the French; Scharbe and See-Rabe

of the Germans; Skarr and Strand-Ravn of the Norwegians; Aalekrage of the Danes; Skarfur of the Icelanders; Málfrán and Mórfrán of the Welsh; Corvorant and Cormorant of the English. It is the *Corvus Aquaticus* of Gesner, Ray, and others; *Pelecanus Carbo* of Linnaeus; *Phalacrocorax Carbo* of Cuvier and others; and *Carbo Cormoranus* of Meyer and others.

Common Cormorant (*Phalacrocorax Carbo*). Adult male, in spring plumage. (Gould.)

It has been a question how the English name of the bird should be spelled, some preferring the form Corvorant, which is the form used by Montagu, Latham, Pennant, and Dr. Caius, the last of whom derives the word from 'corvus vorans.' Cormorant is considered a corruption by those who elect this derivation. Milton, Ray, and Willughby wrote Cormorant, which is the form now generally used by British ornithologists.

The geographical distribution of this bird is very extensive. It is an inhabitant of the New as well as the Old Continent. In the latter it is widely diffused. It is spread over a considerable portion of Europe, especially the north. It is a common bird in England.

The Cormorant swims very low in the water; even in the sea the body is deeply immersed, little more than the neck and head being visible above the surface. It is a most expert diver, pursuing the fish which form its food with great activity under water. It is said to be very fond of eels. It flies with the neck outstretched, and may be often seen drying its drenched plumage on the shore or on insulated rocks. It perches on trees, where it is occasionally known to build its nest, but it mostly selects rocky shores and islands, selecting, according to Selby, the summits, and not (like the Green Cormorant) the clefts or ledges. Upon the Fern Islands its nest is composed entirely of a mass of sea-weed, frequently heaped up to the height of two feet, in which are deposited from three to five eggs of a pale bluish-white, with a rough surface. "The young," says Mr. Selby, "when first hatched, are quite naked and very ugly, the skin being of a purplish-black; this in six or seven days becomes clothed with a thick black down, but the feathered plumage is not perfected in less than five or six weeks. . . . I have repeatedly found that, upon being thrown into the sea, even when scarcely half fledged, they immediately plunge beneath the surface, and endeavour to escape by diving. This they will do to a great distance, using their imperfect wings, and pursuing their submarine flight in the same manner and almost with as much effect as their parents."

The old French quatrain in the 'Portraits d'Oyseaux' gives no bad account of the habits of this bird:—

"Le Cormorant est oiseau bien connu,
Hantant les eaux tant douces que salées,
C'est lui par qui rivières sont pillées,
Et des étangs l'annuel revenu."

Its voracity is indeed great, and the way in which it will dispose of a large fish, a plaice for instance, aided in a great measure by the powers of compression and distention conferred on it by the apparatus noticed above, is surprising. The species is easily domesticated. Montagu, who kept one, gives a favourable account of its disposition, and indeed their docility is shown by the use made of them formerly in fishing. Pennant cites Whitelock, who says that he had a cast of them manned like hawks, and which would come to hand.

Sir George Staunton ('Embassy to China') states that the embassy, in its journey to Han-choo-foo, "had not proceeded far on the southern branch of the canal, when they arrived in the vicinity of the place where the Leu-tze, or famed Fishing-Bird of China (*Phalacrocorax Sinensis*) is bred, and instructed in the art and practice of supplying his owner with fish in great abundance. It is a species of the Pelican, resembling the Common Cormorant, but which, on a specimen being

submitted to Dr. Shaw, he has distinguished in the following terms:—"Brown Pelican or Corvorant with white throat, the body whitish beneath and spotted with brown; the tail rounded; the irides blue; the bill yellow." The bird, an undoubted Cormorant, is figured in the 'Atlas,' pl. 37, and a vignette at the end of the chapter shows two Chinese fishermen carrying their light boat, around the gunnel of which their cormorants are perched, by a pole, resting on their shoulders between them. Sir George further says, "On a large lake close to this part of the canal, and to the eastward of it, are thousands of small boats and rafts, built entirely for this species of fishery. On each boat or raft are ten or a dozen birds, which at a signal from the owner plunge into the water; and it is astonishing to see the enormous size of fish with which they return grasped between their bills. They appeared to be so well trained that it did not require either ring or cord about their throats to prevent them from swallowing any portion of their prey, except what the master was pleased to return to them for encouragement and food. The boat used by these fishermen is of a remarkably light make, and is often carried to the lake, together with the fishing-birds, by the men who are there to be supported by it."

Belon gives an amusing account, in his quaint French, of the chase of this bird during calms, especially in the neighbourhood of Venice, the hunt being carried on in very light boats ("deux ou trois douzaines de compagnie"), each of which, says he, being rowed by five or six men, darts along the sea like the bolt from an 'arbalaste,' till the poor cormorant, who is shot at with bows as soon as he puts his head above water and cannot take flight, after diving to suffocation, is taken, quite tired out by his pursuers.

P. cristatus (Cormoran Largup of Temminck; Crested Corvorant of Pennant; Shag or Green Cormorant of Gould). In the old bird in its winter dress the whole plumage is of the most beautiful resplendent and lustrous green; upper part of the back, scapulars, and wing- and tail-coverts of a fine bronze; each feather framed as it were by a narrow band of beautiful velvety-black; extremity of the wings not reaching beyond the origin of the tail, which is short, rounded, and of a dead black; base of the bill and very small guttural pouch fine yellow; bill brown; feet black; iris green. Length 2 feet 1 or 2 inches.

At the commencement of the spring there rises on the middle of the head, between the eyes, a fine tuft of wide and outspread feathers, about an inch and a half high, capable of erection, and which in that state presents a toupet, or large plume; on the occiput also are ten or twelve rather long and subulate feathers. There are never any white feathers on the neck nor on the thighs, as in the Great Cormorant (last-mentioned species).

Crested Cormorant (*Phalacrocorax cristatus*). Adult, in summer plumage. (Gould.)

The Young of the Year are distinguished from the young of all the other species by their long and slender bill, their short tail, and the wide lustrous borders which surround all the feathers of the mantle. The colour of the upper parts is brown lightly shot with greenish; that of the lower parts is ashy-brown more or less whitish.

The bill of this species is very slender, 2 inches 4 lines long, and longer than the head. Tail very short, composed of twelve feathers. (Temm.)

It is probable that *P. Desmarestii* is identical with *P. cristatus*.

The habits of *P. cristatus* are very similar to those of *P. Carbo*. The nest is placed in clefts and on ledges of cliffs. Mr. Selby found that it was composed of a mass of sea-weed, chiefly *Fucus vesiculosus*, and that the eggs, four or five in number, were smaller than those of *P. Carbo*, but similar to them in outward appearance.

This bird is found in the whole of the north of Europe; it is very common in Iceland, the Orkneys, Feroe Islands, Norway, and Sweden, in the vicinity of great lakes. To these localities must be added the

Mediterranean, if M. Temminck be right in considering *P. Desmarestii* and *P. cristatus* identical.

Plotus (Linn., Klein).—Bill longer than the head, quite straight, firm though slender, obliquely denticulated on the edges, which are bent inwards, and terminating in a very sharp point; face and throat naked; nostrils linear. Feet short and robust. Wings short; second, third, and fourth quills longest; tail very long, the feathers stiff and elastic.

This is the genus *Anhinga* of Brisson; *Plotus* of Scopoli; and *Plinix* of Moehr.

Species of *Plotus*, or Darter, as it has been called by English and American ornithologists, are found in the Old and New Continents.

These extraordinary birds are well described by Buffon when he says, "the *Anhinga* offers us a reptile grafted on the body of a bird." Those who have seen the long neck, and that only, issuing from the water, twisting about among the herbage and among the foliage, say that a casual observer might well take it for a snake. Vaillant states that the neck of the species seen by him in Africa was always in oscillation when the bird was perched; and that any one who saw its tortuous movements among the foliage, the body being concealed, would take it for one of the tree-serpents. The form indeed was considered by the older voyagers as a monster partaking of the nature of the snake and the duck; and Wilson states that in some ancient charts which he had seen, the creature was delineated with all the extravagance of fiction. In flight the neck is stretched out, immovable, in a line with the body.

P. Levallantii (*P. Africanus* of Swainson). Nuptial Plumage.—Bill yellow; feet yellow; all the upper part of the head and back of the head brick-red, bordered with a riband of black which descends to the shoulders; forehead, cheeks, and sides of the neck pure white; throat and anterior part of the neck pale ochraceous-yellow; breast and all the under parts of the body deep black with greenish reflections; the lower part of the neck above the back reddish and ocellated with white; the whole of the mantle and the small coverts brown, with the middle of each feather of a bright rusty colour; tail-feathers and quills brown, some of the latter terminated with rust-colour.

Plotus Levallantii.

Le Vaillant, in his usual lively style, relates how he was induced to visit a rich proprietor in the fertile canton of the Twenty-Four Rivers to the north-east of Swatland, South Africa, after he had determined on not stopping, by the tempting description of two extraordinary birds which habitually haunted the vicinity of this proprietor's habitation, and which, from the description, he knew must be *Anhingas*. They frequented a particular tree, and baffled him more than once; at length he got within shot, and killed them both, right and left. His Hottentots called them *Slange-Hals-Voogel* (Bird with a Serpent's Neck). He describes them as diving ("entre deux eaux") for fish: when they caught a small one it was swallowed whole; when they captured a large one it was carried to a rock or the trunk of a tree, and the bird, fixing it beneath its feet, picked it to pieces with its bill. Though the water is their favourite element, it is upon trees or rocks, he tells us, that it establishes its nest and brings up its young, taking care to place it so that they may be easily precipitated into the river as soon as they are able to swim, or whenever the safety of the little family requires it. He describes it as most difficult of approach, especially when swimming, and when nothing but the head is to be seen; the instant the flint struck the steel the bird dived, and often when it was looked for a-head it had doubled

back in its diving, and then took wing far behind the sportsman. It is found in Senegal, Cape of Good Hope, and part of the coasts of Asia. (Lesson.)

P. Anhinga (*P. Americanus*, Sowerby). Male.—Bill $3\frac{3}{4}$ inches long, rather slender, very sharp pointed, and armed with numerous sharp teeth towards the tip, for the securing its prey; black above, yellow below; bare space round the eye and pouch under the chin yellow; slit of the mouth extending beyond the eyes; irides vivid red; head, neck, and all the lower parts black glossed with dark green; side of the neck, from the eye backwards for more than half its length, marked by a strip of brownish-white, consisting of long hair-like tufts of plumage extending an inch beyond the common surface, resembling the hair of callow young; a few small tufts on the crown; the whole upper parts black, marked in a very singular and beautiful manner with small oval spots and long pointed streaks of limy-white which has the gloss of silver in some lights; middle of the back, primaries,

Plotus Anhinga, male.

Plotus Anhinga, female. (Wilson).

secondaries, rump, and tail-coverts, plain glossy black; on the upper part of the back the white is in very small oval spots lengthening as they approach the scapulars and tertials, on the latter they extend the whole length of the feathers, running down the centre (these are black shafted); the wings long and pointed; lesser coverts marked on every feather with an oval or spade-shaped spot of white; greater coverts nearly all of a limy-white; tail long, rounded, and exceedingly stiff, consisting of 12 broad feathers, the exterior vanes of the four middle ones curiously crimped, the whole black and broadly tipped with dirty brownish-white; thighs black; legs scarcely an inch and a

half long; feet webbed, all the four toes united by the membrane, which is of uncommon breadth; exterior toe, the longest, 3 inches; claws horn-colour, strong and crooked, inner side of the middle one pectinated; legs and feet yellow. All the plumage very stiff and elastic; that of the neck and breast thick, soft, and shining. Length 9 feet 3 inches.

Female.—Differs in having the neck before of a roan colour or iron-gray, the breast the same, but lighter and tinged with pale chestnut; belly as in the male—where the iron-gray joins the black on the belly, there is a narrow band of chestnut; upper head and back of the neck dark sooty-brown streaked with blackish; cheeks and chin pale yellow-ochre; in every other respect the same as the male, except in having only a few slight tufts of hair along the side of the neck; tail 12 inches long to its insertion, generally spread out like a fan, and crimped, like the other, on the two outer vanes of the two middle feathers only. Length 3 feet 5 inches. (Wilson.)

"Here is in this river (St. Juan, East Florida) and in the waters all over Florida," says Bartram, speaking of this species, "a very curious and handsome bird; the people call them snake-birds; I think I have seen paintings of them on the Chinese screens and other Indian pictures; they seem to be a species of *Colymbus*, but far more beautiful and delicately formed than any other that I have ever seen. They delight to sit, in little peaceful communities, on the dry limbs of trees hanging over the still waters, with their wings and tails expanded, I suppose to cool and air themselves, when at the same time they behold their images in the watery mirror. At such times, when we approach them, they drop off the limbs into the water as if dead, and for a minute or two are not to be seen; when on a sudden, at a great distance, their long slender head and neck appear, like a snake rising erect out of the water; and no other part of them is to be seen when swimming, except sometimes the tip end of their tail. In the heat of the day they are seen in great numbers, sailing very high in the air over lakes and rivers. They inhabit the waters of Cape Fear River, and, southerly, East and West Florida."

Mr. Abbot, of Georgia, who agrees with Wilson in opinion that *P. Arkinga* is the female of the Black-Bellied Darter, gives its length as 36 inches, extent 46 inches.

It is found in the Carolinas, Georgia, and the Floridas; common in Brazil and Guyana.

Fregata (Ray).—Bill long, robust, trenchant, depressed at the base, widened on the sides, with a suture above, the mandibles very much hooked at the point, and the gape very wide; nostrils linear; orbits naked; throat dilatable. Wings very long and very narrow, first two quills very long. Feet short; the toes united by a membrane which is deeply notched. This is the genus *Tachypetes* of Vieillot.

The Man-of-War Birds, or Frigates, are eminently raptorial. Ray speaks of their eagle-eye, vulturine claws, and kite-like glidings. Their immense extent of wing and dashing habits have obtained for them the name of the swiftest sailing ships of war that sweep the seas.

P. Aquilus. Tail forked, body black, bill red, orbits black. The male is entirely black: abdomen of the female white. Some accounts state the extent of the wings to be fourteen feet, an almost incredible expanse.

Frigate or Man-of-War Bird (*Fregata Aquilus*); the gular pouch not dilated.

Sloane, who saw them at Jamaica, describes them under the name of Men-of-War Birds, as appearing in the bay near Port Royal. "They fly," says he, "like kites, look black, are very large winged in proportion to their body; they fight with sea-gulls (which are to be found here, and are like ours) for their prey." It is however but an unequal fight, for the poor gull has not much chance when opposed to the swoop of the Frigate. [BOONT.]

The nest is said to be built on rocks in small desert islands, on lofty cliffs, or in high trees in retired situations near the sea. The eggs are stated to be one or two in number, and to be of carnation

tiage and dotted with crimson. The newly hatched young are said to be covered with a gray down.

This bird is very common on the intertropical American coasts, and in the Atlantic and Pacific oceans, but always within reach of land.

PELECANOIDES. [PROCELLARIDÆ.]

PELECANUS. [PELECANIDÆ.]

PELICAN. [PELECANIDÆ.]

PELLORNEUM. [MERULIDÆ.]

PELOCONITE, a Mineral which occurs amorphous. Fracture conchoidal. Hardness 3. Brittle. Colour bluish-black. Streak liver-brown. Lustre vitreous, dull. Opaque. Specific gravity 2.567. Soluble in hydrochloric acid; the solution contains phosphoric acid, iron, manganese, and copper. It is found in Chili.

PELO'RIS. [PECTINIDÆ.]

PELORONTA. [NERITIDÆ.]

PELO'RUS. [FORAMINIFERA.]

PELVIS. [MAN; SKELETON.]

PENÆACEÆ, *Sarcocollads*, a small natural order of Perigenous Exogenous Plants. These plants are shrubs with opposite imbricated exstipulated leaves. The flowers are apetalous, the ovary composed of four carpels, the calyx tubular. Lindley places this order in his Rhamnal alliance, and points out its relations with *Proteaceæ* and *Burseraceæ*. The species are mostly natives of the Cape of Good Hope. A viscid sweetish nauseous gum-resin, called *Sarcocol*, is produced by various species. This substance contains a peculiar principle called *Sarcocollin*, which is converted into oxalic acid by the addition of nitric acid. Although Dr. Lindley has named these plants *Sarcocollads*, he is inclined to doubt, with Endlicher, if this order really produces *Sarcocol* at all; and suggests that it is produced, as *Sesquipedum* and *Galbanum*, by a species of the order *Umbelliferae*. The genera are *Panacæ*, *Sarcocolla*, and *Geisoloma*. There are 21 species. (Lindley, *Vegetable Kingdom*.)

PENÆUS. [PALEMONIDÆ.]

PENELOPE. [CRACIDÆ.]

PENEROPLIS (De Moutfort). [FORAMINIFERA.]

PENGUINS (Manchots of the French), a group of Natatorial Birds, in which the wing, powerless as an organ of flight, is reduced to a mere rudiment as far as feathers are concerned; but it well assists the bird as a species of fin in its rapid diversings and evolutions under water, and even as a kind of anterior extremity when progressing on the land. They seem to be among the *Natatores* what the *Struthionidæ* are among the strictly terrestrial birds.

The Penguins occupy in the southern hemisphere the place filled by the Auk in the northern portion of the globe.

The habits of these birds are highly interesting, and have been described by many travellers. Le Vaillant found in Dassen Island that the smaller crevices of the rocks served as places of retreat for Penguins (*Spheniscus*, probably), which swarmed there above every other kind. "This bird," he says, "which is about two feet in length, does not carry its body in the same manner as others: it stands perpendicularly on its two feet, which gives it an air of gravity, so much the more ridiculous, as its wings, which have no feathers, hang carelessly down on each side: it never uses them but in swimming. As we advanced towards the middle of the island, we met innumerable troops of them. Standing firm and erect on their legs, these animals never deranged themselves in the least to let us pass."

Sir John Narborough says of the Patagonian Penguins, that their erect attitude and bluish-black backs contrasted with their white bellies might cause them to be taken at a distance for young children with white bibs. The towns, camps, and rookeries, as they have been called, of these birds, have proved an ample theme for most of the southern voyagers. Those at the Falkland Islands have attracted particular attention. Some of these assemblies are described as giving a dreary, not to say awful impression of the desolation of the place and the utter absence of the human race. In some of the towns, it is stated, there was a general stillness, and when the intruders walked among the feathered population, to provide themselves with eggs, they were regarded with side-long glances, but they seemed to carry no terror with them. In many places the shores are covered with these birds, and 300 have been taken within an hour; for they generally make no effort to escape, but stand quietly by whilst their companions are knocked down with sticks till it comes to their turn. Cook, speaking of two islands in the high latitudes of the south, describes the cold as intense; the islands were covered with hoarfrost and snow, neither trees nor shrubs appeared, and he saw no living creature except the Shags and Penguins, the last being so numerous that they seemed to encrust the rock.

Some describe the rookeries as designed with the utmost order and regularity, though they are the resort of several different species. A regular camp, often covering three or four acres, is laid out and levelled, and the ground disposed in squares for the nests, as accurately as if a surveyor had been employed. Their marchings and counter-marchings are said to remind the observer of the manoeuvres of soldiers on parade. In the midst of this apparent order there appears to be, according to the same accounts, not very good government, for the stronger species steal the eggs of the weaker, if they are left unguarded, and the King Penguin (*Aptenodytes Patagonica*) is the greatest thief

of all. Three species are stated to be found in the Falkland Islands. Two of these, the King and the Macaroni (*Aptenodytes chrysocome*) deposit their eggs in these rookeries. The Jackass (*Aptenodytes demersa*), which is the third, obtaining its English name from the horrible brayings which it sets up at night, makes its nest in burrows on downs or sandy plains, and does not seem to take invasion so quietly as the other species.

But the dimensions of the rookeries above noticed sink into insignificance when compared with a settlement of the King Penguins (*Aptenodytes Patagonica*) recorded by Mr. G. Bennett, who saw at the north end of Macquarrie Island, in the South Pacific Ocean, a colony of those birds which covered an extent of thirty or forty acres. He describes the number of Penguins collected together in this spot as immense; but observes that it would be almost impossible to guess at it with any near approach to truth, as, during the whole of the day and night, 30,000 or 40,000 are continually landing, and an equal number going to sea. "They are arranged, when on shore, in as compact a manner and in as regular ranks as a regiment of soldiers; and are classed with the greatest order, the young birds being in one situation, the moulting birds in another, the sitting hens in a third, the clean birds in a fourth, &c.; and so strictly do birds in similar condition congregate, that should a bird that is moulting intrude itself among those which are clean, it is immediately ejected from them. The females hatch the eggs by keeping them close between their thighs; and if approached during the time of incubation, move away, carrying their eggs with them. At this time the male bird goes to sea and collects food for the female, which becomes very fat. After the young is hatched, both parents go to sea, and bring home food for it; it soon becomes so fat as scarcely to be able to walk, the old birds getting very thin. They sit quite upright in their roosting-places, and walk in the erect position until they arrive at the beach, when they throw themselves on their breasts, in order to encounter the very heavy sea met with at their landing-place."

Mr. Bennett mentioned several instances of the appearance of Penguins at a considerable distance from any known land. They generally however indicate its neighbourhood. ('Zool. Proc,' 1840.)

Captain Fitz-Roy gives the following interesting account of the mode in which Penguins feed their young. The species on which he made his observations at Noir Island was probably the Jackass Penguin:—

"Multitudes of Penguins were swarming together in some parts of the island, among the bushes and 'tussock' (thick rushy grass) near the shore, having gone there for the purpose of moulting and rearing their young. They were very valiant in self-defence, and ran open-mouthed, by dozens, at any one who invaded their territory, little knowing how soon a stick would scatter them on the ground. The young were good eating, but the others proved to be black and tough when cooked. The manner in which they feed their young is curious and rather amusing. The old bird gets on a little eminence and makes a great noise (between quacking and braying), holding its head up in the air, as if it were haranguing the penguinnery, while the young one stands close to it, but a little lower. The old bird, having continued its clatter for about a minute, puts its head down and opens its mouth widely, into which the young one thrusts its head, and then appears to suck from the throat of its mother for a minute or two, after which the clatter is repeated, and the young one is again fed; this continues for about ten minutes. I observed some which were moulting make the same noise, and then apparently swallow what they thus supplied themselves with; so in this way, I suppose, they are furnished with subsistence during the time they cannot seek it in the water." ('Voyages of the Adventure and Beagle,' King.)

Mr. Darwin pleasantly relates his encounter with one of these birds on the Falkland Islands. "One day," says our voyager, "having placed myself between a Penguin (*Aptenodytes demersa*) and the water, I was much amused by watching its habits. It was a brave bird; and, till reaching the sea, it regularly fought and drove me backwards. Nothing less than heavy blows would have stopped him; every inch gained he firmly kept, standing close before me, erect and determined. When thus opposed, he continually rolled his head from side to side, in a very odd manner, as if the power of vision only lay in the anterior and basal part of each eye. This bird is commonly called the Jackass Penguin, from its habit, while on shore, of throwing its head backwards, and making a loud strange noise, very like the braying of that animal; but while at sea and undisturbed, its note is very deep and solemn, and is often heard in the night-time. In diving its little plumelless wings are used as fins; but on the land as front legs. When crawling (it may be said on four legs) through the tussocks, or on the side of a grassy cliff, it moved so very quickly that it might readily have been mistaken for a quadruped. When at sea, and fishing, it comes to the surface, for the purpose of breathing, with such a spring, and dives again so instantaneously, that I defy any one at first sight to be sure that it is not a fish leaping for sport." ('Voyages of the Adventure and Beagle'; Darwin, 'Researches in Geology and Natural History.')

Bougainville endeavoured to bring home a penguin alive. It became so far tame that it followed the person who fed it; it ate bread, flesh, or fish; but its fare appears to have been insufficient or inappropriate, for it fell away and died.

An elaborate dissection of an adult male Patagonian Penguin (*Aptenodytes Patagonica*, Forster), the total length of which, measured over the back, was 3 feet 2 inches 6 lines, is given by Mr. Reid in the 'Zoological Proceedings' for 1835. The specimen was captured at East Falkland Island, in 51° 32' S. lat.

Mr. Reid describes the bones as very hard, compact, and heavy, having no apertures for the admission of air; but they contain, especially the bones of the extremities, a thin oily marrow.

The muscles were of a dark red colour, very tough, and having a great deal of cellular membrane amongst them. The fasciæ were very thick and strong. In no instance did Mr. Reid observe any tendency to ossification in the tendons. In the tendons of the perforatus of the first and second toes there was a sesamoid bone, scarcely equalling in size a mustard-seed.

The sensations of these curious birds do not seem to be very acute. Sparrman relates that he stumbled over a sleeping one and kicked it some yards without disturbing its rest; and Forster states that he left a number of them apparently lifeless, while he went in pursuit of others; but they afterwards got up and marched off with their usual gravity.

In the arrangement of these birds Mr. Vigors places them with the *Alcedæ*, which also include *Uria*. [GUILLEMOTS; AUK.] Mr. Vigors observes that the groups composing the *Alcedæ* are characterised by having no hind toe, and passes from them to the *Pelecanidæ* by means of *Aptenodytes*. [PELECANIDÆ.]

Head of *Aptenodytes*.

Mr. Swainson observes that the hind toe in the Penguins and Cormorants is placed almost as forward as in the swifts. In the Penguin the tarsus is so short as almost to be confounded with the sole of the foot; and it is probably rested upon the ground for its whole length when the bird walks, just as in the bear and other plantigrade quadrupeds; it is also, he adds, remarkably broad; the hind toe is placed in front, and on the inner margin; but it is so unusually small that, but for its short but well-defined claw, it would not be perceived. This claw is without any vestige of a web, or of a lobe, and is quite disconnected from the others; of the three anterior toes the middle is the longest, the outer rather less, and the inner the shortest. The whole foot is remarkably flattened, as if to enable the bird to cover a greater breadth of ground. ('Classification of Birds,' vol. i.)

Foot of *Aptenodytes*.

The *Alcedæ* of Mr. Swainson consist of the genera *Uria*, *Alca*, *Mormon*, *Chimercina* (Each.), *Phalaris*, and *Aptenodytes*. The family is placed between the *Colymbidæ* and the *Pelecanidæ*.

According to Mr. G. R. Gray, the genera of the *Alcedæ* are subdivided into the sub-families *Alcanæ*, *Phalarinæ*, *Spheniscinæ*, and *Urianæ*.

The *Spheniscinæ* comprehend the genera *Spheniscus*, Brissou; *Eudyptes*, Vieillot; *Pygoscelis*, Wagler; and *Aptenodytes*, Forster. ('List of the Genera of Birds,' 1840.) Specimens of each of these genera are to be seen in the British Museum.

Spheniscus (Brissou).—Bill compressed, straight, irregularly furrowed at the base; end of the upper mandible hooked, that of the lower mandible truncated; nostrils median and exposed. Wings improper for flight.

S. demersus (*Aptenodytes demersa*, Gmelin). Bill and feet black; the former with a yellowish transverse band near the apex; eyebrows and pectoral band white; body above black or black-speckled; white beneath.

This bird is found in the South Seas—Atlantic and Antarctic; and in great abundance at the Falkland Islands and Cape of Good Hope.

Spheniscus demersus.

Eudyptes, Vieillot (*Catarrhactes*, Brissou).—Bill straight at the base, compressed, furrowed obliquely, pointed above, upper mandible hooked, lower mandible rounded or truncated at the point; a

Crested Penguin (*Eudyptes chrysocome*).

furrow originates from the nostril, and terminates at the lower third of the border. Wings reduced to rudiments, improper for flight.

E. chrysocome (*Aptenodytes chrysocome*, Gmelin), the Crested Penguin of Latham, Manchot Sautour of Bougainville and Bnffon. Bill reddish-brown; frontal crest, consisting of very narrow loose feathers, black and erectile; auricular band deflected, sulphureous. Body, above bluish-black, below velvety-white; wings black above, white below; feet yellowish.

M. Lesson has given a good account of its habits, as well as of those of others of the species, in the 'Zoologie de la Coquille.' He states that it lives in all the seas of the southern hemisphere, far from the land; for he killed individuals in 43° 8' 33" S. lat., 56° 56' 49" W. long., voyaging in couples, doubtless male and female.

Aptenodytes (Forster).—Bill longer than the head, slender, straight, bent at the point; both mandibles equally pointed, rather obtuse; the upper mandible furrowed throughout its length; the lower mandible largest at the base, and covered with a naked smooth skin; nostrils linear, hidden by the frontal feathers. Feet short and stout; toes directed forwards; great toe very short. Wings featherless, reduced to rudiments or winglets covered with hairy feathers.

A. Patagonica. Lower half of the demi-bill red; head and throat covered with very black feathers; a yellow orange band, widest towards the occiput, occupies each side, to unite upon the breast, and separate the black of the throat from the gray-ash which covers the back; the feathers of the belly have the whiteness and lustre of satin, and a yellow tint more and more deepened mingles in it towards the upper part of the breast; two bands of deep black occupy the sides; toes strong and robust; wings more elongated than in the other penguins. Height, when erect, upwards of three feet.

It is found in the southern hemisphere in high latitudes, Strait of Magalhaens, Falkland Islands, Antarctic Islands, &c. Weddell ('Voyage to the South Pole') gives a highly interesting account of the habits of this species.

Aptenodytes Patagonica.

The type of the genus *Pygoscelis* of Wagler is *Aptenodytes Papua* of Gmelin, an inhabitant of Papua, or New Guinea, among other localities.

PENICILLUM. [MOULDINESS.]

PENICILLUS (Linnaeus), a name for some forms of Corallines.

[CORALLINACEÆ.] It is now applied to a genus of *Confervaceæ*.

PENNATULA. [POLYPIFERA.]

PENNATULARIA. [POLYPIFERA.]

PENNINE, a Mineral belonging to the Hydrous Silicate of Magnesia series. It is near Chlorite, and occurs in hexagonal tables. It is found in the Pennine Alps.

PENNY-CRESS. [THLASPI.]

PENNYROYAL. [MENTHA.]

PENNYWORT. [HYDROCOTYLE.]

PENTACRINUS. [ENCHINITES.]

PENTACTÆ, a sub-family of *Holothuriadæ*, a family of *Echino-dermata*. [HOLOTHURIADÆ; ECHINODERMATA.] It includes the genera *Psolinus*, *Cucumaria*, and *Ocnus*.

Psolinus (Forbes) has an irregular ovate body, arcuated with five rows of distant suckers, those below always bent; tentacula ten; dental apparatus short, truncate; no gizzard.

P. brevis, of Forbes and Goodsir, is the only species. It was discovered in the Shetland seas, adhering to the stems of *Laminariae*. It links the family of *Polidae* with *Pentactae*. It is about half an inch in length, of an ovate form, with both its extremities bent upwards. The body is pinkish-white, with minute papillae. The tentacula are long, pedicled, and digitate at the extremity. It is sluggish in its movements, but moves its tentacula freely.

Cucumaria has the body regular, more or less pentangular, with five longitudinal rows of approximate suckers; ten tentacula; dental apparatus composed of nearly square plates.

The species are called Sea-Cucumbers. They are the most typical of the *Holothuriadae*, and their popular name is very expressive of their usual form. They have all of them the power of changing their shape, so that sometimes they are very long, and others are oval or round. They usually live among sea-weeds or in mud, and are supposed to seize their prey by their large tentacula. They are found very generally throughout the seas of the globe. The following are the British species described by Professor E. Forbes in his 'History of British Star-Fishes':—

C. frondosa (*Holothuria frondosa*, Gunner), the Great Sea-Cucumber. It has been principally found off the coasts of Scotland.

C. pentactes (*Holothuria pentactes*, Müller), the Angular Sea-Cucumber. It has been taken on the coasts of Devonshire and Dorsetshire, and is found in the seas of France and Norway.

C. communis, Common Sea-Cucumber. Great numbers of these animals have been observed off the coast of Fifeshire, and been dredged in the north and south of Ireland, by Mr. W. Thompson and Dr. Ball.

C. fusiformis, the Long Sea-Cucumber. This is the longest of all the species in proportion to its thickness.

C. hyalina, the Glassy Sea-Cucumber. It is remarkable for its hyaline glassy appearance. It inhabits the Shetland seas.

C. Drummondii. This species was named after Dr. Drummond, who discovered it in Belfast Bay.

C. Hyndmanni is named after Mr. Hyndman, who dredged it in Belfast Bay. It has been since taken in large numbers off the western coast of Ireland.

C. fucicola, the Tangle Sea-Cucumber. It has been found in the Shetland seas.

Ocnus (Forbes and Goodsir) has the body regular, cylindrical, pentagonal, with five rows of distant suckers on the angles; tentacula ten; dental apparatus very short.

Professor E. Forbes describes two species of this genus, which he calls, on account of its size as compared with the Sea-Cucumber, the Sea-Girkin. The two British species are *O. branneus* and *O. lactea*, distinguished by their colour, the latter being milk-white, the former brown.

PENTADESMIS, a genus of Plants belonging to the natural order *Clusiaceae*. *P. Butyracea* is a tree found in Sierra Leone, from which a fatty substance is obtained, which has given rise to its name of the Butter-Tree and Tallow-Tree. It has an ovate fleshy fruit, about as large as a citron, and its stamens are collected into five parcels, whence its botanical name.

PENTALASMIS. [CIRRIPEDIA.]

PENTAPLATARTHUS. [PAUSIDÆ.]

PENTREMITES. [ENCRINITES.]

PEONY. [PÆONIA.]

PEPO, a kind of fruit of which the Gourd is the type. It has an inferior seed-vessel, filled with pulp inclosed within a hard pericarp, and furnished with parietal placentae. [FRUIT.]

PEPPER. [PIPER; PIMENTO.]

PEPPERMINT. [MENTHA.]

PEPPER-MOTH. [BISTON.]

PEPSIN, a substance found in the gastric acid of man and the lower animals. If the glandular portion of the stomach is treated with extremely dilute acids a substance is thrown down from the fluid by corrosive sublimate, which Schwann first called Pepsin. Wasmann afterwards obtained pepsin in a purer form. He proceeded in the following manner:—The glandular layer in the stomach of the pig, which extends chiefly from the greater curvature towards the cardia, was carefully detached and washed, without being cut up, then digested with distilled water at a temperature of from 30° to 35°. After some hours the fluid was poured away, the membrano was again washed in cold water, and then digested in the cold with about six ounces of distilled water, and repeatedly washed, till a putrid odour began to be developed. The filtered fluid was transparent, viscid, and without any reaction; it was now precipitated with acetate of lead or corrosive sublimate; the precipitate was carefully washed and decomposed with sulphuretted hydrogen; the pepsin was then precipitated by alcohol from the watery solution in white flocks.

The pepsin thus obtained, forms, when dry, a yellow, gummy, slightly hygroscopic mass; in its moist state it is white and bulky; it dissolves readily in water, and always retains a little free acid so as to reddens litmus; it is precipitated by alcohol from its watery solution; mineral acids induce a turbidity in a solution of neutralized pepsin, which disappears on the addition of a small excess of the acid; but if there be a considerable excess of the acid, there is a flocculent deposit. It is only imperfectly precipitated by metallic salts, and not

at all by ferrocyanide of potassium. It has been asserted that pepsin is coagulated by boiling, but Frierichs has shown that the coagulation is merely dependent on its admixture with albumen. This substance possesses the converting power so strong that, according to Wasmann, a solution containing only 1-60,000th part of this substance dissolved albumen in six or eight hours. Similar experiments have been made by Pappenheim, Valentin, and Elsasser.

C. Schmidt has proposed a new view with regard to the nature of the digestive principle. He regards it as a conjugated acid, whose negative constituent is hydrochloric acid, with Wasmann's uon-acid, or coagulated pepsin, as an adjunct; and assumes that it possesses the property of entering into soluble combinations with albumen, gluten, chondrin, &c. According to him, it more nearly resembles ligno-sulphuric acid than any other conjugated acid, and as this becomes disintegrated into dextrin and sulphuric acid, so the pepsin-hydrochloric-acid becomes separated at 100° into Wasmann's coagulated pepsin and hydrochloric acid, and in either case it is equally impossible to reproduce the conjugated acid from its proximate elements after their separation. On bringing the complex acid in contact with an alkali, the adjunct—the substance which has been in combination with the hydrochloric acid—is precipitated. Schmidt believes that he has ascertained that an artificial digestive mixture which has expended its solvent and digestive powers, regains them on the addition of free acid; and that when hydrochloric acid is added, the pepsin-hydrochloric-acid is expelled from its combination with albumen, &c., and thus regains its former properties, while the newly added hydrochloric acid enters into its well-known soluble combinations with albumen, &c. By the repeated addition of hydrochloric acid, a digestive fluid or this pepsin-hydrochloric-acid might preserve its digesting power for ever, unless the fluid became saturated with the dissolved substances, or the conjugated acid underwent decomposition.

(Lehmann, *Physiological Chemistry*, translated for the Cavendish Society.)

PERAMELES. [BANDICOOT; MARSUPIATA.]

PERCH. [PERCIDÆ.]

PERCIDÆ, or *Percoides* of Cuvier, a family of Acanthopterygious Fishes, of which the Common Perch may be regarded as the type. They have the body covered with scales whose outer surface is more or less rough, and the free margins of which are denticulated; the operculum and preoperculum are variously armed with spines, and denticulated at the outer margin; they not only have teeth in both jaws, but the vomer and palatine bones are also furnished with them: the number of rays to the branchiostegous membrane varies from five to seven; they never fall short of the lower nor exceed the higher number. The flesh of these fishes is generally well-flavoured and wholesome. They inhabit both salt and fresh water.

The first division of the Percoides, according to Cuvier, comprises all those species which have the ventral fins placed under the pectorals, five soft rays to the pectoral fins, seven branchiostegous rays, and two dorsal fins. This section includes the following genera:—

1. *Perca* proper, in which the preoperculum is denticulated; the operculum is produced behind into a flattened spine; the infra-orbitals are obscurely denticulated, and the tongue is smooth. The Common Perch (*Perca fluviatilis* of Linnæus) is the best example. It is a common fish in the fresh-waters of Great Britain. Closely allied to this is the *P. Italica* of Cuvier and Valenciennes, a species found in tolerable abundance in some parts of Italy; it differs from the *Perca fluviatilis* in being of a shorter and deeper form, and is destitute of the black bands. Several true perches are found in North America; species have also been discovered in Java and New Zealand: it is highly probable therefore, from the extensive geographical range of the Perches proper thus exhibited, that very many species still remain to be discovered.

2. *Labrax* (Cuv. and Val.) differs chiefly from the true Perches in having the infra-orbitals destitute of denticulations as well as the suboperculum; the operculum (which, as well as the preoperculum, is entirely covered with scales) has two spines on the posterior part, and the tongue is furnished with minute teeth. [LABRAX.]

3. *Lates* (Cuv. and Val.), a genus also closely allied to *Perca* proper, in fact differs only in having the infra-orbitals more deeply denticulated as well as the humerals; large spines are observable on the angle of the preoperculum; the anterior dorsal is shorter and higher than in the Perch; the tongue is smooth, as in the last-mentioned fish. The fishes of this sub-genus are usually of large size, good eating, and are chiefly found in the rivers in the warmer parts of the Old World.

4. *Centropomus* (Lacép.) includes those perch-like fishes whose operculum is produced behind, but the produced part is rounded at the apex; in the fins and denticulated preoperculum they resemble the perch. In the only species of this genus hitherto discovered the head is more pointed than in the preceding genera. [CENTROPOMUS.]

5. *Leucoperca* (Cuv. and Val.) differs from both the preceding genera in having larger sharply-pointed teeth intermixed with the ordinary small teeth; the form of the body is more elongated, and the first dorsal fin is large. The *L. Sandra* (Cuv. and Val.) is found in the rivers and lakes of the north-eastern portions of Europe, and is known to the Germans by the names of Sander, Sandel, or Sandat; it is the

Schell of the Austrians, and the Nagmaul of the Bavarians. A second species, the *L. Volgensis* of Gmelin, inhabits the rivers of Russia, and a third is found in the United States.

6. *Huro* (Cuv. and Val.).—This genus is founded on a fish described by Sir John Richardson, which, with most of the essential characters of the perches, differs in having the opercula simple, a character in fact not found in either of the other genera here described. The species alluded to inhabits Lake Huron, and is called by the inhabitants the Black Bass: it is one of the best-flavoured fishes of that lake.

7. *Etelis* (Cuv. and Val.).—In this genus, as in *Leucoperca*, there are larger teeth intermixed with the ordinary minute ones, but here the larger teeth are confined to the jaws, and are not found intermixed with the palatine teeth, as in *Leucoperca*; the operculum is terminated by two spines, whilst in the genus just mentioned it is simple. Only one species of *Etelis* is known; its body is elongated, the muzzle is rather obtuse, the eyes very large, and the outer rays of the tail-fin are elongated. This fish (the *E. carbunculus*, Cuv. and Val.) is also remarkable for its brilliant red colour, and is adorned with longitudinal golden stripes. It is found in the region of the Seychelle Islands, north of Madagascar.

8. *Nipho* (Cuv. and Val.).—This genus is founded on a single species found in the Japanese Sea, and is remarkable for the large spines with which the opercula are armed; the preoperculum is strongly denticulated at its margin and furnished with a long and powerful spine at its angle, and the operculum has three of these large spines; the first dorsal is large, and its spinous rays are strong; the body is somewhat elongated, and the head is pointed. The authors last quoted apply to this species the name *N. spinosus*.

9. *Enoplosus* (Lacépède) is also founded upon a single species (from Australia) originally described in White's 'Journal of a Voyage to New South Wales,' in which work the fish is mistaken for a *Chaetodon*, no doubt from its short, deep, and compressed form, and produced muzzle. Like the true Perches, it has two dorsal fins, but these are much extended in the vertical direction; the third ray of the first dorsal is very large and long, and the six anterior rays of the second dorsal are also much elongated; the infra-orbital is denticulated, and so is the preoperculum, which is moreover furnished with a strong spine; the operculum is simple, that is, destitute of spines. It is the *Enoplosus armatus* of Cuv. and Val., a fish of small size, being seldom more than 8 or 10 inches in length; the body is adorned with seven or eight black bands on a silvery ground; some of these bands however are abbreviated.

10. *Diploprion* (Kuhl and Van Hasselt), like the two preceding genera, contains but one species (*Diploprion bifasciatum* of the authors just quoted). This fish is of a short and high form, having a large head somewhat obtusely terminated in front; its colour is yellow; a broad black vertical mark runs through the eye, and a still broader band crosses the body. The infra-orbital is entire, the preoperculum is denticulated, and the operculum is armed with three strong spines. It is found off the coast of Java.

11. *Apogon* (Lacépède).—In this genus the first and second dorsal fins are small in antero-posterior extent, and widely separated; the general form of the body is ovate, but somewhat suddenly less deep behind the second dorsal; the head is without scales, large, and obtuse in front; the scales are very large, and easily dislodged; the preoperculum is denticulated. Many species of this genus inhabit the Indian seas, but that which is most generally known (the *A. naxmullorum*) is found in the Mediterranean. It is a small fish, rarely more than 5 or 6 inches in length, and of a golden-red colour, with a black spot on each side at the base of the tail-fin; there is also generally a spot of the same colour near each angle of this fin, another on the posterior dorsal, and a brown tint between the eye and the tip of the muzzle. Besides these larger blotches, the body is marked with minute black specks.

12. *Cheilodipterus* (Lacépède) has larger pointed teeth mixed with the ordinary ones; the preoperculum is denticulated, and the operculum is entire. [CHEILODIPTERUS.]

13. *Pomatomus* (Cuv. and Val.).—In this genus the dorsal fins are small in antero-posterior extent, and widely separated; the second dorsal fin and the anal fins are thick and covered with small scales; the body is somewhat elongated and thick; the head is large, and the eyes very large; the opercula are covered with scales; those on the body are large, and easily dislodged.

Only one species of this genus is known, the *Pomatomus telescopium* of Risso, and this is said to be exceedingly rare, living, it appears, in very deep water. Risso states that at Nice, where the species has been found, only two specimens were taken during thirty years. The individual from which Messrs. Cuvier and Valenciennes's description is taken was about 20 inches (French measure) in length. The colour of this fish is brownish-violet, with blue and reddish reflections. The authors just mentioned do not appear quite satisfied as to the true affinities of this genus.

14. *Ambassis* (Cuv. and Val.).—This genus is founded upon a small fish found off the coast of the Isle of Bourbon; its principal characters consist in the double series of denticulations on the lower portion of the preoperculum, a denticulated infra-orbital, a protracile mouth, and a small decumbent spine in front of the first dorsal fin, the point of which is directed forwards. In the form of the body it approaches

the common perch. It is the *A. Commersonii* (Cuv. and Val.): a second species is found off the Malabar coast, and there are several in the Indian seas, most of which are described by Hamilton in his 'Account of the Fishes found in the River Ganges and its Branches,' under the generic name *Chamdia*.

15. *Aspro* (Cuv. and Val.).—The species of this genus have the body elongated, slender, and approaching to a cylindrical form; the eye is moderate, and placed in the upper part of the head; the muzzle is obtuse, and the mouth is rather small; the first and second dorsals are widely separated, and the ventral fins are large. Two species are known; one found in the Rhône, the Saône, and some other rivers of France, is about six or seven inches in length, of a reddish or yellowish brown colour, and has four black bands extending across the back. It is the *A. vulgaris* of Cuv. and Val., and *Perca aspera* of Linnaeus. A second species of *Aspro* (the *A. Zingel* Cuv. and Val.), found in the Danube and its tributaries, attains a much larger size.

16. *Grammistes* (Cuv. and Val.).—The species composing this genus have small scales; their operculum and preoperculum are armed with spines, but not denticulated; the anal fin has no distinct spinous rays; the body is usually moderately deep, somewhat compressed, and suddenly less deep towards the tail; the head is moderately large, the eyes moderate, and the first and second dorsal fins are placed near each other.

The *G. orientalis* (Cuv. and Val.) is of small size; its colour is deep brown, and the head and body are adorned with numerous longitudinal white lines; the number of these lines, it would appear, varies in different individuals. It inhabits the Indian seas.

This genus terminates the first division of the *Percoides* of Cuvier and Valenciennes, a section sufficiently extensive both as to genera and species, and (if we except a few species) in all probability a natural one.

The second division comprises those species in which the first or spinous dorsal is united with the second or soft-rayed dorsal, so as to form one continuous fin, and is composed chiefly of the great genus *Serranus*. [SERRANUS.]

The third division embraces those Percoid Fishes which differ from the preceding in having less than seven branchiostegous rays. The principal genera contained in this division are noticed under the proper heads. Like the *Serrani*, they have the first and second dorsal fins united, but there is often a deep emargination between the spinous and soft-rayed portion.

The fourth division is composed of such species as have more than five soft rays to the ventral fins, and more than seven branchiostegous rays. It contains the following genera:—

1. *Myripristis* (Cuv. and Val.), or fishes having the above characters, combined with a short deep and somewhat compressed form of body, which is suddenly contracted near the tail, and furnished with large and strongly-serrated scales, the head large, the mouth also large, and the eye moderate; the preoperculum is denticulated, and the operculum is serrated, and produced into a strong and large spine; there is a strong spinous ray in front of the ventral fins, and three or four spines in front of the anal, one of which at least is large: the first and second dorsals are almost separated by a deep emargination. The species of this genus inhabit the tropical seas of both the old and new world, and are usually of small size, seldom exceeding seven or eight inches in length: their colouring is usually very brilliant.

2. *Holocentrum* (Cuv. and Val.).—This genus, like the last, contains fishes of very brilliant colouring, the prevailing hue being shades of red. It differs chiefly from *Myripristis* in having a strong spine on the angle of the preoperculum: the operculum is strongly serrated, and armed with large spines. The species are found in the seas of tropical climates.

3. *Beryx* (Cuv. and Val.).—In this genus there is no spine on the angle of the preoperculum, and it moreover has but one rather short dorsal fin, which is not emarginated. [BERYX.]

In this division Messrs. Cuvier and Valenciennes also place Dr. Shaw's genus *Trachichthys*, founded on a fish from the coast of Australia (*T. Australis*, Shaw), which apparently differs chiefly in having a double keel on the abdomen, which is strongly serrated; the preoperculum is armed with a spine.

In the fifth division of Percoid Fishes the ventral fins are placed in advance of the pectorals. It contains the genera *Trachinus*, *Percis*, *Pinguipes*, *Percophis*, and *Uranoscopus*.

In the sixth and last division the ventral fins are placed behind the pectorals. It comprises the genera *Sphyræna*, *Paralepis*, and *Polynemus*.

PERCNOPTERUS. [VULTURIDÆ.]

PERCOIDEÆ. [PERCIDÆ.]

PERCIDÆ, the name of a family, or, according to some, a sub-family of *Tetraonidæ*: in the latter case the form should be *Percidinæ*.

The genus *Perdix*, Briss., in Mr. Swainson's arrangement, is made to contain the sub-genera *Perdix* (Partridges); *Chalopus* (Francolins); *Coturnix* (Quails); *Ptilopachus*, Sw.; and *Oryx*, Stephens.

The *Percidinæ*, according to Mr. G. R. Gray's arrangement, form the first sub-family of the *Tetraonidæ*, and consist of the following genera:—*Ithaginis*, Wagler; *Francolinus*, Briss.; *Perdix*, Lath.; *Starna*, Bonap.; *Lerua*, Hodgk.; *Arborophila*, Hodgk.; *Coturnix*, Briss.; *Ptilopachus*, Swains.; *Liponyx*, Vieill. [TETRAONIDÆ]; *Oryx*, Stephens;

Lophortyx, Bonap.; *Callipepla*, Wagler; *Odontophorus*, Vieill.; and *Tetraoallus* (*Lophophorus* of Jardine and Selby), J. E. Gray.

The birds of this group are widely spread over the earth, no quarter of the globe being without some of the family, all of which are more or less esteemed as affording a nutritious and sapid food to man.

Perdix (Ray; *Starna*, Bonap.).—Bill short, strong, naked at the base; upper mandible convex, deflected towards the lip; nostrils basal, lateral, the orifice partly concealed by an arched naked scale; wings short, concave, rounded in form; the first three feathers shorter than the fourth or fifth, which are the longest in the wing; tail of fourteen or eighteen feathers, short.

P. cinerea; *Starna cinerea*, Bonap. This well-known object of every European partridge-shooter is too familiar to require description.

It is the Perdix, Pernisette, Pernigona, and Starna, of the Italians; Perdris, Perdris Gringette, Perdris Griesche, Perdris Grise, Perdris Gouache, and Perdris des Champs, of the French; Rebhubn of the Germans; Coriar of the Welsh; Partridge of the English.

Mr. Gould (and he is corroborated by other authors) considers this species as strictly European, though M. Temminck speaks of it as a visitor to Egypt and the Barbary coast.

The ardent temperament of the Partridge has been the theme of many writers on natural history from Pliny downwards, and the parental affection of the female for her young seems to be not less strong than the sexual ardour of the male. The rough nest, which is placed on the ground in corn-fields, meadows, &c., contains from twelve to eighteen or even twenty eggs of a greenish ash-colour; and the hen sits so close that her head not unfrequently falls before the scythe of the mower, as represented in one of Bewick's admirable cuts. To relate all the anecdotes of the maternal affection of this bird would be endless—and indeed the male watches over the young with paternal care: one or two must suffice. Pennant records a strong instance:—A partridge, followed by a large covey of very young birds, was surprised by a violent shower of rain. "She collected them under her," says Pennant, "and to secure them further, spread her wings to prevent every injury. In vain! The storm increased, yet she would not quit her charge; she preferred death, and we found her lifeless (with all the little brood) with distended wings, retaining her attempt to preserve them even to the very article of death." Mr. Selby relates that a person engaged in a field not far from his residence had his attention arrested by some objects on the ground, which upon approaching he found to be a male and female partridge engaged in battle with a carrion crow: so absorbed were they in the issue of the contest, that they actually held the crow till it was seized and taken from them by the spectator of the scene. Upon search, the very lately hatched young were found concealed among the grass, and the crow had been doubtless attacked by the parents during his attempt to carry off some of their offspring. The wiles and stratagems put in practice by the hen to draw the intruder from the place where her affrighted young have taken refuge are wonderful: she will limp about as if lame of a leg or wing, and so induce one unaccustomed to her deceptions to follow her from the brood, to which she flies back by a circuitous route. White saw a hen partridge come out of a ditch, and run along shivering with her wings, and crying out as if wounded and unable to get from him. While the dam acted this distress, the boy who attended White saw her brood, which was small and unable to fly, run to an old fox-earth for shelter. Markwick too observes that it is not uncommon to see an old partridge feign itself wounded, and run along on the ground fluttering and crying before either dog or man, to draw them away from its helpless unfledged young ones. "I have seen it often," says Markwick, "and once in particular I saw a remarkable instance of the old bird's solicitude to save its brood. As I was hunting a young pointer, the dog ran in on a brood of very small partridges; the old bird cried, fluttered, and ran tumbling along just before the dog's nose, till she had drawn him to a considerable distance, when she took wing and flew still farther off, but not out of the field; on this the dog returned to me, near which place the young ones lay concealed in the grass, which the old bird no sooner perceived than she flew back again to us, settled just before the dog's nose again, and by rolling and tumbling about drew off his attention from her young, and thus preserved her brood a second time. I have also seen, when a kite has been hovering over a covey of young partridges, the old birds fly up at the bird of prey, screaming and fighting with all their might to preserve their brood."

Aristotle describes his *Perdix* as tumbling about to draw intruders from her nest, and fixing their attention till the young have time to escape. ('Hist. Anim.' ix. 8.)

The pairing time is generally about the beginning of February, but notwithstanding the ardour of these birds, the attachment soon seems to be directed to another object, if any accident happen to that first selected; at least as far as the female is concerned. White mentions a sportsman whose zeal for the increase of his game being greater than his humanity, he, after pairing time, always shot the cock bird of every couple of partridges upon his grounds, supposing that the rivalry of many males interrupted the breed: he used to say, that though he had widowed the same hen several times, yet he found she was still provided with a fresh paramour that did not take her away from her haunt. The same delightful author states that he knew a

lover of setting, an old sportsman, who had often told him that soon after harvest he had frequently taken small coveys of partridges, consisting of cock birds alone, which he pleasantly used to call old bachelors. It thus appears that the number of males much exceeds that of the females: the rivalry between the amorous combatants in the spring—and their battles are long and bloody—would seem to be the usual provision to secure the strongest males for the continuation of the species. They roost on the ground together, generally in large fields far from hedges or coverts, probably, as White observes, to secure themselves from pole-cats and stoats. There are accidental pied or whitish varieties.

Common Partridge (*Perdix cinerea*).

The above form has been separated from the other partridges, *Perdix Græca*, Briss., *P. rubra*, *P. petrosa* &c., by Prince C. L. Bonaparte. The first of these (*P. saxatilis* of Meyer, La Bartavelle) is most probably the Πέρδιξ of Aristotle. All these, which are European, as well as *P. Chukar* from the Himalaya Mountains, have a rudimentary blunt spur on the tarsus, which, with their general plumage and red legs and bill, seem to justify the Prince's separation.

The Greek Partridge inhabits the Alps, the Tyrol, Switzerland, Italy, Turkey, and the Grecian Archipelago. *P. petrosa* (the Barbary Partridge) is common on that part of the African coast and in the southern portions of Europe, especially those which are washed by the Mediterranean Sea. In the mountainous parts of Spain, and in the islands of Majorca and Minorca, Sardinia, Corsica, Malta, and Sicily, it is abundant; but it is rare in France, and not known in the north of Europe. *P. rubra*, the Common Red-Legged or Guernsey Partridge, is abundant in France and Italy, rare in Switzerland, and still rarer in Germany and Holland. Mr. Gould observes that it is confined to the European continent and the islands of Guernsey and Jersey, but M. Temminck ('Manuel,' part iv.) states that it is found in Japan, where it was observed by Dr. Von Siebold and M. Bürger, identical in form and colour of plumage. It has been introduced into our preserves, and is now rather plentiful in some parts, especially in Suffolk. But we doubt whether those who have introduced it have much reason to be pleased with the importation. They persecute almost to extermination the Common Partridge (*Starna cinerea*), a much better bird, whether regard be had to the sports of the field or the pleasures of the table. They are most determined runners, and few birds are more calculated to injure the behaviour of a well-bred and well-broken pointer or setter than the Red-Legged Partridge; if anything can make him puzzle, that partridge will. Though the flesh is not so juicy as that of the Common Partridge, a well fed plump young Red-Legged Partridge, split down the back and broiled upon a good clear fire, is not bad eating. It is probably the *Perdix* of the Romans. Martial (xiii. 76), in allusion to the insano epicurism of the Romans, which seems to have valued price more than flavour, says

"Carior est Perdix: sic capiti illa magis."

Francolinus, Briss.; *Pternistes*, Wagler; *Chaetopus*, Swainson.—Bill stout, moderate in size, convex above, and slightly curved downwards at the tip. Nostrils basal, lateral, partially closed by a naked over-arching membrane. Tail of twelve feathers, moderate, slightly rounded. Feet naked, 4-toed, tarsi of the male armed with strong blunt spurs.

The rudimentary spurs of the Red-Legged Partridges become in the *Francolins* well developed.

The species occur on the old continent and its islands. The form occurs in Europe, Asia, and Africa. The *Francolins* are forest birds, perch on trees, and feed on seeds, bulbs, &c.

P. vulgaris, the European *Francolin*, *Lo Francolin à Collier Roux* of the French, *Francolino* of the Italians, is a fine and handsome bird; and the plumage of the adult male is rich.

Mr. Gould, who has given beautiful figures of the male and female,

of the natural size, in his 'Birds of Europe,' says, "In the bird before us we trace, or fancy we can trace, one of those unions through which the splendid-coloured Pheasants of the East are united to the sober-coloured Quails and Partridges of the European continent, its form and habits connecting it with the latter, while its colouring manifests a relationship to the beautiful Oriental genus *Tragopan*. The near relationship which we fancy exists between the genera *Francoelinus* and *Tragopan* consists in their general style of colouring, in their short spurs, and in the conformation of the beak. Another section of the genus *Francoelinus*, peculiar to Africa, exhibits also a form differing from these in the structure of the beak, in which particular, as well as in the uses to which it is applied in obtaining food, it assimilates to the oriental genus *Lophophorus*; still between these groups we may yet expect to find others, harmonising with each so as to form a complete concatenation."

This Francolin haunts humid places, perches on trees, and feeds, like the common partridges (which, as Mr. Gould observes, it resembles in the form of the bill), on insects, seeds, &c., but not on bulbs, like others of the genus. M. Temminck, in the fourth part of his 'Manuel,' mentions myrtleberries and the tender tops of herbs as forming part of its food. Nothing particular seems to be known about its nest, &c.

This species is widely distributed. In Europe its habitat appears to be exclusively confined to the southern regions, as Sicily, Malta, and the Neapolitan territories, but it is also found in the north of Africa, and over the greater portion of the Asiatic continent, and in the Himalaya Mountains.

F. Ponticrianius, *Perdix Ponticriana* of Latham, Ferruginous and Gray Francolin, appears to be confined to Asia.

This species, according to Colonel Sykes, is the Tectur of the Mahrattas, and is called a partridge in the Dukhun (Deccan), where it is the most common of birds, frequenting gardens and cultivated lands. The Colonel describes the frides as intense red-brown, and its length, inclusive of the tail (which is 3 inches 6-10ths) as 14 inches. He states that it is not met with in the Ghauts, unless in well cultivated valleys, and not at all on the mountains. It roosts on trees, in which situation the Colonel, on more than one occasion, shot them during the day-time; but this was a rare occurrence. ('Zool. Proc., 1832.')

Gray Francolin (*Francoelinus Ponticrianius*).

Another Francolin, *Francoelinus spadiceus*, measuring with the tail (which is 5 inches) 14 inches 7-10ths, is very common in the thick brushwood of the Ghauts. Colonel Sykes had both sexes alive in his possession for some time, and has no doubt that they might be successfully introduced into Europe. He describes them as excellent eating, and says that they rarely take wing or perch. The male has a harsh triyllabic call, Kok-kut-ree, whence the Mahrattan name Koku-tree. The female in confinement uttered little notes, like the twittering of a chicken. A male in Colonel Sykes's collection had three large spurs on one leg and two on the other. ('Zool. Proc., 1832.')

F. pileatus (Andrew Smith) is an African species.

The expedition under the direction of Dr. Andrew Smith saw the first specimens of this handsome Francolin on the banks of the Marikwa River, which flows in a north-easterly direction from Kurichane. "It showed," says Dr. Smith, "but little disposition to resort to the jungle, though when disturbed in more open localities, which it by choice frequents while feeding, it, like *Francoelinus Natalensis*, seeks concealment in the bosom of the thickets. Early in the morning specimens were observed in moderate abundance upon the

open grassy plots which occurred intersecting the wooded regions that skirted both sides of the stream, and there they appeared to find their food in plenty, which was found to consist of small bulbous roots, seeds, insects, &c. To the same localities these birds were also observed to resort towards evening; but at that period they were less readily discovered, owing to their being commonly more silent at that time. During the middle of the day they were rarely observed, and from what was ascertained there were grounds for believing they repose while the sun is warm, and that while enjoying rest they are generally perched upon dwarf trees or shrubs, no doubt to be the more secure from the teeth of the numerous predatory quadrupeds which are constantly traversing the woods in quest of prey."

Francoelinus pileatus. (Smith.)

F. Swainsonii of the same author, with its naked throat, wrinkled space round the eye, and more sombre plumage, seems to be a step towards some other rasorial forms, and to differ so much from its congeners as almost, if not quite, to justify separation.

Coturnix (Brisson).—The species of this genus are vernacularly known as Quails.

The bill is naked at the base, slender, convex above, curved towards the end; no red eye-brow. Tarsus spurless. Tail short. Wings rounded. First quill of equal length with the rest.

They are found in the Old World and Australia only.

C. dactylisonana, Mayer (*Tetrao Coturnix*, Linn.; *Perdix Coturnix*, Latham).

This well known bird, a description of which would be superfluous, seems to be the *Opus* of Aristotle, who mentions the bird repeatedly in such terms as to its habits and migration as to leave little or no doubt on the point; and the *Coturnix* of the Romans. It is the Quaglia of the Italians; Caille of the French; Wachtel of the Germans, Soffiar and Rhine of the Welsh; and Quail of the English; Lohah and Lowa of the Mahrattas.

Geographical Distribution.—The Quail is very widely distributed. "No individual of the Gallinaceous order," says Mr. Gould, "enjoys so wide a range in the Old World as the common quail; it is abundant in North Africa, most parts of India, and if we mistake not China; while the whole of the southern portions of Siberia, and every country in Europe except those approximating to the polar circle, are visited by it annually, or adopted for a permanent abode. A considerable number are stationary in the southern portions of Europe, such as Italy, Spain, and Portugal, but their numbers are greatly increased in the spring by an accession of visitors which emigrate from the parched plains of Africa in search of more abundant supplies of food and a congenial breeding-place. So vast and countless are the flocks which often pass over to the islands and European shores of the Mediterranean, that a mode of wholesale slaughter is usually put in practice against them, a circumstance which no doubt tends to limit their inordinate increase."

In this country the bird is not very abundant; and the supply for the London market comes principally from France. It arrives here in spring, generally early in May, and departs in October. The males come first, betray themselves by their thrice repeated whistle, and are

frequently lured within reach of the fowler by the imitation of the female's note on a quail-pipe; sometimes by the voice, but the performer must be a perfect mimic.

The ardent and pugnacious nature of these birds was taken advantage of by the ancients, and quail-fighting was a favourite amusement of the Greeks and Romans, as it still is of the Chinese. Their food consists of grain and seeds, insects, and slugs or worms. They are fattened for the table on hemp-seed principally. Pennant is too general when he says that the ancients never ate these birds, supposing them to have been unwholesome, as they were said to feed on hellebore. Pliny indeed ('Nat. Hist.,' x. xxiii.) says they were not eaten on account of their feeding on poisonous seeds; and also because they were subject to the epilepsy, or falling sickness; but this vulgarity did not, we suspect, banish so delicious a bird from the tables of the better informed. (Athenæus, 'Deipn.,' ix. xlvii; ibid. xlviii.; xi. cxiv.)

The Quail is polygamous; and the nest of the female, if nest it may be called—for it is little more than a hole scratched in the ground, generally in some field of green wheat—contains, in this country, from six to twelve or fourteen bluish leeky-green or oil-green eggs. On the Continent, as many as eighteen or twenty have been found; but here six or eight is the usual number of a Bevy, as the brood is called. Covey is the term applied to a family of partridges.

Quails are noted by Hasselquist as having been seen by him in Galilee. The Quail of the Israelites (*Tetrao Israelitarum*, Hasselq.) was considered by him to be a new species of *Tetrao*: he found it at the Jordan, and in the wilderness near the mountains of Arabia Petrea. Col. Sykes states that the Common Quail is the identical species on which the Israelites fed. This is perhaps not the place to discuss such subjects, but it may be necessary to remind the reader that Rndbeck asserted that the living food which "at even came up and covered the camp" (Exod. xvi. 13) was a Flying-Fish. We dismiss this at once. Ludolph, who thought that the animal was a locust, is, at first sight, more worthy of attention; but the word *שָׂרָא* (*sheer*, 'flesh') (Psalm lxxviii. 27) could hardly have been applied to locusts. Then, according to good authorities (Bochart; Harris), the Hebrew word in Exodus is *סֵלַב* (*selav*, Arabic 'selwee' or 'selvai', a quail), and the Septuagint and Vulgate both lead to the conclusion that it was certainly a bird, and almost certainly a quail. See further Scheuchzer, 'Physica Sacra' (vol. i. p. 173) where the Hebrew is translated upon both sides of the page 'coturnix,' as it is at p. 180; but the plate referred to, tab. clxi., represents the Israelites collecting locusts, and beneath the plate is printed "Exod. xvi. 13, Selavim, Locustæ." In the very next plate however, tab. clxii., representing many birds, we have the same chapter and verse quoted, with the following translation: "Selavim. Coturnices, aliaque." Fig. 2 of that plate is no had representation of a quail. There can be little doubt that quails formed the seasonable supply; and, if this be admitted, we have, as Col. Sykes observes, proof of the perpetuation of an instinct (migration) through upwards of 3300 years, the fact recorded having occurred 1491 years before Christ.

Col. Sykes, in his valuable paper 'On the Quails and Hemipodii of India' ('Zool. Trans.,' vol. ii.), in which he states that he found the tongue and the caeca of birds to be of considerable importance in indicating affinities or dissimilarities between genera, notices *C. dactylisonans*, *C. textilis*, *C. erythrorhyncha*, *C. Argoondah*, and *C. Pentah*.

C. Argoondah, the Rock-Quail of Dukhun (Deccan), "is readily distinguished by the numerous transverse narrow black bars upon the breast; but the young males and the females want these bars, and vary so much in the markings on the back, that with those disposed to manufacture species from plumage alone, the eleven specimens before me from Dukhun would furnish at least four new species." (Sykes.)

Rock-Quail (*Coturnix Argoondah*). (Sykes.)

The flesh is perfectly white. Col. Sykes says that this is the species used for Quail fights by the natives, and not *C. dactylisonans* or *C. textilis*.

Ortyx (Stephens).—Bill short, very high; culmen much elevated and curved, gonyes thick and ascending; nostrils large, naked. Tarsus smooth; lateral toes unequal; no spurs. Tail moderate.

The species are found in America only.

O. Virginianus, Virginian or Maryland Quail. This, the Quail of the inhabitants of New England, the Partridge of the Pennsylvanians, has the bill black; line over the eye down the neck and whole chin pure white, bounded by a descending band of black, which spreads broadly over the throat; eye dark hazel; crown, neck, and upper part of breast, red brown; sides of the neck spotted with white and black on a reddish brown ground; back, scapulars, and lesser coverts, red brown, intermixed with ash and sprinkled with black; tertials edged with yellowish white; wings plain dusky; lower part of the breast and belly pale yellowish white, beautifully marked with numerous curving spots or arrow-heads of black; tail ash, sprinkled with reddish-brown; legs very pale ash. Length nine inches; extent fourteen inches (male). The female differs in having the chin and sides of the head yellowish brown. (Wilson.)

Virginian Quail (*Ortyx Virginianus*).

Wilson states that this well-known bird is a general inhabitant of North America, from the northern parts of Canada and Nova Scotia to the extremity of the peninsula of Florida; and that it was seen in the neighbourhood of the Great Osage village, in the interior of Louisiana. They are, he adds, numerous in Kentucky and Ohio, and he quotes Pennant for their introduction into the island of Jamaica, where they thrive greatly, breeding twice in the year; he also quotes Captain Henderson as authority for their abundance near Balize, on the Bay of Honduras; but there is something in the style of Wilson that makes it almost unpardonable not to give his own words, and, in justice to that most graphic describer and the reader, we shall permit him to go on with his interesting history of this bird in his own way. "They rarely," continues Wilson, "frequent the forest, and are most numerous in the vicinity of well-cultivated plantations where grain is in plenty. They however occasionally seek shelter in the woods, perching on the branches or secreting among the brush-wood; but they are found most usually in open fields, or along fences sheltered by thickets of briars. Where they are not too much persecuted by the sportsmen, they become almost half domesticated; approach the barn, particularly in winter, and sometimes in that severe season mix with the poultry to glean up a subsistence. They remain with us the whole year, and often suffer extremely by long hard winters and deep snows. At such times the arts of man combine with the inclemency of the season for their destruction. To the ravages of the gun are added others of a more insidious kind. Traps are placed on almost every plantation, in such places as they are known to frequent. These are formed of lath or thinly-split sticks, somewhat in the shape of an obtuse cone, laced together with cord, having a small hole at the top, with a sliding lid to take out the game by. This is supported by the common figure-4 trigger, and grain is scattered below and leading to the place. By this contrivance ten or fifteen have sometimes been taken at a time. These are sometimes brought alive to market, and occasionally bought up by sportsmen, who, if the season be very severe, sometimes preserve and feed them till spring, when they are humanely turned out to their native fields again, to be put to death at some future time *secundum artem*. Between the months of August and March great numbers of these birds are brought to the market of Philadelphia, where they are sold from 12 to 18 cents a-piece.

"The Quail begins to build early in May. The nest is made on the ground, usually at the bottom of a thick tuft of grass that shelters and conceals it. The materials are leaves and fine dry grass in considerable quantity. It is well covered above, and an opening left on one side for entrance. The female lays from 15 to 24 eggs, of a pure white without any spots. The time of incubation has been stated to me by various persons at four weeks when the eggs are placed under the domestic hen. The young leave the nest as soon as they are freed from the shell, and are conducted about in search of food by the female, are guided by her voice, which at that time resembles the twittering of young chickens, and sheltered by her wings in the same

manner as those of the domestic fowl, but with all that secrecy and precaution for their safety which their helplessness and great danger require. In this situation, should the little timid family be unexpectedly surprised, the utmost alarm and consternation instantly prevail. The mother throws herself in the path, fluttering along, and beating the ground with her wings, as if sorely wounded; using every artifice she is master of to entice the pursuer in pursuit of herself, uttering at the same time certain peculiar notes of alarm well understood by the young, who dive separately amongst the grass, and secrete themselves till the danger is over; and the parent, having decoyed the pursuer to a safe distance, returns by a circuitous route to collect and lead them off. This well-known manoeuvre, which nine times in ten is successful, is honourable to the feelings and judgment of the bird, but a severe satire on man. The affectionate mother, as if sensible of the avaricious cruelty of his nature, tempts him with a larger prize to save her more helpless offspring; and pays him, as avarice and cruelty ought always to be paid, with mortification and disappointment."

Wilson adds, that "the flesh of this bird is peculiarly white, tender, and delicate, unequalled in these qualities by that of any other of its genus in the United States."

Lophortyx (Bonaparte).—Separated by Prince C. L. Bonaparte from the other *Ortyx*, and differing from them in the ornament of a curious crest, &c.

L. Californicus is a native of California and may be taken as an example.

Lophortyx Californicus.

The editor of the 'Voyage of La Peyrouse' figured this species in the Atlas, stating that they were plentiful in the low woods and plains of California, where they assembled in bands of two or three hundred, and became fat and well flavoured. Mr. Archibald Menzies brought home skins of them from Vancouver's voyage. Captain Beechey, R.N., laudably anxious to naturalise so elegant and delicious a bird in this country, where they would be a great addition to the game preserves, brought a number of living specimens with him as he returned from his well-executed voyage of discovery. His good intentions were however frustrated by the death of all the females on the passage. The males were presented by him to the Zoological Society of London, and one of these lived in the gardens for a considerable time. It is not improbable that these birds might be naturalised in this country.

Hemipodius, Temm.; *Turnix*, Bonn.; *Tridactylus*, Lacép.; and *Ortyxis*, Ill.—Bill moderate, slender, straight, very much compressed, curved towards the point; nostrils basal, lateral, linear, slit longitudinally down to about the middle of the bill, and partially closed by a naked membrane. Tarsus long; only three toes, all of which are directed forwards and entirely divided. Tail-feathers weak, hidden by the upper coverts. Wings moderate; first quill longest.

The species are found in Europe, Asia, Africa, Australia, and Oceania.

Colonel Sykes, in his paper above alluded to, describes three species—*H. pugnax*, *H. Taigoor*, and *H. Dussumieri*. In the stomach of the first he found the remains of black ants, minute coleopterous insects, and grass-seeds; the flesh was in brown and white layers, and the Colonel states that its pugnacious qualities are quite unknown in Dukhun, and even in Java. They were frequently in pairs, but mostly solitary, haunting cultivated lands, especially chillie fields (*Capricum annuum*). Their flight he describes as lazy and short, nor are they readily put on the wing. He adds that the Zoological Society had a specimen from Madras, and that it would appear therefore to have an extended geographical range over the Eastern islands and India. We

shall presently notice *H. Taigoor*. Of *H. Dussumieri*, the Button-Quail of European sportsmen in India, he says that it affects short thick grass and fields of pulse of *Dolichos biflorus*, *Phaseolus Max*, and *Ervum Lens*. He never found the bird otherwise than solitary, and says that it is so difficult to flush, that it not unfrequently rises from beneath the feet; and when on the wing, its flight is so abrupt, angular, and short, that it is generally down before the gun is well up to the shoulder.

H. Taigoor is chestnut above, feathers margined with straw colour, and with undulated bands of black; wing-coverts straw-colour banded with black; quills brown, chin and throat white, breast banded with black and white, belly and vent dilute ferruginous, irides pale-yellow, bill blackish. Length of the body 4 inches 8-10ths, of the tail 1 inch 7-10ths. (Sykes.)

Hemipodius Taigoor. (Sykes.)

H. Lepurana (Smith), is an African form of this genus.

Hemipodius (Turnix) *Lepurana*, female. (Smith.)

Only a very few specimens of this quail, says Dr. Smith, were obtained, and these not until after the expedition had reached the country north of Latakoo. The grassy valleys south-east of Kurri-chane were the only localities in which they were discovered, and even then they appeared to be but thinly scattered, for more than a single individual was seldom found in or even near the same place. When the birds were disturbed, they seldom flew far before they alighted, upon which it would seem that they continued their retreat, for none of those flushed a second time were ever found near the situations where they had been marked down. The food consists of seeds and small insects, with which the birds swallow a considerable quantity of fine gravel.

Dr. Smith remarks that in the Museum of the Army Medical Department at Fort Pitt, Chatham, there are the male and female of an Indian species of *Hemipodius* very closely resembling the Doctor's *Hemipodius Lepurana*. They differ however, he observes, in so many minor points, that he feels disposed to regard them as belonging to a distinct species. In the Catalogue of the Fort Pitt Collection, Dr.

Smith has named this Asiatic species *Hemipodius Sykesii*, in honour of Colonel Sykes, who has added so much to our knowledge of the zoology of India. ('Illustrations of the Zoology of South Africa.')

Before we quit this sketch of the Partridges and Quails, we must notice two forms which particularly demand attention, as leading to other types. The first of these, the Sanguine Partridge (*Perdix cruenta*, Pl. Col., 332), appears to bear the following generic names: *Ithaginis*, Wagler, *Plectrophorus*, J. E. Gray, and *Ptilopachus*, Sw. It is described as a pheasant in 'Linn. Trans.,' vol. xiii, and may be considered as uniting the Partridges with the Pheasants and the Polyplectrons, like the latter of which, it has often more than one spur upon the tarsi. The plumage of this bird, which is a native of Nepal, is brilliant, and the feathers of the head and neck are elongated.

The *P. Lerwa*, described by Mr. Hodgson ('Zool. Proc.,' 1833) inhabits, according to that gentleman, the northern region of Nepal, and forms by its half-plumed tarsi a sort of link between the Partridges and the Grouse, the latter of which it resembles in its habits. It is found close to the permanent snows, among rocks and low brushwood, feeding upon aromatic huds, leaves, and small insects. The plumage is black, lineated transversely with white and chestnut; the breast is brown. Mr. Hodgson remarks that the great comparative expanse of the wing, the diminution of its rounded form by the second quill-feather being the longest, the increased length and strength of the tail, and the extent of the feathering of the tarsi, are very remarkable characters, which give to this species a strong interest.

PERDICINÆ. [PERDIDÆ.]

PERDIX. [PERDIDÆ.]

PERDIX. [EXTOMOSTOMATA.]

PEREGRINE FALCON. [FALCONIDÆ.]

PERIANTH. [FLOWER.]

PERIBOLUS. [CYPRIDÆ.]

PERICARDIUM. [HEART.]

PERICARP. [FRUIT.]

PERICERA. [MAHDE.]

PERICHÆTIUM is a name given by writers on Mosses to the leaves that surround the bulbous base of the stalk or seta of the seed-vessel, or sporangium.

PERICLASE, a Mineral, occurring crystallised in regular octohedrons. Primary form a cube. Cleavage in three directions parallel to the faces of the cube. Colour obscure green. Hardness equal to felspar. Lustre vitreous. Translucent. Specific gravity 3.78. It is found in the lava of Vesuvius. Its analysis by Damour gives:—

Magnesia	92.57
Oxide of Iron	6.91
Insoluble Matter	0.86
	—100.34

PERICRANIUM, the fibrous membrane covering the bones of the skull. It is identical with the periosteum. [BONE.]

PERIDIUM. [INFUSORIA.]

PERIDOT. [CHRYSLITE.]

PERIECHOCRINUS. [ECHINODERMATA.]

PERIODUS. [FISH.]

PERIOSTEUM. [BONE.]

PERIOSTRACUM. [SHELL.]

PERISTEDION, a genus of Fishes belonging to the *Acanthopterygii* with hard checks. The body is covered with bony plates, forming a defensive armature. The nasal bone is divided into two points. The mouth has no teeth.

P. Malarmat, the Mailed Gurnard, was taken, according to Mr. Yarrell, off Plymouth in 1836. It is also a native of the Mediterranean. It is easily known from the other gurnards by its elongated and bifurcated nasal bones. It frequents deep water over rocky ground, approaching the shallows only at the period of spawning. It swims with great rapidity, occasionally breaking its nose against the rocks. It is fished in the Mediterranean, and as an article of food is in greatest estimation during Lent.

PERISTERA. [COLUMBIDÆ.]

PERISTOMIANS. [PALUDINIDÆ.]

PERISTOMIUM, in Mosses, is the ring or fringe of bristles or teeth which are seated immediately below the operculum, and close up the orifice of the seed-vessel. [MUSCL.]

PERITONEUM is the membrane by which the walls of the abdominal cavity are lined, and all the abdominal organs are covered. The name is also sometimes applied to the cavity itself. The arrangement of the peritoneum is in every respect similar to that of other serous membranes [MEMBRANE], except that at the extremity of the Fallopian Tube it communicates with the mucous membrane of that tube, and thus is indirectly exposed to the external air. It is the peritoneum, and the epithelium covering it, which gives to all the organs within the abdomen their peculiar shining surfaces, and which by its duplicatures forms the mesentery, omentum, and other folds by which those organs are attached to each other and to the wall of the abdomen, and through which their vessels pass. [MESENTERY; OMENTUM]

PERIWINKLE. [LITTORINIDÆ.]

PERIWINKLE, a Plant. [VINCA.]

PERLIDÆ. [NEUROPTERA.]

PERNIS. [FALCONIDÆ.]

PERODICTICUS. [LEMURIDÆ.]

PEROPHORA. [CLAVELINIDÆ.]

PEROVSKITE, a Mineral. Its primary form the cube. Cleavage parallel to the faces of the cube. Colour gray or iron black. Streak grayish white. Hardness 5.5. Lustre metallic. Opaque. Specific gravity 4.071. It is found at Achmatook, near Slatoust in the Ural. Rose states that it consists principally of titan acid and lime.

PERSE'A, a genus of Plants belonging to the natural order *Lauraceæ*. *P. gratissima* is the Avocado Pear of the West Indies, and receives its name in consequence of the resemblance in form between its fruit and that of a European pear. The plant which bears it is a tree about the size of an apple-tree; the leaves are oblong, veiny, and the flowers small, and of a greenish-yellow colour. The fruit is the size of a large pear, and is regarded as one of the best produced in the West India Islands. In the inside it is yellow, and contains a kernel inclosed in a soft rind. In taste it is said to resemble the peach, but to be much more agreeable, though not so sweet. It is sometimes eaten with pepper and salt, but more frequently with a little sugar and lime-juice. Three varieties are mentioned, the red, the purple, and the green.

Avocado Pear (*Persea gratissima*).

PERSEPHONA, Dr. Leach's name for a genus of Brachyurous Crustaceans, placed by M. Milne-Edwards among the tribe of Leucosians. [OXYSTOMA.]

It has the following generic characters:—External and internal stems of the exterior jaw-feet gradually lessening from their base, the external stem being very obtuse at the extremity. Carapace rounded, depressed, and dilated on each side; front rather advanced. Great joint of the abdomen of the male composed of three pieces soldered together. First pair of feet much stouter than the others, which have their two last joints compressed.

P. Latreillii. Anterior part of the shell gradually and obtusely dilated, covered with granulations; three equal recurved spines at its posterior part; arms tuberculous. Length two inches and a half.

Persephona Latreillii.

PERSICA. [AMYGDALUS.]

PERSICARIA. [POLYGONUM.]

PERSICOLA. [VOLUTIDÆ.]

PERSIMON, or PERSIMMON. [DIOSPYROS.]

PERSPICILLA (Swainson), a genus of Water-Chats (*Fluvicolinae*).

PERSPIRATION. [SKIN.]

PERU, BALSAM OF. [MYTOSPERMUM.]

PERUVIAN BARK. [CINCHONA; QUINQUINA.]

PETAL. [COROLLA; MORPHOLOGY; FLOWER.]

PETALITE, a Mineral which occurs massive. Structure perfectly lamellar in one direction. Cleavage parallel to the lateral planes and both diagonals of a rhombic prism. Fracture uneven. Hardness 6.5. Brittle. Colour grayish, greenish, or reddish-white. Streak white. Lustre vitreous, inclining to resinous. Translucent. Specific gravity 2.42 to 2.45. When heated in acids it undergoes partial decomposition; emits a blue phosphorescent light when gently heated. When by itself, it melts with difficulty, and only on the edges; but with borax it fuses into a colourless glass. It occurs at Utö in Sweden, and in North America. It consists, according to Gmelin, of—

Silica	74.17
Alumina	17.41
Lithia	5.16
Lime	0.32
Water	2.17

—99.23

PETASITES, a genus of Plants belonging to the natural order *Compositæ*, the sub-order *Tubulifloræ*, the tribe *Eupatorieæ*, and the section *Adenostyleæ*. The heads are many-flowered, subdioecious; the female florets are filiform, obliquely truncate, or shortly ligulate; in many rows in the female heads, none or in one row in the male heads. The male florets tubular; few and central in the female heads, occupying the whole disc in the male heads. Receptacle naked; involucre in one row.

P. vulgaris (*Tussilago Petasites*, Smith), the Common Butter-Bur, has a dense oblong thyrse, with cordate unequally-toothed leaves, downy beneath, and the lobes approximate. The plant is very abundant in wet meadows and by river-sides. It has long creeping roots, by means of which it is rapidly and extensively reproduced, and is a great pest in moist meadows, where it delights to grow. It puts forth its flowers in April and May before its leaves. On account of its early flowering the Swedish farmers plant it near their bee-hives. Dr. Sibthorp found this plant in Greece, and believed it to be identical with the *Petasites* of Dioscorides. This is the specific name of the plant, and comes from 'petasus,' a broad covering for the head. This plant produces the largest leaves of any in Great Britain, sometimes measuring three feet broad. The Butter-Bur was at one time supposed to be a remedy of value in the plague, from which it has got the name of Pestilent-Wort.

P. fragrans, Fragrant Coltsfoot, has a fastigate thyrse, radiant heads, roundish cordate unequally-toothed leaves, and downy beneath. This plant blossoms early, has a sweet scent, and has found very generally a place in gardens. It is a desirable flower where bees are kept.

PETAURUS. [MARSUPIATA.]

PETIOLE, the Leaf-Stalk. [LEAF.]

PETIVERIA (named after James Petiver), a genus of Plants belonging to the natural order *Petiveriaceæ*. It has 6, 7, or 8 stamens; 4 permanent styles, at length becoming spiny and reflexed; the point is armed with spines at the apex. The species are West Indian herbs, and in pastures are troublesome weeds, giving an unpleasant flavour to the milk of cows which feed upon them.

P. alliacea, Guinea-Hen Weed, is a small hush with a disagreeable odour. It bears an erect downy stem, not branched, and of a deep green colour. The leaves are oblong-ovate or oblong-lanceolate, acute and scabrous at the edge, glandular near the petiole, which is both glandular and downy; the stipules are small and spiny. The spikes are long, slender, and drooping at the upper end. The flowers are white. The juices of this plant are excessively acrid, and if a small portion of it be chewed it will render the tongue as dry, rough, and black as in cases of malignant fever.

The negroes consider it a sudorific, and say that fumigations or vapour-baths of it will restore motion to paralysed limbs. The roots are used in the West Indies as a cure for toothache. The plant is rejected by most animals as food. The Pintado alone seems fond of it; hence its common name, Guinea-Hen Weed.

Martian says *P. tetrandra*, another species, is employed in Brazil, under the name of Raiy de Pipi, in warm baths and lotions for defective contractility of the muscles, or in paralysis of the limbs.

(Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

PETIVERIACEÆ, *Petiveriada*, a small natural order of Exogenous Plants, of which the principal genus is *Petiveria*. [PETIVERIA.] There are 2 other genera and 10 species.

PETREL. [PROCELLARIIDÆ.]

PETRICOLA. [LITHOPHAGIDÆ.]

PETRIFACTIONS, one of the general terms by which naturalists have at different times sought to designate the vast variety of plants and animals whose remains are preserved in the earth. It may be thus considered as an equivalent for such expressions as 'formed

stones,' 'imbedded fossils,' 'organised fossils,' 'organic remains,' &c.

[ORGANIC REMAINS.]

PETROCINCLA. [MERULIDÆ.]

PETROICA. [SYLVIIDÆ.]

PETROLEUM. [NAPHTHA.]

PETROMYS. [HYSTRICIDÆ.]

PETROMYZIDÆ, a family of Chondropterygious Fishes. These fishes constitute the section *Cyclostomi* of the 'Règne Animal,' and are distinguished by their imperfectly-developed skeleton, their want of pectoral and ventral fins, combined with an eel-like form of body. The mouth is circular, consisting of a cartilaginous ring which supports the lips, this ring being formed by the soldering together of the palatine and mandibular bones. The branchiæ, instead of being pectinated as in most other fishes, are purse-shaped; they are moreover fixed, and open externally by several apertures.

From the very imperfect state of their skeleton (which consists chiefly of a ribless series of cartilaginous rings), and some other peculiarities in their structure, these fishes may be regarded as the lowest of the vertebrate animals.

The genus *Petromyzon*, as now restricted, contains the fishes commonly known as Lampreys. These eel-like fishes are of a cylindrical form, compressed towards the tail, and destitute of scales; they have seven branchial openings on each side, and a small opening connected with these on the upper surface of the head, situated nearly between the eyes; the mouth, or maxillary ring, is armed with strong teeth, and on the inner disc there are smaller rasp-like tubercles; there are moreover two longitudinal series of small teeth on the tongue, which is so formed that, by its movement in the mouth, it acts as a piston, and enables the animal to attach itself by suction to any foreign body.

P. marinus, Linn., the Lamprey, is usually about two feet in length, of a yellowish colour marbled with brown; its two dorsal fins are distinctly separated; the second one joins with the tail fin, as well as a small strip which represents the anal fin.

"The lampreys, like the sharks and rays," says Mr. Yarrell, "have no swimming bladder, and being also without pectoral fins, are usually seen near the bottom. To save themselves from the constant muscular exertion which is necessary to prevent them from being carried along with the current of the water, they attach themselves by the mouth to stones or rocks, and were in consequence called *Petromyzon*, or Stone-Sucker; while the circular form of the mouth induced the name *Cyclostomes*, or round-mouthed fishes, which was bestowed upon them by M. Duméril."

The Lamprey is highly esteemed for the table, and is consequently much sought after in the various rivers in which it is found. According to the author just mentioned, it is rather common during the spring and summer season in some of the rivers on the southern coast of England, particularly the Severn; and is found in smaller numbers in several of the rivers of Scotland and Ireland about the same period of the year. "In Scotland," Sir W. Jardine says, "they ascend our rivers to breed about the end of June, and remain until the beginning of August. They are not furnished with any elongation of the jaw, afforded to most of our fresh-water fishes, to form the receiving furrows at this important season; but the want is supplied by their sucker-like month, by which they individually remove each stone. Their power is immense. Stones of very large size are transported, and a large furrow is soon formed. The *P. marinus* remains in pairs, two on each spawning-place; and while there employed retain themselves affixed by the mouth to a large stone."

The Lamprey feeds upon soft animal substances, and often attacks fishes of large size; and fixing itself upon them, it eats the flesh by means of its rasp-like teeth.

P. fluviatilis, the Lampern, or River Lamprey, is common in many of the English rivers. "Formerly," says the author of the 'History of British Fishes,' "the Lampern was considered a fish of considerable importance. It was taken in great quantities in the Thames, from Battersea Reach to Taplow Mills, and was sold to the Dutch as bait for the trnhot, cod, and other fisheries. Four hundred thousand have been sold in one season for this purpose, at the rate of forty shillings per thousand. From five pounds to eight pounds the thousand have been given; but a comparative scarcity of late years and consequent increase of price has obliged the line fishermen to adopt other substances for bait. Formerly the Thames alone supplied from one million to twelve hundred thousand lamperns annually. They are very tenacious of life, and the Dutch fishermen managed to keep them alive at sea for many weeks."

This fish is usually about a foot in length, and coloured like the common eel. The lip surrounding the mouth has a continuous row of small points; there are two large teeth on the maxillary ring; and the dorsal fins, which are elongated, are distinctly separated.

P. Planeri, the Fringed-Lipped Lampern, has the two dorsal fins placed close together; it is of a shorter and stouter form than the Common Lampern, and may moreover be distinguished from it by the lips being furnished with numerous papillæ, forming a thickly-set fringe. The Fringed-Lipped Lampern appears to be usually smaller than the common species. It is found in the Tweed, and in some of the streams in the southern parts of Great Britain, but appears to be comparatively scarce.

The second genus of *Petromyzidæ* is the *Mixine* of Linneus. In

this genus the maxillary ring is altogether membranous, and only furnished with a single tooth on its upper part; the series of teeth on the tongue are strong, and arranged in two rows on each side, so that the jaws of these fishes appear to be lateral, like those of insects, or the *Nereides*, a circumstance which induced Linnæus to place them in the class *Vermes*. The mouth is circular, and furnished with eight cirri; in its upper margin is a spiracle which communicates with its interior. The body is cylindrical, and furnished with a fin which surrounds the tail. The skeleton is here reduced to a mere cartilaginous tube. These singular fishes pour out such an abundance of mucus through the pores of their lateral line, that the water in the vases in which they are kept seems to be converted into a jelly. They attack and pierce other fishes like the Lampreys. A certain Myxine found in the South Seas (*Petromyzon cirrhatus* of Forster), owing to its possessing seven branchial apertures like the Lampreys, has furnished the type of Duméril's sub-genus *Heptatrema*. In the sub-genus *Gastrobranchus* (Bloch), the intervals of the branchiae, instead of having separate openings, communicating with a common canal on each side, each of which terminates in a distinct hole situated under the heart. To this section belongs the Myxine, Glutinous Hag, or Borer of English authors, the *Mixine glutinosa* of Linnæus, and *Gastrobranchus cecus* of modern authors. [MYXINE.]

The next genus of this section (*Ammocetes* of Duméril) has the same general form as the Lampreys, and the branchial orifices are the same; but the mouth is semicircular, and the lip only covers the upper portion; hence the fishes have not the power of fixing themselves, like the true Lampreys. They have no teeth, but the mouth is furnished with a series of fleshy tubercles.

The fish found in our streams, and known by the names Pride, Sandpride, and Mud-Lamprey (*Ammocetes branchialis*, Cuvier), affords an example of this genus. This little fish, which is seldom more than six or seven inches in length, and about the thickness of a quill, lives chiefly in the mud at the bottom of fresh-water streams, and is said to be much preyed upon by eels.

The last division of this family is the genus *Amphioxus* of Yarrell, and this contains but one species, a most extraordinary little fish, which, it appears was first described by Pallas under the name of *Limax lanceolatus*, but had not been seen since his time till the subject of Mr. Yarrell's description was discovered by Mr. Couch on the shore near Polperro. [BRANCHIOSTOMA.]

PETROMYZON. [PETROMYZIDÆ.]

PETROPHILA. [MERULIDÆ.]

PETROSEL'NUM (*Petroselinon*, which means Rock Parsley, rock being the habitat of the species), a genus of Plants belonging to the natural order *Umbellifera*. It has an obsolete calyx; roundish entire incurved petals, scarcely emarginate, contracted into an inflexed lobe. The disc is short and somewhat annulate. The fruit ovate and contracted at the side. The species are smooth-branched herbs. The leaves decomposed, with wedge-shaped segments. The involuclers many-leaved; the flowers are white or greenish, uniform; those of the disc often sterile. The stamens longer than the corolla.

P. sativum, Common Parsley, has tripinnate shining leaves; leaflets of the lower leaves ovate-cuneate, trifid, and toothed; of the upper leaves ternate, lanceolate, entire. It grows wild on rocks and old walls, and is extensively cultivated. [PARSLEY, in ARTS AND SC. DIV.]

P. segelum, Corn Honewort, has pinnate lower leaves; nearly sessile leaflets, ovate and serrated, the upper leaves entire or trifid. The umbels are very irregular, the general involucre having from one to two leaves. The flowers are whitish, the stem erect, roundish, nearly leafless above, from a foot and a half high. It is found on damp fields in a calcareous soil in Great Britain, France, and Switzerland. Goodyer has given an accurate account of this herb, and says that the origin of its name was from the fact of its having cured a swelling in the cheek called a 'hone.'

(Babington, *Manual of British Botany*; Lindley, *Flora Medica*.)

PETRO'SILEX. This name has probably been given to two different minerals, namely, compact quartz and compact felspar; the latter has also been termed Fusible Petrosilex. [FELSAPAR.]

PETTY CHAPS. [SYLVIADÆ.]

PETUNTZE, the Chinese name for a white earth used with Kaolin in the manufacture of porcelain. It is stated that while the former [KAOLIN] is derived from the decomposition of the felspar of granitic rocks, the latter, or Petuntze, is the same mineral which has not suffered decomposition, and that on account of its fusibility it is employed in glazing the porcelain.

PEUCE, a Fossil Coniferous Tree, of which the species occur in the Oolitic strata. (Witham.)

PEUCE'DANUM (*Πευκεδανον* of Theophrastus and Dioscorides, from *πεύκη* a pine, on account of the resinous smell of the plant), a genus of Plants belonging to the natural order *Umbellifera*, and the tribe *Pucedaneæ*. It has a calyx of five teeth, obovate petals, contracted into an inflexed segment, emarginate or nearly entire. The fruit has a dilated thin flat margin, the carpels with equidistant ridges, three dorsal filaments, two lateral close to the base of the dilated margin obsolete. The interstices have single linear vittæ. The species are perennials, generally smooth. The leaves are pinnated, more or less compound. The flowers are white, yellow, or yellowish-green.

P. officinale, Sulphur-Wort, or Hog's-Fennel, is a smooth herb three or four feet high, with a resinous juice and a strong sulphureous smell. The leaves are four or even five times ternate, with linear-lanceolate acuminate flaccid segments. The involucre 3-leaved and deciduous; the pedicels much shorter than the fruit. The fruit of a pale-brown colour, the vittæ of a deep chocolate; the primary ridges much depressed and paler. The commissure a light fawn-colour with two crimson vittæ very evident upon it. It is a native in marshy and shady places throughout Europe and in Great Britain. The juice of the root of this plant is resinous and has a peculiarly strong smell. Many stimulating qualities have been attributed to it, and it is reputed anti-spasmodic and diuretic, but it seems to be rather a dangerous internal remedy.

P. oreoselinum has a taper striated stem. Ternate leaves with the petioles broken back, the leaflets remote, ovate, deeply pinnatifid and shining. The fruit is roundish oval. The flowers white with a tinge of blue. The leaves and stem are bitter and aromatic, as is the fruit in a higher degree. They were formerly used as stimulants, and are still esteemed in some countries.

P. montanum is a native of the north and middle of Europe, and has a tapering simple root with many long fibres. The stem is erect, from four to five feet high, hollow, deeply furrowed, smooth branched, and corymbose at the top, and of a bright purple colour at the base. There are about five or six leaves on a stem, which are alternate, remote, and with bipinnate divisions; the leaflets are opposite, deeply pinnatifid, dark green, and smooth; the petioles striated, smooth, with a reddish membranous margin. The flowers are white and numerous; the fruit a very light straw-colour, shining and obovate. The root is said to supply the place of ginger in Russia. The whole plant abounds in a white bitter foetid juice which soon hardens into a brown acrid resin. It is famous in Courland as a remedy for epilepsy.

P. palustre has 3-pinnate leaves pinnatifid with linear-lanceolate acuminate segments, the general involucre of many persistent lanceolate deflexed leaves. The stem is furrowed, and from three to five feet high. The flowers are white. It is found in Great Britain, but rarely. Any common garden soil will suit the species of *Peucedanum*, and they are easily raised from seed.

PEZI'ZA. [HYMENOMYCETES.]

PEZO'PORUS. [PSITTACIDÆ.]

PHACOCHE'ERUS. [SUIDE.]

PHACOLITE. [CHABASITE.]

PHACOPS. [TRILOBITES.]

PHENICORNIS. [LANIADÆ.]

PHENO'GAMOUS or PHANERO'GAMOUS PLANTS are those which have visible flowers and seeds. The words are used indifferently in contradistinction to Cryptogamous, which includes those plants which either have no sexes or none which are distinctly visible.

PHAËTON, Linnæus, a genus of Palmipede Birds, placed by some ornithologists among the *Pelecanidæ*, and by others among the *Laridæ*.

This genus, so well known to navigators as the harbinger of the tropics, is distinguished at once by the two long slender tail-feathers, which have obtained for the species, of which two only are recorded, the French name of Paille-en-Queue. Their length of wing and comparatively feeble feet proclaim them formed for flight, and they are accordingly swift and untired on the wing, disporting in the air far at sea; and when on land (to which they do not often retreat for any length of time together, except at the period of nidification), perching on rocks and trees. They rarely quit the torrid zone and its neighbourhood.

M. Leason remarks that the two species form a well-defined artificial and purely geographical group. Their habitual domicile in the torrid zone does not separate them from the land; and they can reach, as they do nearly every night, the isles and lofty rocks that serve them as a place of refuge. Nevertheless M. Leason met with them so often in sea-tracts entirely devoid of land, and heard them so often above his head in the calms and fine tropical nights, that he thinks they should be considered as oceanic birds.

The same author remarks that sudden squalls or hurricanes, so frequent in the equatorial zone, often sweep these birds beyond their natural limits; and he thus accounts for seeing them, as he many times did, in 30° S. lat.

The Common Tropic-Bird (*Phaëton aethereus*), he says, "semble être confiné dans l'océan Atlantique, et s'arrêter dans les mers de l'Inde." The other species (*Phaëton phenicurus*), he remarks, appears to belong more particularly to the great equinoctial ocean. Nevertheless, he adds, that both species exist in nearly equal numbers at the islands of Mauritius and Bourbon. He describes the flight of these birds as calm, quiet, and composed of frequent strokes of the wing, sometimes interrupted by a sort of falls or sudden movements.

Mr. G. R. Gray makes the *Phaëtoninæ*, consisting of the genus *Phaëton* only, the second sub-family of his *Pelecanidæ*, placing it between the *Plotinæ* and the *Pelecaninæ*. ('List of the Genera of Birds,' 1841.)

Phaëton, Linnæus (*Lepturus*, Mæhr; *Tropicophilus*, Leach).—The bill is strong, stout, hard, trenchant, compressed, convex above,

denticulated on its edges, inclined towards the end, pointed; nostrils linear, covered by a naked membrane; face feathered; feet very short; wings long; first quill the longest; tail short, excepting two very long slender tail-feathers.

P. atherus, Linn., the Tropic Bird of Catesby, Sloane, and others. The following is Catesby's description:—

"This bird is about the size of a partridge, and has very long wings; the bill is red, with an angle under the lower mandible, like those of the gull kind, of which it is a species; the eyes are encompassed with black, which ends in a point towards the back of the head; three or four of the larger quill-feathers towards their ends are black tipped with white; all the rest of the bird is white, except the back, which is variegated with curved lines of black; the legs and feet are of a vermilion red; the toes are webbed; the tail consists of two long straight narrow feathers almost of equal breadth from their quills to their points.

"These birds," says the same author, "are rarely seen but between the tropics, at the remotest distance from land. Their name seems to imply the limits of their abode; and though they are seldom seen but a few degrees north or south of either tropic, yet one of their breeding-places is almost nine degrees from the northern tropic, namely, at Bermudas; where, from the high rocks that environ those islands, I have shot them at the time of their breeding; but those cliffs being inaccessible, prevented my seeing their nests and eggs. They breed also in great numbers on some little islands at the east end of Porto Rico."

There was a specimen in Tradescant's Museum.

Tropic Bird (*Phaeton atherus*.)

P. phanicurus. Length from the extremity of the bill to the origin of the tail, 13 inches 6 lines; of the bill from the point to the commissure, 3 inches 8 lines; breadth across the expanded wings, 31 inches. Length of the tail, 5 inches; of one lengthened tail-feather (brin) taken at the extremity of the tail, 7 inches 6 lines; of the second and smaller long tail-feather (brin) taken from its origin, 6 inches. Ten tail-feathers, without counting the long one, which at its origin is enlarged like the other feathers; the tail forms a fan. Feet, taken from the leg to the toes, 3 inches. Legs white, with a light bluish tint in some places; webs partly black, that between the hind toe pale flesh-colour slightly glazed with white. Bill red, denticulated; nostrils near the origin of the bill, rather large, presenting forwards a canal which scarcely extends to the middle of its length, and of a blackish tint. Plumage satin-white; in front of the eyes a large brown spot. The anal feathers present a great black spot in their centre, as well as some of the feathers which approach the body. The long tail-feathers (brins) are red, the smallest being of the deepest hue. The shafts of the greater quill-feathers, of the tail-feathers, and the long tail-feathers (brins), are black, but towards the extremity they are white. (Mannell.)

PHAKELLOPLEURA, the Rev. Lansdown Guilding's name for a genus of Chitons, with rather small dorsal plates, and the fleshy zone ornamented with a broad single row of elongated spiculate fasciculi. *Chiton fascicularis* is an example of this genus. [CHITONIDÆ.]

PHALACROCORAX. [PELECANIDÆ.]

PHALÆNA, one of the three Linnean genera of Lepidopterous Insecta. It corresponded to the division *Nocturna* in the arrangement of Latreille. It included the Night-Moths. The *Phalæne* are now distributed among many genera, all of which form part of the division *Heterocera* in M. Boladuvai's arrangement of *Lepidoptera*.

PHALA'NGER. [MARSUPIATA.]

PHALANGI'STA. [MARSUPIATA.]

PHALANX. [SKELETON.]

PHAL'ARIS, a genus of Grasses, of which the seed of one of the species is extensively employed as food for birds, and commonly known as Canary seed. The species of the genus are found in warm parts of the world; but *P. Canariensis*, a native of the Canary Islands, is naturalised in Europe, and is the only one which is cultivated. The seed is imported into the south of Europe from Barbary. It is also cultivated in the Isle of Thanet and some other parts of Kent. It is sown in February and reaped about the end of September; but being a plant of southern climates, and late in ripening its seed, it is an uncertain crop. The produce is from thirty to forty bushels per acre, but sometimes even fifty bushels are obtained.

PHAL'AROPUS. [SCOLOPACIDÆ.]

PHAL'ERIS. [AUK.]

PHALLUS, a genus of Plants belonging to the natural order *Fungi* and the division *Angiogastres*. [GASTEROMYCETES.] In this genus the peridium assumes the form of a volva, and the column-like receptacle of the other forms becomes here a stipes, which is surmounted with a rudimentary pileus.

The species, which are sometimes called Stinkhorns, are solitary fungi, growing frequently on wood, and not uncommonly on ordinary soil. They frequently come up in great numbers after rain. All the species emit, whilst growing, a most disgusting odour. They are however very curious in their structure, and will well repay examination. In their early stages of growth they are enveloped in a white volva, which gives them the appearance of an egg. In this state it remains for two or three days, during which time the cells arrange themselves into the ultimate forms which they assume. When fully formed they suddenly burst the volva, and in six or eight hours attain their greatest development. Bulliard asserts that this bursting is sometimes attended with a report as loud as that of a pistol.

P. fetidus, the Stinking Phallus, is a common species in England. Although this fungus gives out but little scent in its young stage, directly it bursts the smell becomes intolerable. The summit is then covered with a dark green viscid slime, which is at first of a considerable thickness, but in a few hours it liquefies and drops off, and a cellular structure on the surface of the cap is then exposed. This slimy substance, which is the seat of the odour of the plant, also contains the sporidia. Disagreeable as is the odour of this plant, it is more so at first than afterwards, and at a short distance from the plant than close to, and persons have overcome all feelings of dislike to it. Some have even gone so far as to eat it, and have pronounced it as not disagreeable.

(Burnett, *Outlines of Botany*.)

PHANERO'GAMOUS. [PHÆNOGAMOUS.]

PHANEROTINUS, a genus of Fossil *Gasteropoda*, from the Mountain-Limestone of England and Ireland. (Sowerby.)

PHAPS. [COLUMBIDÆ.]

PHARBITIS, a genus of Plants belonging to the natural order *Convolvulaceæ*. It has 5 sepals, a campanulate funnel-shaped corolla, 1 style, a capitate granular stigma, a 3-celled rarely 4-celled ovary, and 2-seeded cells. The species of this genus are easily distinguished from others of the same order. They are mostly climbing American herbs, usually beset with retrograde hairs.

P. Nil has twining annual round hairy branches, and stem stalked; 3-lobed downy leaves; axillary peduncles, from 2- to 3-flowered. The flowers large, of a beautiful light bright blue-colour; the capsule is much shorter than the calyx, smooth, 3-celled, with two seeds in each cell. The seeds are sold in the apothecaries' shops of Calcutta under the name of 'Kala Dana,' and are said to act as a purgative and an effectual speedy cathartic. They are roasted like coffee, powdered, and administered in doses of from 30 to 40 grains. It is a native of the tropics in every part, and in the South Sea Islands. There are about 15 species of this genus, but the one described is the only one of use.

(Lindley, *Flora Medica*.)

PHARMACOLITE, a Mineral consisting of Arseniate of Lime; it occurs crystallised and fibrous, and there is a variety, called Haidingerite, which differs in crystalline form and composition.

The primary form of Pharmacolite is an oblique rhombic prism. Cleavage parallel to the oblique diagonals of the terminal planes. Fracture uneven. Hardness 2.0 to 2.5; easily scratched. Colour white. Lustre vitreous. Transparent; translucent; opaque. Specific gravity 2.640 to 2.8.

Fibrous Pharmacolite occurs in white diverging needles and small globular and botryoidal masses, which are frequently coloured by arseniate of cobalt.

When heated by the blowpipe, Pharmacolite emits the alliaceous smell, and fuses with difficulty into a white enamel; it dissolves in nitric acid and without effervescence.

This mineral is found at Andreasberg in the Harz, and in Thuringia, and at Wittichen, near Fürstenberg in Germany, and some other places.

The Pharmacolite of Wittichen was analysed by Klaproth, and that of Andreasberg by John. The results were—

	Klaproth.	John.
Arsenic Acid	50.54	45.68
Lime	25.00	27.28
Water	24.46	23.86
	100	96.82

PHARMACOSIDERITE, *Cubic Arseniate of Iron, Cube Ore*, a Mineral occurring crystallised and sometimes massive. Primary form a cube. Cleavage parallel to the primary planes, indistinct. Colour of various shades between light-green and bottle-green, and yellowish and brownish green; streak paler. Fracture uneven; cross-fracture uneven or imperfectly conchoidal. Hardness 2.5. Brittle. Lustre vitreous. Transparent, translucent. Opaque. Specific gravity 2.9 to 3.0. Massive variety amorphous, structure granular. It is found in Cornwall, and more rarely at St. Leonard in France, Schneeberg, Schwartzberg in Saxony, and Franklin, North America. Its analysis by Berzelius gives—

Arsenic Acid	38.00
Peroxide of Iron	40.56
Phosphoric Acid	0.70
Oxide of Copper	0.60
Water	10.57
Insoluble Matter	0.35
	100.78

PHARYNX is the cavity in which the food is received in its passage from the mouth to the œsophagus or gullet. In man it is somewhat funnel-shaped, having its widest part above, where it is fixed to the base of the skull. The nasal passages, the mouth, and the air passages, open into the pharynx in front; behind it is attached to the spinal column; and at its sides it is bounded by the deep vessels and muscles of the neck. It is lined by a mucous membrane, but is chiefly composed of layers of strong muscular fibres, called the constrictors of the pharynx, by whose successive contractions the food received from the mouth is gradually forced from above downwards into the œsophagus.

PHASCOCHÆRUS. [SUIDÆ.]

PHASCOGALE. [MARSUPIATA.]

PHASCOLARCTOS. [MARSUPIATA.]

PHASCOLOMYS. [MARSUPIATA.]

PHASCOLOTHEURIUM. [MARSUPIATA.]

PHA'EOULUS, a genus of Plants of the tribe *Phaseoleæ*, in the natural order *Leguminosæ*. The name is said to be derived from *Phaselus*, a little boat, which the pods are thought to resemble; but it may be that the meaning of 'boat' is derived from the resemblance of a boat to the form of a bean. Two species are very well known in this country, *P. vulgaris*, the Common Kidney Bean, and *P. multiflorus*, the Scarlet Runner; their unripe pods being much esteemed as legumes, and also for pickling. The ripe seeds are however employed on the continent, and form the Haricots of the French. The genus is however one of which the species are indigenous in tropical parts both of the Old and New World. Several are cultivated in India, and are some of the principal articles of the agriculturist's attention, as the ripe seeds of several species form pulses which are much used by the natives as a portion of their diet, and some of which, like the Kidney Bean, abound in nutritious matter.

Phaseolus is characterised by having a bell-shaped 2-lipped calyx. The corolla is papilionaceous, and has the keel, as well as the diadelphous stamens and the style, spirally twisted. The legume is compressed or cylindrical, with two valves, and is many-seeded, with more or less conspicuous cellular partitions between the seeds. The hilum of the seed is oval-oblong. The plants are herbaceous or suffrutescent in habit. The leaves are pinnately trifoliate, the leaflets with partial stipules. Racemes axillary. Pedicels usually in pairs, single flowered.

P. vulgaris, Kidney-Bean, is said to be a native of India, but Dr. Royle states that seeds were brought to him from Cashmere, and he is therefore inclined to consider that it was introduced into Europe from the most northern parts, such as Cabul and Cashmere, and that this accounts for our being able to cultivate it at a lower temperature than other species of the genus.

P. multiflorus, the Scarlet Runner, is a native of South America. Both are delicate, and cannot be safely plauted in the open air till the beginning of May.

P. Mungo, or Moog, is one of the dry leguminous grains of India, which are of great value whenever the periodical rains fail and rice cannot be grown, and famine is the consequence.

P. Max, Kala Moog of the natives, and Black Gram of the English, is like the former, but distinguished by its black seeds, and is, like it, found in a cultivated state: it takes about the same time to ripen, and yields nearly the same produce.

P. radiatus, called by the natives Mash and Oorud, is, like the two former, found in a cultivated state, and is the most esteemed of all the Indian leguminous plants. Besides using it as an article of diet, the natives make bread of the meal for some of their religious ceremonies.

P. aureus, or Sona Moog of the Bengalees, is found in a cultivated state in the Bengal presidency, but is not known on the Coromandel

Coast. It is sown, like the others, about the end of October or beginning of November, and reaped in February or the beginning of March.

P. aconitifolius, Moth of the natives, is cultivated in the north-western provinces, and used for feeding cattle.

PHASIANELLA. [TROCHIDÆ.]

PHASIANIDÆ, a family of Rasorial Birds related to the *Pavonidæ*. [PAPONIDÆ.]

Mr. G. R. Gray arranges the *Phasianidæ* as the second family of *Rasores*—*Cracidæ* being the first, and he divides the *Phasianidæ* into the sub-families *Pavonina*, *Phasianina*, *Gallina*, and *Meleagrina*. The *Phasianina* consist of the genera *Argus*, *Phasianus*, *Syrnaticus*, *Tharomalea*, and *Gennæus*. The *Gallina* comprehend the genera *Euplocamus*, *Monaulus*, *Lophophorus*, *Gallus*, and *Tragopan*.

Phasianus (Linn.).—Bill of mean length, strong; upper mandible convex, naked at the base, and with the tip bent downwards. Nostrils basal, lateral, covered with a cartilaginous scale; cheeks and region of the eyes destitute of feathers, and covered with verrucose red skin. Wings short, the first quills equally narrowed towards their tips, the fourth and fifth the longest. Tail long, regularly wedge-shaped, and composed of 18 feathers. Feet having the three anterior toes united by a membrane as far as the first joint, and the hind toe articulated upon the tarsus, which in the male birds is furnished with a horny cone-shaped sharp spur. (Gould.)

The type of this genus is generally considered to be *P. Colchicus*, Linn., the Common Pheasant, a bird which, though not originally British, is completely naturalised in our islands, and indeed appears to adapt itself with great facility to most countries where ordinary care is taken to preserve it, and the temperature is not too low for its constitution. The species is too well known to need description.

If we are to listen to the tales which form that period of history which borders upon fable, we owe this ornament of our preserves and tables to Jason and his companions, who brought it from Colchis in the good ship *Argo*. Martial thus notices its introduction into Europe (lib. xiii, ep. 72): *Phasianus loquitur*—

"Argivâ primum sum transportata carinâ;
Ante mihi necum nil nisi Phasis erat."

In Greece it soon became known under the name of *Φασιανός* and *Φασιανός ὄρνις* (*Phasian bird*). (Aristophanes, 'Clouds,' 110; 'Birds,' 68.) Indeed it had become sufficiently celebrated in the time of Aristophanes to form a proverb—"Not if you would give me the pheasants which Leogoras feeds," says Strepsiades, in the 'Clouds' (109, 110). Aristotle writes succinctly but clearly of the habits of the Pheasant as a well-known bird ('Hist. Anim.,' v. 31; vi. 2); nor is Athenæus silent concerning so delicate a dish, which appears to have become more common as luxury waxed strong, nor regarding the royal conduct of Ptolemy, who, though he kept them and provided them with hens (*νομάδας ὄρνιθας*) for multiplication, being aware of their excellence for the table, appears not to have tasted them. From the same author it would appear that the ancients, contrary to the opinion of modern epicures, thought the cock birds the best. ('Deipn.,' xiv, lxi. p. 654.) It is the *Phasianus* of the Romans (Pliny, 'Nat. Hist.,' x, xlvi; xi, xxxvii), but seems to have only been within reach of the wealthy. Thus Martial (xiii, xlv. 'Pulli Gallinacei')—

"Si Lihycæ nobis volucres et Phasides essent,
Accipere: at nunc accipe cortis aves."

And again, in the epigram addressed to Bassus (iii. 58), which gives so pretty a picture of a genuine rural Roman villa, and so agreeably fills the imagination with country sights and sounds—

"Vagatur omnis turba sordidæ cortis,
Argutus anser, gemmæque pavones,
Nomenque dehæ quæ rubentibus pennis,
Et picta perdis, Numidicæque guttate,
Et implorant phasianæ Colchorum.
Rhodias superbi fœminas premunt gali
Sonantque turres plausibus columbarum,
Gemit hinc palumbus, inde cercus turtur."

The Pheasant has now been spread over the whole of temperate Europe and the greater part of the old continent; and it is probable that it will be introduced with success wherever the face of the country and the supply of food are congenial to it, and the temperature does not vary too much from that of its native river, the ancient Phasis and the modern Faz, along whose banks Miugrelia, formerly Colchis, extends, between 42° and 43° N. lat., 41° 19' and 42° 19' E. long. [PHASIS, in GEOG. DIV.] It is even said to be common in Siberia, a much colder climate, which would prove the facility with which it adapts itself to temperature; and an attempt has, we believe, been made to introduce it into North America, a locality well suited to its habits.

The south of Europe owed the Pheasant, in all probability, partially to the Greeks, and more proximately to the Romans. It is the *Phasianus* of the Italians, and *Faisan* of the French. More doubt hangs about its introduction into Great Britain, and the time of that introduction. We are told that the price of one was 4*d.* in the time of our first Edward (1299). In 'The Forme of Cury,' which is stated

to have been compiled by the chief master-cook of King Richard II., we find a receipt "for to bolle Fesant, Pturch (partridges), Capons, and Curlew," which carries us back to 1351. We read of the

"Fawken and the Fessant both,"

in the old ballad of the 'Battle of Otterbourne.' At the 'Intronization of George Nevell,' archbishop of York, in the reign of our fourth Edward, we find among the goodly provision "Fessantes, 200." In the 'Northumberland Household-Book,' begun in 1512, "Fessantes" are valued at twelve pence each. In the charges of Sir John Nevile, of Chete, at Lammis Amizes, in the twentieth year of the reign of King Henry VIII., we find twelve pheasants charged twenty shillings; and they seem to have maintained their value, as, among the expenses of the same Sir John Nevile, for, as he writes it, "the marriage of my son-in-law, Roger Rockley, and my daughter Elizabeth Nevile, the 14th of January, in the seventeenth year of the reign of our sovereign lord King Henry VIII.," is the following:—"Item in Pheasants 18, 24 shillings." We trace the birds in 'A C. Mery Talys,' printed by John Rastell, where we read of "Mayster Skelton, a poyet lauryat, that broughte the byshop of Norwiche ii. fessantys." Rastell began to print as early as 1517, and ceased in 1533. In Turberville's 'Booke of Falconrie' the 'Fesant' and 'Fessants'—for, with the licence of the time, it is spelled both ways—are mentioned as the subjects of hawking, and so the bird may be traced as a dish for the table, or the object of field sports, down to the present time.

Hen pheasants in this country begin to lay in April, and deposit from eight or ten to fourteen olive-brown eggs, in a rough nest on the ground. Sometimes two will lay in the same nest. The young make their appearance towards the end of May or beginning of June.

Where the country is favourable it is easy to get up a head of pheasants, with the aid of good keepers; but it is more difficult to keep them at home, for they are wandering birds, and will often leave the place where they are bred, in search of food more agreeable to them and localities more congenial to their habits. Warm covers and water are absolutely necessary; and if they are plentifully supplied with grateful food, but few of them will become vagrants. Jerusalem artichokes, potatoes, and buckwheat, as well as barley, are favourites. Small stacks of the latter grain in the straw are frequently placed about the preserves, and there the pheasants may be seen scratching at their feeding-time; but this mode of supply is objectionable, as the poacher soon finds out the several points of attraction, and avails himself of them accordingly. Mr. Yarrell states that one good mode of inducing them to stop at home is to sow, in summer, beans, peas, and buckwheat mixed together, leaving the whole crop standing on the ground. The strong and tall stalks of the beans carry up and sustain the other two, and all three together afford for a long time food and cover. ('History of British Birds.') The same author tells us that at the end of autumn he has found the crops of the birds distended with acorns of so large a size, that they could not have been swallowed without great difficulty. In December 1834 we saw eight ripe acorns and a ripe hazel-nut taken out of the crop of a hen pheasant from Sussex. The acorns had begun to germinate with the heat and moisture of the crop, and they were sent up to the Gardens of the Zoological Society in the Regent's Park, and there planted. For autumnal and winter home-feeding we have seen potatoes used with excellent effect, not only in keeping the birds from wandering, but in increasing their weight and fatness. Carts loaded with raw potatoes were from time to time driven into the covers, and the potatoes were scattered about by hand. The pheasants soon found them out, and thrived accordingly, without being collected together at particular spots, as they too often are to their destruction. They are very general feeders; neither blackberries, sloes, nor haws come amiss to them, and grain, seeds, and tender leaves find their way into the pheasant's crop as well as insects. Mr. Selby observed that these birds sought after the root of the acrid Bulbous Crowfoot (*Ranunculus bulbosus*, Common Buttercup) in May and June, and a friend informed Mr. Yarrell that they also feed on the Pilewort Crowfoot (*Ranunculus Ficaria*). Mr. Selby further states that the bulb of the garden tulip is an article of diet which the pheasant omits no opportunity of obtaining, and which, however deeply buried, the bird is almost certain to reach by means of its bill and feet. The size to which these birds attain when well fed is considerable. In the catalogue of Norfolk and Suffolk birds, by the Rev. Revett Sheppard and the Rev. William Whitcar ('Linn. Trans.,' vol. xv.), the weight of a cock pheasant killed at Campsey Ash, where the birds were well fed with potatoes, buckwheat, and barley, is stated at four pounds and a half. "Some winters since," says Mr. Yarrell, "my friend Mr. Louis Jaquier, then of the Clarendon, produced a brace of cock pheasants which weighed together above nine pounds. The lighter bird of the two just turned the scale against four pounds and a half; the other bird took the scale down at once. The weights were accurately ascertained in the presence of several friends to decide a wager, of which I was myself the loser."

The assumption of the plumage of the cock pheasant by the female when, through old age or organic defect, she is no longer capable of reproducing the species, is by no means uncommon, not more rare indeed, if so much, as it is in the pea-fowls (*Pavonidæ*), common poultry, &c.; indeed John Hunter ('Animal Economy') remarks that

* Alluded to in Shakspeare's 'Much Ado about Nothing.'

this change has been principally observed in the common pheasant. Mr. Yarrell, in his 'History of British Birds,' also refers to this fact. Blumenbach, in his interesting paper, 'De anomalis et vitiosis quibusdam nius formativis aberrationibus commentatio,' read before the Göttingen Royal Society in July, 1812, has entered fully and particularly into this subject. The species in which he had known the change of plumage to be observed were—*Columba Cenas*, *Phasianus Gallus*, *Colchicus*, and *Pictus*, *Pavo cristatus*, *Otis tarda*, *Emberiza paradisea* and *longicauda*, *Pipra rupicola*, and *Anas Boschas*. Alluding to the eggs which have been sold as Cock's Eggs, he observes, that to him it seems most probable that such specimens have been laid by hens which had either assumed the plumage of cocks from their youth up, or upon whom the change had come in their old age. Though such phenomena are usually gallinaceous, they are not confined to that family; for he relates that Professor Erhard sent to him an egg laid by a canary bird that sang loudly and excellently, having all the appearance of a cock bird. The egg was one-half less than the usual size, but of the ordinary form and colour.

Hen pheasants which have begun to put on the livery of the male are not always incapable of producing eggs. Sir Philip Egerton has informed us that a hen pheasant at Oulton Park, Cheshire, which had nearly assumed the plumage of the cock, laid a nest full of eggs, from which she was driven by the curiosity of persons who came to gaze at so strange a sight. She then laid another nest full of eggs, sat upon them, and hatched them; but the young all died soon after they were excluded.

There are white and pied varieties. The Ring-Necked and Bohemian Pheasants appear to be considered as varieties by Mr. Yarrell; Temminck and Sir W. Jardine consider the former to be completely distinct. The English reader will find the reasons for the latter opinion stated at length in 'The Naturalist's Library' ('Ornithology'), vol. iii.

Various instances of the Common Pheasant breeding with other gallinaceous birds are on record. Edwards has figured a bird supposed to have been produced between a pheasant and a turkey. Three or four of these were discovered in the woods near the house of Henry Seymour, Esq., of Handford, Dorsetshire, and he shot one in October 1759, the bird which he sent to Edwards. Mr. Yarrell ('British Birds') observes that he has twice been shown birds that were said to be the produce of the Pheasant and the Guinea Fowl, and the evidence of the plumage was in favour of the statement. We have seen such a bird, and its feathers corroborated the allegation that it had been so produced. Hybrids between the Pheasant and Gray Hen are also recorded. [BLACK-COCK.] Mr. Thompson of Belfast describes ('Magazine of Zoology and Botany') another hybrid shot at Lochnew, Wigtonshire, where it had been seen several times on the wing by persons who supposed it to be a wild turkey. In the surrounding plantations pheasants and black grouse were numerous; but this individual, which was preserved for Sir Andrew Agnew, Bart., M.P., was the only one of the kind observed. Mr. John Leadbeater, in 1837, exhibited a hybrid between the Pheasant and Black Grouse, shot near Alnwick, at a meeting of the Zoological Society. This the Duke of Northumberland presented to the British Museum.

The union between the Common Hen and the Cock Pheasant is by no means rare, as is well known to those whose homesteads border upon pheasant preserves. The produce of this union is called a Pere.

Before we leave the True Pheasants we must notice some of the magnificent Indian species, which exhibit such a prodigality of splendour and beauty in their plumage as almost realises the birds which we read of in fairy tales. Such are the well-known gorgeous Gold-Pheasant (*Phasianus pictus*, Linn.: Genus, *Thaumalea*, Wagler; *Chrysolophus*, J. E. Gray; *Nycthemerus*, Sw.), the equally well-known delicately-pencilled Silver-Pheasant (*Phasianus Nycthemerus*, Linn.: Genus, *Gennarus*, Wagler; *Nycthemerus*, Sw.; *Euplocamus*, J. E. Gray), and the noble Reeves's Pheasant (*Phasianus reevesi*, Temm.: Genus, *Symaticus*, Wagler).

The first two of these (natives of China) are common in almost every aviary, and there is no reason why they should not thrive well if turned out in our preserves; the second species has, we believe, been so turned out with success; the last is also found in China, but, as it would seem, on the very confines of the empire. It is very rare in Pekin. Dr. Latham's description was taken from Sir John Anstruther's drawings, and from some writing under them in the Persian language it appeared that the bird was called Doondurour, or Loug-Tall, and it was found on the snowy mountains of Surinagar.

To Mr. Reeves we are indebted for the first individual ever brought alive to Europe. It was a male, and continued to live for some time in the garden in the Regent's Park. Tail-feathers from it were exhibited to the Society in 1831, measuring each about 5 feet 6 inches in length. A second male specimen was also sent to their menagerie by the same liberal donor in 1834.

Then there are the beautiful Diard's Pheasant (*Phasianus versicolor*, Vieill.), which haunts the Japanese woods, and exhibits the manners and habits of our Common Pheasant; the rare and elegant Sömmering's Pheasant (*P. Sömmeringii*, Temm.), also a native of Japan.

We should also call the reader's attention to the beautiful *P. Stacii* (figured and described by Mr. Gould in his 'Century') as one of the True Pheasants; and to *P. Pucrasia* and *P. albo-cristatus*, also there figured. *P. Pucrasia* appears to lead the way from the True Pheasants

a, Silver Pheasant; b, Gold Pheasant; c, Reeves's Pheasant (*Syrnaticus reevesii*), males.

to the *Lophophori*; and *P. albo-cristatus* to be an *Euplocamus*, which, even more immediately than *E. ignitus*, forms a transition from the genus *Phasianus* to the genus *Gallus*.

The Argus Pheasant, which is not a species of *Phasianus* [PAVONIDÆ], has been brought alive to this country, and a specimen is now in the Gardens of the Zoological Society of London in the Regent's Park.

Euplocamus (Temm.).—Sir George Staunton, in his 'Embassy to China,' first made this highly-interesting form known to European

presents to his guest of several specimens, and among them was this beautiful pheasant, which was sent to England and described by Dr. Shaw.

E. ignitus, the Fine-Backed Pheasant of Java, the Macartney Cock, *Phasianus ignitus*, Latham. Length of adult male about two feet. Skin of the nostrils stretching backwards over the sides of the head behind the eyes, and bluish-purple. A crest upon the crown of the head composed of naked-shafted feathers, expanding at their tips into slender spreading barbs. Head, neck, breast, belly, and upper part of the back, deep chalybean or steel-blueshot black; lower part of the

Fine-Backed Pheasant (*Euplocamus ignitus*), male.

zoologists. His host at Battavia had, it appears, a very curious collection in the several departments of natural history. He made

Fine-Backed Pheasant (*Euplocamus ignitus*), female.

back fiery orange-red or flame-colour, varying in intensity according to the incidence of the light, and passing like a zone round the body, though more obscure on the abdomen; rump and tail-coverts broad and truncated, brilliant bluish-green with a paler bar at the tip. Tail when erect folded in some degree like that of a hen; the middle

feathers white, and the outside ones black with green reflections. Legs and feet vermillion, spurred.

Female.—Length about 20 inches. Plumage almost entirely rich cinnamon-brown; feathers of the upper parts slightly mottled with black; throat white; lower parts of a paler tint than those above, and having the feathers bordered with white. Elongated head-feathers capable of being erected into a crest, but not equal to that of the male. Tail folded. Legs spurless.

It is a native of Sumatra. ('Atlas' to Staunton's 'Account of Lord Macartney's Embassy to China'.)

Gallus (Brisson).—Bill moderate, strong, convex above, curved towards the point, naked at the base, and furnished with two pendant and compressed caruncles or wattles. Head surmounted with a fleshy erect or comb. Tarsi (in the male) furnished with a long and recurved spur; the hind toe only resting on the ground at its tip. Wings short and graduated. The 14 tail-feathers forming two vertical planes with the backs of the feathers towards each other, and so making what may be called a folded tail; the middle feathers longest and recurved.

The ancestors from which our domestic poultry have descended were undoubtedly natives of Asia; but some doubt still hangs over the questions of the precise breed from which they came, and the exact locality where they were found. That fowls were domesticated at a very early period there is no doubt, and both historians and poets speak of the high antiquity of the race. Thus Ptolemy relates why the cock is called *Περσικός όρνις* (the Persian Bird), and how it reigned over that country before Darius and Megabazus. (Aristoph., 'Birds,' 483 et seq.)

To the forests and jungles of India we must look for the race in a state of nature; and though the denizens of our farm-yards may be the result of a mixture of many of the species which there inhabit, zoologists in general agree with M. Temminck in thinking that to the Malay Gigantic Cock or Fowl (*Gallus giganteus*, Temm.), and the Bankiva Cock (*G. Bankiva*, Temm.), we are chiefly if not entirely indebted for our common poultry.

The Domestic Cock and Hen are the '*Αλεκτρίων*' and '*Αλεκτορίς*' of the Greeks; *Gallus* and *Gallina* of the Romans; *Gallo* and *Gallina* of the Italians; *Haus Hahn* and *Haus Henne* of the Germans; and *Coq* (*Gau*, *Geau*, *Gal*, *Gog*), *Galline*, and *Poule*, of the French.

Bold, ardent, and vigilant, the cock has been always considered the emblem of watchful courage, whilst the hen has been considered a pattern of maternal solicitude. In this and other polygamous species, the object to be attained is the effective impregnation of the greatest numbers of females by the most vigorous male. In the cock accordingly the spurs are developed as the sexual organs are matured; and it is principally with these weapons of combat that the battle which is to leave the field in the possession of the strongest is decided. The conqueror in his turn, as the weakness of age comes upon him, yields to a younger and more powerful rival; and thus a numerous, healthy, and stout progeny is secured.

How the Domestic Cock and Hen were introduced into Greece and the south of Europe is not known; upon such occasions of doubt the Phœnicians are usually resorted to; but we are ignorant of proof which can bring home the benefaction to them more than others. We find it early on the Greek and Roman coinage, and upon gems; and it figured in the public shows of those nations. It was dedicated to Apollo, to Mercury, to Æsculapius, and to Mars. Socrates, in his dying moments, reminded his disciples that he "owed a cock to Æsculapius." The Rhodian fowls (Martial, iii. 58, above quoted) and those from the Isle of Delos were celebrated for their superiority in fight and their delicacy for the table. The luxurious Roman had his hens fed, perhaps crammed, with meal in the dark. Thus Martial (xiii. 62, '*Gallina Altilia*'):—

"*Pascitur et dulci facilis gallina farina,
Pascitur et tenebris: ingeniosa gula est.*"

Nor was the same gastronomer ignorant of the value of the capou. (Martial, xiii. 63.)

The bird appears to have been in Britain before the invasion of Julius Cæsar, who tells us that the Britons abstained from tasting the hare, the hen, and the goose; though they bred them for their pleasure. This abstinence seems to have originated in superstitious feeling: "*Leporem et gallinam et anserem gustare fas non putant; hæc tamen alunt, animi voluptatisque causa.*" ('*De Bello Gallico*,' lib. v.) The race is now spread all over the civilized world.

M. Lesson asks if it is not remarkable to find the Domestic Hen, differing in nothing from that of our countries, in all the islands of the South Sea, and among people with whom Europeans have certainly never communicated? Cocks and hens, he tells us, were very common at Oualan for example, and the natives were ignorant that these birds were good to eat. They were found among the Papuans, and among others there was a white variety with all the feathers frizzled.

G. giganteus, the Gigantic Cock, the Kulm Cock of Europeans, often stands considerably more than two feet from the crown of the head to the ground. The comb extends backwards in a line with the eyes; it is thick, a little elevated, rounded upon the top, and has almost the appearance of having been cut off. The wattles of the under

mandibles are comparatively small, and the throat is bare. Pale golden-reddish hackles ornament the head, neck, and upper part of the back, and some of these spring before the bare part of the throat. Middle of the back and lesser wing-coverts deep chestnut, the webs of the feathers disunited; pale reddish-yellow long drooping hackles cover the rump and base of the tail, which last is very ample and entirely of a glossy green, of which colour are the wing-coverts; the secondaries and quills are pale reddish-yellow on their outer webs. All the under parts deep glossy blackish-green with high reflections; the deep chestnut of the base of the feathers appears occasionally, and gives a mottled and interrupted appearance to those parts. (Jardine principally.)

Lieutenant-Colonel Sykes, in his Memoir on the Birds found in the Dukhun (Deccan), states that it is only there met with as a domestic bird, and that he has reason to believe that it is not a native of India, but has been introduced by the Mussulmans from Sumatra or Java. The iris, he says, of the real game bird should be whitish or straw-yellow. The Colonel landed two cocks and a hen in England in June, 1831; and they bore the winter well. The hen laid freely, and in September, 1832, had reared two broods of chickens. The cock had not the shrill clear pipe of the domestic bird, and his scale of notes appeared to be more limited. A cock in the Colonel's possession stood 26 inches to the crown of the head, but they attain a greater height. The length from the tip of the bill to the insertion of the tail, 23 inches. Hen one-third smaller than the male. ('Zool. Proc,' 1832.)

G. Bankiva, the Bankiva Cock, is the *Coq et Poule Bankiva* of Temminck; *Ayam Utan*, or *Brooga* ('Linn. Trans.,' xiii.); *Javan Cock* of Latham; and many Bantams resemble it very closely.

The space round the eyes and throat bare, comb much developed, deeply lobed along the upper ridge, wattles of the lower mandible rather large; long, clear, brilliant, golden-orange hackles cover the head, sides of the neck, back, and rump. Upper part of the back below the hackles bluish-black, the middle and lesser wing-coverts rich deep-chestnut, with the webs of the feathers disunited; greater coverts steel-blue, secondaries the same, with a broad chestnut border; quills brownish-black, edged with pale reddish-yellow. Tail black, richly glossed with green and blue. Under parts black.

Bankiva Cock (*Gallus Bankiva*).

Sir W. Jardine states that he has seen three or four specimens of another bird very closely allied to *G. Bankiva*, but rather larger, and certainly distinct: they were all from the continent of India.

G. aneus, the Bronzed Cock, figured by M. Temminck from a specimen sent from the interior of Sumatra by M. Diard. This is somewhat larger than the Bankiva Cock, and its large comb is without dentilations; indeed the edge is quite unbroken; the feathers of the head, neck, and upper part of the back are rather elongated, but not hackles. The Fork-Tailed Cock (*G. furcatus*, Temm.; *G. Javanicus*, Horsf.) has the comb also entire, and the throat is adorned with a single large wattle springing from the centre. The head, neck, and upper part of the back are covered with feathers, which are not hackles, shorter and more rounded than those in the Bronzed Cock.

G. Sonneratii. This is the *Coq Sauvage* of Sonnerat; *Coq et Poule de Sonnerat* of Temminck; *Sonnerat's Wild Cock* of Latham; *Rahn*

Komrah of the Mahrattas; Jungle Cock and Jungle Fowl of the English sportsmen in India.

The size of the male is nearly equal to that of a domestic cock; but the bird is altogether lighter, more graceful, and has a higher bred look about it; comb large, and with an unequal margin, but though this margin is jagged, it is not deeply denticulated; wattles double, depending from the base of the lower mandibles; hackles of the neck and of the wing and tail-coverts dark-grayish, with bright golden-orange shafts dilating in the centre and towards the tip into a flat horny plate. In some of these feathers the shaft takes an elliptical or oar-like shape; in others it puts on the appearance of a long inverted cone, from the

Jungle Cock (*Gallus Sonneratii*), male.

Jungle Fowl (*Gallus Sonneratii*), female.

centre of the base of which a battledore-like process arises. The substance and appearance of these plates have been not inaptly compared with the wax-like plates which ornament the wings and tail of the Bohemian Chatterer. [BOMBYCILLA.] The effect produced by this modification of the shafts is singular and beautiful. Feathers of the middle of the back, breast, belly, and thighs, deep rich gray, with paler shafts and edges; tail generally rich deep-green; the feathers which immediately succeed the hackles are rich purple, with a pale-yellow edge; those next in succession are golden-green, with gray

edges, and all are glossed with brilliant metallic reflections. Bill, legs, and feet, yellow. The living bird presents altogether a rich and striking object, especially when the sun shines on the plumage.

Female less than the cock by about a third, without comb or wattles, but a trace of nakedness round the eye. The plumage (generally) is without the horny structure which distinguishes that of the male. Upper parts uniform brown; neck feathers with dark edges, those of the back and wing-coverts with a pale streak along the shaft, and those of the wings, tail-coverts, and tail, waved and mottled with darker pencillings; throat and front of the neck white; feathers of the rest of the lower parts grayish-white, edged with dark brown, which predominates towards the vent. Legs and feet bluish-gray.

Colonel Sykes, in his valuable Catalogue, notes this noble bird as being very abundant in the woods of the western Ghauts, where (and this is well worthy the attention of ornithologists) he says there are either two species or two very strongly marked varieties. In the valleys, at 2000 feet above the sea, he tells us Sonnerat's species is found slender, standing high upon the legs, and with the yellow cartilaginous spots on the feathers, even in the female. In the belts of wood on the sides of the mountains, at 4000 feet above the sea, there is a short-legged variety. The male has a great deal of red in the plumage, which Sonnerat's has not; the female is of a reddish-brown colour, and is without cartilaginous spots at all: "in fact," continues the Colonel, "the female of this variety is the *G. Stanleyi* of Mr. Gray's 'Illustrations.'"

Dr. Latham remarks that this Jungle Fowl is by far the holdest and strongest for its size, and that it is anxiously sought after by cock-fighters in Hindustan, who rely on it for victory when pitted against larger game cocks.

Individuals of this species have been exhibited alive in the Gardens of the Zoological Society in the Regent's Park.

But whatever may have been the source or sources from which our domestic poultry sprang, and the probability is that more than one wild race have contributed to improve it, the varieties in a reclaimed state are almost infinite. The Spanish breed, entirely black, grows to a considerable size, and the eggs are remarkable for their volume. The Dorking poultry have long been celebrated, and they are known principally by having supernumerary toes. The true Dorkings are purely white, and are much esteemed for the table. Dr. Latham mentions one of this breed that weighed nearly 14 lbs. Some of the Sussex fowls are very fine. The fancy breeds are very numerous; for an account of these see POULTRY, in ARTS AND SC. DIV.

Tragopan, Cuvier (*Cerionis*, Swainson).—Head crested on the crown, partly naked (on the cheeks and round the eyes), the naked parts terminating in horn-like caruncles behind the eyes; under the lower mandible and on the forepart of the throat a subpendent composite carunculated wattle. Tarsi armed with a blunt spur in the male; unarmed in the female.

Mr. Gould ('Century of Birds from the Himalaya Mountains') remarks that the genus *Tragopan* appears to take an intermediate station between that of *Meleagris* and the more typical *Phasianidae*, forming one of the links of a chain connecting these groups of the Rasorial order. The affinity of this genus, he observes, to that of *Meleagris*, is evident in many characters; nor are some wanting which indicate a relationship to *Numida*, and even to *Francolinus*. [PERDIDICIDÆ.]

T. Satyrus appears to have been the only species originally known. Mr. Gould, in his 'Century,' describes another species, *T. Hastingsii*, and refers to another, which Dr. Gray, of the British Museum, has dedicated to M. Temminck. ('Indian Zoology.')

T. Hastingsii. Head of the adult male covered with a pendent crest of feathers, which, as well as the ear-coverts and throat, are black; the neck and shoulders are rich maroon; the chest rich glossy orange-red; the naked skin around the eyes is red; the fleshy horns and wattles mingled blue and purple; the upper parts exhibit a mixture of zigzag lines and marks of dark and light brown, with numerous and distinct spots of white; each of the upper tail-coverts ends in a large white eye, bordered on the sides with brown, and tipped with black; the tail deepens till it ends in uniform black; the feathers of the under surface are maroon, largely tipped with black, in the centre of which is a large white spot; the beak is black, the tarsi brown.

In the young male the plumage is much less brilliant, the wattles being of a pale flesh-colour, and little developed, as is also the naked skin of the face.

The plumage of the female consists of a uniform brown, mottled and barred with mingled lines and dots of various tints, the feathers of the back and chest having a central dash of a lighter colour; the head is crested, with short rounded feathers; the sides of the cheeks are clothed, and there are neither fleshy horns nor wattles. (Gould.)

Mr. Gould observes, that although this species and *T. Satyrus* are closely allied to each other, and doubtless possess similar habits and manners, he is led to believe that their local distribution is somewhat different; at least, he generally receives but one species in a collection from the same quarter; *T. Satyrus* being transmitted from the Nepaulese hills, while *T. Hastingsii* is sent from the more northern range of the Himalayas. He further well observes that the changes of plumage which birds of this genus, especially *T. Hastingsii*, undergo in passing

from youth to maturity (and this is well illustrated in Mr. Gould's beautiful plates), are such as to have caused an apparently erroneous multiplication of species.

Tragopan Hastingsii, male.

Tragopan Hastingsii, female.

T. Satyrus, according to the same author, is an exclusive inhabitant of the colder regions of the mountains, in conjunction with the *Lophophorus*, its approximate relative, feeding on grains and roots, the larvae of ants, and other insects. [PAPONIDÆ.]

PHASIANUS. [PHASIANIDÆ.]

PHASIDÆ, a tribe of Orthopterous Insects, embracing a number of exotic forms which have been often included in the *Mantida*, from which they are distinguished by the fore-legs being of the ordinary size, and fitted like the rest for walking rather than running. From the other *Orthoptera* they are distinguished by the hind legs not being saltatorial.

The body is generally long and slender. The head is of moderate size, of an oval subdepressed form, corrected, with large globular eyes, in front of which the antennæ are placed, which are variable in form, but ordinarily long, slender, and composed of a great number of articulations. The ocelli are rudimentary or obsolete. The labrum is deeply notched in front; the jaws are strong and horny. The dorsal surface in both sexes consists of nine segments, but only seven are distinct in the females. All the legs are alike, being long and slender, often armed with short spurs along the edges. The fore wings are of small size, and attached at the posterior part of the mesothorax. The true wings are very large and attached to the anterior part of the metathorax. "As they far exceed the wing-covers in size, it is essential that provision should be made for their defence. This is effected not as in the earwig, by the transverse folding of the

wing so as to enable it to be folded beneath the small wing-cover, but by the front margin of the hind wing being greatly thickened, serving as a flat plate, beneath which the other part of the wing is folded longitudinally, the latter part being often differently coloured. Thus in some species the short wing-covers and the front margin of the wing are pale-green, whilst the other part of the wing is pink. Many species however remain throughout their lives without ever acquiring wings or wing-covers." (Westwood, 'History of Insects.')

The odd appearance of these insects have got for them the name of Walking-Sticks, Straws, Leaves, Spectres, &c., and certainly nothing can be imagined more curious than the forms they assume. In many instances they might be mistaken for a portion of the branch of the trees on which they rest.

PHEASANT. [PHASIANIDÆ.]

PHEASANT'S-EYE. [ADONIS.]

PHENAKITE, a Mineral, occurring crystallised. Primary form a rhomboid. Cleavage parallel to the primary faces. Colourless; also bright wine-yellow, inclining to red. Hardness above 6.0. Lustre vitreous. Transparent to opaque. Specific gravity 2.969. It is found near Freiberg and near Framont. Its analysis by Hartwall gives—

Silica	55.14
Glucina	44.47
Alumina and Magnesia	0.39
	—100

PHE'NE. [VULTURIDÆ.]

PHERU'SA, a genus of *Crustacea* belonging to the order *Edriophthalmia*.

PHIBALU'RA (Vieillot), a genus of *Ampelidæ* (Fruit-Eaters or Chatterers), placed both by Mr. Swainson and Mr. G. R. Gray in the sub-family of *Bombycillina*, the Swallow-Chatterers of the former zoologist. The genera included by both in the sub-family are the same; Mr. Swainson's genera being *Phibalura*, *Bombycilla* [BOMBYCILLA], and *Procnias*, and those of Mr. Gray *Phibalura*, *Bombycilla*, and *Tersa*, Vieillot, the latter being the *Procnias* of Illiger and others.

It is a native of South America. A beautiful figure accompanies Mr. Swainson's description in the 'Zoological Illustrations,' first series.

PHILADELPHACEÆ, *Syringas*, a natural order of Exogenous Polypetalous Plants, with an inferior ovary, the principal genus being that after which the order is named. [PHILADELPHUS.] The species are American, European, and Asiatic shrubs of temperate climates, with opposite leaves, distinct styles, and capsular fruit, containing a large number of minute seeds. Their nearest affinity is, on the one hand, with *Myrtaceæ*, from which they differ in having separate styles, dotless leaves, and albuminous seeds, and on the other with *Sarifragaceæ*, from which they strictly inferior fruit, opposite leaves, and parallel styles sufficiently distinguish them. Many of the species, especially in the genus *Deutzia*, are clothed with beautiful stellate hairs, which are composed of silica. They form excellent opaque objects for examination with the microscope. [DEUTZIA.] The only other genus in this order is *Decumaria*.

Deutzia scabra.

1, a vertical section of a flower deprived of petals; 2, a transverse section of the ovary; 3, one of the stellate hairs.

PHILADELPHUS, a genus of Plants the type of the natural order *Philadelphaceæ*, which is also the name of a tree, now unknown, mentioned by Athenæus, but was applied to the present genus by Bauhin. *Philadelphus* is characterised by having a calyx with an obovato-turbinate tube and a 4-5-partite limb. Petals vary in number

from 4-5. Stamens 20-40, free, are shorter than the petals. Styles 4-5, united together, or more or less distinct. Stigmas 4-5, oblong or linear, generally distinct. Capsule 4-5-celled, many-seeded. Seeds dust-like, inclosed in a membranous aril, oblong, and fringed at one end.

The plants consist of shrubs with white pedicellate flowers arranged in a corymbose cyme, in a panicle-like manner, or sometimes in the axils of their leaves, supported by bracts.

The greatest number of species are indigenous in North America, whence they have been introduced into the shrubberies of this country, to which they form a highly ornamental addition. A species has also been discovered in the Himalayas, at elevations of 6000 and 7000 feet, of which there are two varieties, sometimes considered distinct species, *P. tomentosus* being apparently only a more advanced state of *P. triflorus*. The best known species however is *P. coronarius*, commonly called Syringa, which is so easy of culture, and found in most gardens. It is supposed to be a native of the south of Europe, but it has hardly ever been found in a wild state, and even in these few cases it may have escaped from cultivation. As one species has been found in the Himalayas, there is no reason why other species should not exist still farther to the north-west, as in the Hindoo-Koosh, and that the Syringa may be found to be one of those plants which was in early times introduced from some part of the Persian Region of botanists into the south of Europe.

PHILANDER. [DIDELPHINA.]

PHILEDON. [MELIPHAGIDÆ.]

PHILEMON, Vieillot's name for a genus of Birds (*Anthrochara*, Vig. and Horsf., *Merops*, Lath.) placed by Mr. G. R. Gray in his sub-family Meliphagine.

PHILESIACEÆ, *Philesiads*, a small natural order of Plants belonging to Lindley's class of Dictyogens. It has bisexual trihexapetaloidæous flowers, with consolidated carpels and parietal placentæ. The species are twining or upright shrubs, with ribbed or 1-nerved coriaceous deciduous reticulated leaves. This order is nearly related to *Smilacæ* and *Roxburghiaceæ*, with which latter order it was combined by Lindley, and also with *Amaryllidacæ*. The species are found in the southern provinces of Chili. It has two genera and two species, *Philesia buxifolia* and *Lapageria rosea*. The latter has eatable berries, and roots useful as a substitute for sarsaparilla.

PHILLIPSIA, a genus of *Trilobites*, found in the Mountain-Limestone Strata of England and Ireland. (Portlock.)

PHILLIPSITE, a Mineral, the primary form of which is a right rhombic prism. It occurs crystallised only in masses which have much the appearance of Harmotome. Cleavage imperfect. Fracture conchoidal. Hardness 4.5. It scratches carbonate of lime. Colour white, flesh-red, or grayish. Streak white. Lustre vitreous. Transparent, translucent, opaque. Specific gravity 2.0 to 2.2. This mineral occurs with Gmelinite in the county of Antrim, and at the Giant's Causeway; at Capo di Bove, near Rome; in Sicily; in the lavas of Vesuvius, and at Marburg in Hesse, &c. The analysis from the last-mentioned place, by Gmelin, gives—

Silica	48.02
Alumina	22.61
Potash	7.50
Lime	6.56
Water	16.75

—101.44

PHILLYREA, the *Φαλλυρεα* of Dioscorides, is a genus of Mediterranean Evergreen Plants, many varieties of which are cultivated in our gardens. They are much like the evergreen shrubs called *Alaternus*, from which however they are readily known by their leaves being opposite, not alternate. Some botanists regard them as species of olive, to the fruit of which that of the *Phillyrea* has much resemblance. The hardiest and handsomest variety is *P. obliqua*; the most tender and the least beautiful is *P. angustifolia*.

PHILOMELA, a genus of Birds belonging to the family *Sylviadæ*. *P. Luscinia*, the Nightingale, is the most celebrated of the song-birds of the Old World. This well-known species is the 'Αγδών of the ancient Greeks; *Luscinia* of the Romans; Rossignuolo, Ruisenuolo, and Uaignuolo, of the Italians; Rossignol of the French; Ruisenor of the Spanish; Nachtigall of the German; Nachtergahl of the 'Fauna Svecica'; Nattergale of Brunnioh; and Eos of the Welsh.

It is the *Luscinia* of Gesner, Aldrovandus, Willughby, Ray, and Brehm; *Motacilla Luscinia* of Linnæus; *Sylvia Luscinia* of Latham and others; *Curruca Luscinia* of Fleming; and *Philomela Luscinia* of Selby, Gould, and Swainson.

The Nightingale, or Night-Singer, is a migratory bird, visiting us early in the spring (about the middle of April), and leaving us about August or September. The male birds arrive first, and are instantly sought after by the bird-catchers, who generally make the most of the interval of ten days or a fortnight that elapses before the arrival of the females, well knowing that those males which are taken after they have paired seldom survive. The bird-fanciers have a notion that a Surrey nightingale possesses the finest quality of tone. To dwell upon the richness and variety of its song, a subject which has employed the pens of poets of all ages, and of all countries where the bird is known, would be superfluous here; but there are points con-

nected with the habits and geographical distribution of the bird which require notice.

Nightingale (*Philomela Luscinia*, Selby).

M. Temminck states that the Nightingale haunts woods, thickets, and gardens; that it is common in nearly all the parts of Europe to Sweden inclusive; and that it migrates in winter into Egypt and Syria. Hasselquist saw it among the willows of Jordan and the olive-trees of Judea. Mr. Strickland saw it at Smyrna on the 5th of April. Prince C. L. Bonaparte notes it ('Specchio Comparativo') as common in the neighbourhood of Rome, which it leaves in winter only.

Pennant ('Arctic Zoology') says that it visits the temperate parts of Russia, and even some parts of Siberia. The same author ('British Zoology') remarks that the Nightingale is a species that does not spread itself over our island. "It is not," says Pennant, "found in North Wales, or in any of the English counties north of it, except Yorkshire, where it is met with in great plenty about Doncaster. It has also been heard, but rarely, near Shrewsbury. It is also remarkable that this bird does not migrate so far west as Devonshire and Cornwall, counties where the seasons are so very mild that myrtle flourish in the open air during the whole year; neither is it found in Ireland. Sibbald places Nightingales in his list of Scotch birds; but they certainly are unknown in that part of Great Britain, probably from the scarcity and the recent introduction of hedges there; yet they visit Sweden, a much more severe climate." The editor of the last edition of the 'British Zoology' states that in 1808 a Nightingale was several times heard in the gardens of the Earl of Lonsdale, in Fisher-street, Carlisle. M. Nilsson notes its arrival in Sweden by the 1st of May. Montagu informs us that it is said to be found only as far north as Yorkshire (his observations being confined to Britain), and certainly not farther west than the eastern borders of Devonshire; although they are plentiful both in Somersetshire and Dorsetshire. Mr. Yarrell ('History of British Birds') says:—"When we consider that this bird extends its visits during the summer as far north as Russia and Sweden, its very limited range in this country is unaccountable. It is found in Sussex, Hampshire, Dorsetshire, and the eastern part only of Devonshire, along the line of our south coast. It has been heard about Teignmouth and Exmouth, but no farther west in that direction. In North Devon it has been heard near Barnstaple, but not in Cornwall or Wales. A gentleman of Gower, which is the peninsula beyond Swansea, procured from Norfolk and Surrey, some few years back, some scores of young Nightingales, hoping that an acquaintance with his beautiful woods and their mild climate would induce a second visit; but the law of nature was too strong for him, and not a single bird returned. Dyer, in his 'Grougar Hill,' makes the Nightingale a companion of his muse in the vale of Towey, or Caermarthen; but this is a poetical licence, as the bird is not heard there."

Mr. Yarrell, who remarks that it is not included by Mr. Rylands in his 'Catalogue of the Birds of Lancashire,' though it has been heard as high up as Carlisle, but no farther, goes on to state that on the eastern side of our island the bird frequents Essex, Suffolk, Norfolk, some of the more wooded parts of Lincolnshire, and several parts of Yorkshire; but not higher than five miles north of the city of York, as he learned from his friend and correspondent Mr. Thomas Allis. Mr. Yarrell states his belief that it has not been heard in Scotland or in the Scottish islands, which, he adds, considering that it visits Denmark, is extraordinary.

The following is a description of this bird:—Rich brown above; rump and tail with a reddish tinge; throat and middle part of belly

dirty or grayish white; lateral parts of the neck, breast, and flanks, gray; bill and legs light brown. Sexes alike.

The Nightingale shuns observation, shiding in the thickest coverts, and in these the nest is sometimes placed on a low fork, but generally on the ground. Withered leaves, particularly those of the oak, very loosely conjoined with dried bents and rushes, and lined internally with fine root-fibres, form the structure. The eggs, of an olive-brown, are four or five in number. After the young are hatched, generally in June, the melodious song of the male ceases, and is succeeded by a low croak, varied occasionally with a snapping noise; the first is considered to be meant for a warning, and the last as a defiance. The food consists of insects, such as flies and spiders, moths and earwigs. Green caterpillars were the food brought by the parent birds to the nest of young nightingales taken by Colonel Montagu. It is not improbable that the bird's choice of localities is in some measure determined by the absence or presence of some favourite insect food.

There is another European Nightingale (the Thrush Nightingale, *Philomela Turdoides* of Blyth, *Luscinia major* of Brisson, *Sylvia Philomela* of Bechstein) inhabiting central Europe. The song of this species is loud, but far inferior to that of the true Nightingale. It is said to be common in Egypt.

PHILOMELINÆ. [SYLVIADÆ.]

PHILOSCIA. [ISOPODA.]

PHILYDRACEÆ, *Waterworts*, a natural order of Endogenous Plants, constituted by Brown to receive the genera *Phylidrum* and *Helaria*. They are allied, according to Lindley, to *Commelinaceæ*, *Orchidaceæ*, and *Xyridaceæ*. The species are grassy-looking plants, with dipetalous flowers, no calyx, three stamens, of which two are abortive, and an embryo in the axis of fleshy albumen; they have erect stems, and ensiform leaves. They are found in Australia, Cochin China, and China. (Lindley, *Vegetable Kingdom*.)

PHILLYRA, a genus of *Crustacea*. [OXYSTOMA.]

PHLEBOPTERIS, a genus of Fossil Ferns, from the Oolite of Yorkshire. (Brongniart.)

PHLEGM, a common name for Mucus. [MUCUS.]

PHLEUM, a genus of Grasses, contains, among many unimportant species, one of considerable agricultural value. This, the *P. pratense*, Meadow Cat's-Tail Grass, is a general inhabitant of the most fertile pastures, and is regarded as a sign of rich soil. It bears its flowers in a long cylindrical soft head, and is extremely like the Meadow Fox-Tail [*Alopecurus*] in appearance, from which it differs in having unequal glumes, and two paleæ instead of one. This plant is very productive, especially in the early spring, and is a very general component of hay. Nevertheless, according to Mr. Low, it is not a peculiarly good hay-grass, from the wiriness of its stem and the shortness of its aftermath. It is of the greatest use when the object is to procure a sward of permanent herbage. [GRAMINACEÆ.]

PHLEOMYS. [MURIDÆ.]

PHOCA. [PHOCIDÆ.]

PHOCÆNA. [CETACEA.]

PHOCIDÆ, a family of Marine Carnivorous *Mammalia*, including the animals called Seals.

The Amphibious *Carnivora* of Cuvier form a perfectly natural group. Their feet are so short and enveloped in the skin that they are not available for any purpose on land, except a kind of creeping; and indeed terrestrial progression is affected by means of a sort of shuffling jumping motion, in which the spine and the muscles of the body are principally employed, though the extremities are used in getting or rather climbing out of the water upon a rock or other projecting body. The webbed intervals of the toes, which last are completely enveloped in membranes that leave a considerable power of expansion to the extremity, serve as excellent oars, and these animals therefore pass the greatest part of their life in the sea, coming on shore only to bask and sleep in the sun, and suckle their young ones. Cuvier remarks that their elongated body, their very moveable spine, provided with muscles which put it in action with powerful flexibility, their narrow pelvis, their close thick fur, all unite to make them good swimmers, and the details of their anatomy confirm the impression produced by their external form. ('Règne Animal.')

Two genera only, taking the term genus in its most comprehensive sense, belonging to this group, have as yet been discovered—the Seals (*Phoca*, Linn.), and the Walrus or Moose (*Trichechus*, Linn.).

In the structure of their skull the Seals closely approach the Otter. If the skull of the Common Seal (*Phoca vitulina*) be compared with that of an otter, a great resemblance will be found to exist between them in the shortness of the muzzle, the compression of the interorbital region (which is greater in the Seal), the width and flatness of the cranium, and especially of the whole region of its base or under part, with the exception of the tympanic portions, which are large and convex. The orbit is very large in the Seal, and the frontal bone does not complete it backwards by a postorbital apophysis, nor is it distinguished from the temporal bone, except by the convexity of the last-named portion of the skull. The temporal crests are but little marked, and the occipital crest is insensible. The frontal bone does not form in front that triangular enlargement, the traces of which are still to be found in the Otter; but the postorbital apophysis of the zygomatic arch is very strongly marked, and the jugal and temporal bones equally contribute to form it. The intermaxillary bones termi-

nate near the nasal, without reaching to them; their suture below traverses the palate opposite the canines, and even in the middle opposite to the first molars. The bones of the cranium are thin, and there are no frontal sinuses.

The skull of the Monk-Seal (*Phoca Monachus*, Herm.) presents, independently of its size, some rather striking differences when compared with that of the *P. vitulina*. The zygomatic arches are more open and robust in the former; the anterior region of the frontal bone is convex; a very marked sagittal crest commences on the middle of the orbits and proceeds to join an occipital crest as strongly marked, which notches the back part of the cranium with a re-entering angle. There is also a notch at the posterior border of the palate, and the intermaxillary bones are very distinctly articulated to the nasal. On the anterior border of the orbit is a projecting point formed by the maxillary bone; and an obtuse longitudinal crest projects under the basilar region. In the upper jaw there are only four pointed molars, the external ones being very slightly the largest; below there are four, also smaller; altogether five molars on each side of each jaw, less trenchant, and with lateral points much less marked than in *P. vitulina*.

Skull of Monk-Seal (*Phoca Monachus*), seen from above.

Skull of Monk-Seal, seen from below.

Skull of Monk-Seal (profile).

The shoulder-blade of the Seal (Cuvier takes the last-named species as the principal type) widens very much from before backwards; its antespinal fossa is much wider than the other; the anterior border is very convex, and the anterior angle is lost in this convexity. The posterior edge is slightly concave, and the posterior angle rather sharp; the spine projects but little, and is terminated by a small depressed acromion, which does not advance so far as the edge of the articular surface. The acromial tuberosity is almost obsolete. In *P. vitulina* and *P. munita*, the antespinal fossa and the shoulder-blade together are much smaller, and there can hardly be said to be an anterior angle. In *Otaria*, on the contrary, the antespinal fossa is still wider in proportion than in *P. Monachus*; it is divided longitudinally by a ridge less elevated than the spine and without an acromion. The humerus is remarkable for its relative brevity, and for the great projection of

its internal tuberosity and of its deltoid crest; its lower pulley is hollowed by an obtuse gorge and divided into two parts—one external and wider, convex in two directions, for the head of the radius; one internal and narrower, for the cubit. Both the *P. vitulina* and the *P. mirata* have the internal condyle pierced with a hole for the cubital artery, but this hole is wanting in *P. Monachus* and *Otaria*. The upper head of the radius is rounded and has a simple concavity, is short and very much compressed, and dilated vertically for its lower two-thirds.

The ulna or cubit is very much compressed on its upper part, where the olecranon is much higher than it is long, and gives off a pointed apophysis towards the lower part. The hand of the Seal, being principally destined for swimming, is cut obliquely, so that the thumb forms its point and its most powerful edge; it has nevertheless only two phalanges as in ordinary, but its metacarpal bone and its two phalanges make it longer and stouter than the other fingers. The articulations of the phalanges are not well marked. The ungual phalanges of the Seals have one remarkable conformation, namely, that the point which is sheathed in the claw comes out, in some degree, from the upper surface of the bone, and the rest of the bone forms, as it were, two little wings. In the *Otaria*, which have no claws before, the ungual phalanx is simply depressed and obtuse.

The pelvis of the Seals, and especially the ossa ilii, are reduced to very small dimensions.

Of all the bones of the Seals the femur is the most extraordinary for its shortness; it is hardly longer than it is wide: in the lower part especially it is flattened and dilated laterally, having a crest at its internal border and a tuberosity on its external border. Its rotular pulley is flat and nearly vertical. The articular surfaces for the tibia are wider than they are long.

The tibia is twice and a half as long as the femur, and is rather stout, especially above, where in age it becomes soldered with the fibula, but always remains distinct from it below. The interval between them is rather wide. The fibula itself is rather stout.

The astragalus of the Seals is very extraordinary; for instead of being more or less hollow in the middle of its articular surface, it offers to the leg a convex pulley formed of two faces, which together form a projecting angle like a roof, and one of which responds to the tibia, and the other (the largest) to the fibula. This bone has not only an apophysis forward for the scaphoid bone, but has another backward, terminated by a tuberosity and forming a sort of internal heel, so that if looked at separately from the rest it might be taken for the os calcis. Upon this tuberosity of the astragalus the long flexor of the toes passes in a groove.

The great and little toes are larger than they are long, and the middle toe is the shortest, so as to give the hind foot a forked appearance; the great toe nevertheless has but two phalanges. All the articulations of these phalanges are as little developed as in the fore feet.

The ribs are angular rather than flat, and slight when compared with those of the Dugongs. In the Seals there are ten whose cartilages are attached immediately to the sternum, and nine only in *Otaria*. The ninth rib in the Seals is attached to the side of the eighth bone of the sternum, and the tenth, as ordinarily, to the interval of the eighth and ninth: this last is cylindrical, longer than the others, and terminated by a cartilaginous dilatation. The others are depressed. In front of the first and last pairs of ribs there is in the Seals a pointed cartilaginous prominence, which in *Otaria* is ossified, and makes part of the body with the first bone. ('Ossements Fossiles.')

Skeleton of Seal (*Phoca vitulina*).

In these Pinnigrade *Feræ* the whole form is adapted for progression in water. Instead of the lengthened anterior extremities and phalanges of the bats, framed to support a wing for their passage through the air, we have all the bones of those extremities in the Seal short and compact, in order to support the finlike arm and deteriorated hand. We have the conical shape of the body and the extremely narrow pelvis, to favour that shape so as to produce the least resistance in passing through the water, with the short femur and posterior extremities directed backwards. In the skull we have the defective orbit observable in all the *Carnivora*, by which space is gained for the zygomatic arch and the highly developed temporal muscle. The broad development of the transverse processes of the atlas is here also remarkable, and the cervical vertebrae are framed for extensive motion.

The spinous processes of the vertebrae have a posterior deflection so as to act in unison for the necessary aquatic progression. The clavicle is absent, as in the *Feræ* generally, but the scapula is broad. The number of carpal bones is the same as in the lion, and the number of ribs may be stated at fifteen pairs.

Considerable differences exist in the crania of the various *Phocidæ*, well justifying, with other discrepancies of structure, the division of the family into several genera.

The Stomach of the Seal (*Phoca vitulina*) differs from the ordinary form: the oesophagus enters directly at the left extremity, so that there is no blind sac in the stomach.

The seals have the power of opening or closing their nostrils at pleasure, and the interval between their respirations is very long. This may be observed in those which are kept in confinement; and the closing appears to be effected by sphincter-like muscles acting upon valves which shut the aperture most effectually. Such a provision is absolutely necessary for animals that pass so much of their life in the water and take their food there: for ordinarily the seal eats in the sea, though it can eat upon land, as those who have seen the individual fed, in the Gardens of the Zoological Society in the Regent's Park, well know. The breathing is not only slow, it is also irregular. After opening the nostrils and making a strong expiration, the animal inspires a large quantity of air, and closes the nostrils. In the intervals of this infrequent respiration, it is evident, from the free motion of the ribs and the general deportment of the animal, that the lungs receive their regular supply of air. In a state of nature a quarter of an hour and as much as twenty-five minutes have been known to elapse between their descent from the surface and their ascent thither for the purpose of obtaining a fresh supply; and in confinement they have been observed to remain asleep with the head under water for an hour at a time, and consequently without breathing during that period. To account for this power physiologists were of opinion that the foramen ovale remained unclosed in these animals, and that thus the sanguiferous circle was not interrupted during the time of their stay under water; but Cuvier and Lawrence found it closed in the seals dissected by them, and we must look to some other conformation for the endowment of this faculty. Thus Cuvier states that there is a great venous sinus in their liver, which assists them in their divings by rendering their respiration less dependent upon the circulation; and Mr. Houston has pointed out other venous reservoirs in the neighbouring parts. These provisions seem to be quite different from the great arterial plexus first pointed out by John Hunter in the *Cetaceæ*; for in the Seals the blood appears to be laid up not in a network of vessels, but, so to speak, in wide canals. The term *veineux* is certainly used by Cuvier, and a reservoir of arterial blood would, reasoning from analogy, be required for the purpose of keeping up healthy life during submersion; but there can be little or no doubt that these reservoirs are intimately connected with the power of remaining long beneath the water, though, as yet, the mode of operation is not satisfactorily made out, as it is in the Whales. The last-mentioned author states that their blood is very abundant and very black.

The Brain of the Seals is well developed, and the degree of sagacity and attachment shown in domestication (for they are very easily tamed and taught to perform tricks) is evidence of superior intelligence. This has been long ago observed:—"Accipiant disciplinam," says Pliny ('Nat. Hist.' ix. 13), "voceque pariter et visu populum salutant, incondito frenitu: nomine vocati respondent." F. Cuvier too saw one display much intelligence; he performed what he was ordered to do. When desired to raise himself erect on his hind legs and to take a staff in his flippers, like a sentinel, he obeyed the word of command: he would lie down on his right side or on his left, according to order, and tumble head over heels when directed to do so. He gave a paw when requested, like a dog, and protruded his lips for a kiss. This animal appeared to be very fond of its master.

Blumenbach remarks that it has long been known that the sclerotic coat in several mammals is, as in the human subject, not of equal strength throughout; but that its posterior part is much thicker than its anterior. It has also been conjectured that this structure might influence what are termed the internal changes of the eye, by which the form of the eyeball, and consequently the length of its axis and the relative situation of the lens are adjusted according to the proximity or distance of the object, or indeed with reference to any other relations. Blumenbach remarks that he flatters himself that he has ascertained the truth of this conjecture by discovering the admirable structure of this coat in warm-blooded animals, which have not only the power of seeing at various distances, but also in two media of such different density as air and water. In the eye of the Greenland Seal, where he first noticed the fact, the cornea was thin and yielding; the anterior segment of the sclerotica, or that which is immediately behind the latter membrane, was thick and firm; its middle circle thin and flexible; and lastly, the posterior portion very thick, almost cartilaginous. The whole eyeball was surrounded with very strong muscles; and it may be easily understood how their action, modified according to circumstances, produces the requisite changes; how the axis of the eye is shortened when the animal sees in the air, by bringing the lens nearer to the back of the globe, in order to obviate the strong refraction which the rays of light undergo in

passing from the thin medium of air into the thicker one of the eyes, and vice versa.

The Auditory Nerve in the Seal is very large, and though the articular aperture is closed by a mechanism somewhat similar to that which shuts the nostrils in order to protect the internal parts of the organ from the consequences of the great pressure of the water when the animal is in deeps, it is evident that Seals hear very well even under water. The senses of taste, smell, and touch, are all well developed in the *Phocidæ*.

The student will find several preparations illustrative of the anatomy of the Seals in the Museum of the Royal College of Surgeons.

The following are the genera into which the Linnæan genus *Phoca* has been divided:—

Caloccephalus (F. Cuv.).—Molars formed principally of one great point placed in the middle, one smaller situated below, and two, also smaller, placed posteriorly. Cranium convex on the sides, flattened on the top: slight rugosities, instead of occipital cristæ.

C. vitulinus. This is the *Phoca vitulina* of Linnæus; Le Veau Marin and Phoque Commun of the French; Vecchio Marino of the Italians; Lobo Marino of the Spanish; Meerwolf and Meerhund of the Germans; Zee-hund of the Dutch; Sæl-hund of the Danes; Sial of the Swedes; Common Seal and Sea-Calf of the English; and Moelrhon of the Welsh.

The ground-colour of the hair or skin, when the animal is alive and dry, is pale whitish-gray with a very slight tinge of yellow; when just out of the water and wet, the ground-colour is ash; after death, and, as seen in museums, the ground-colour is pale yellowish-gray, the oil having penetrated the skin, and rendered the hair of a more yellow hue. The body above is clouded and marbled with blackish-gray. Space round the eyes and muzzle, sides of the body, all the lower parts and the feet, pale grayish, becoming nearly white beneath. There is some brown on the muzzle and upper part of the tail; whiskers moderate, undulated. Claws black, and rather strong. Length from 3 to 5 feet.

It inhabits the northern seas generally, the coasts of England, France, &c. It is comparatively scarce on the southern coasts of Britain now, but still haunts the estuary of the Tees.

Dental Formula:—Inisors, $\frac{6}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5} = 34$.

Teeth of *Caloccephalus*.

Mr. Farrington, then of Dinas in Caernarvonshire, wrote thus to Pennant:—"The seals are natives of our coasts, and are found most frequently between Llyn in Caernarvonshire and the northern parts of Anglesey; they are seen often towards Carreg-y-Moelrhon, to the west of Bardsey, or Ynys Enlli, and the Skerries, commonly called in the British language Ynys-y-Moelrhoniad, or Seal Island. The Latin name of this amphibious animal is *Phoca*; the vulgar name is sea-calf, and on that account the male is called the hull, and the female the cow, but the Celtic appellation is 'Moelrhon,' from the word 'moel,' bald, or without ears, and 'rhon,' a spear or lance. They are excellent swimmers and ready divers, and are very bold when in the sea, swimming carelessly enough about boats; their dens or lodgments are in hollow rocks or caverns near the sea, but out of the reach of the tide. In the summer they will come out of the water to bask or sleep in the sun, on the top of large stones or shivers of rocks, and that is the opportunity our countrymen take of shooting them; if they chanced to escape, they hasten towards their proper element, flinging stones and dirt behind them as they scramble along, at the same time expressing their fears by piteous moans; but if they happen to be overtaken, they will make a vigorous defence with their feet and teeth till they are killed."

Dr. Borlase, in a letter dated October, 1763, gives the following account:—"The seals are seen in the greatest plenty on the shores of Cornwall in the months of May, June, and July. They are of different sizes; some as large as a cow, and from that downwards to a small calf. They feed on most sorts of fish which they can master, and are seen searching for their prey near the shore where the whistling fish, wrasse, and polacks resort. They are very swift in their proper depth of water, dive like a shot, and in a trice rise at fifty yards' distance, so that weaker fishes cannot avoid their tyranny except in shallow water. A person of the parish of Sennan saw not long since a seal in pursuit of a mullet (that strong and swift fish); the seal turned it to and fro in deep water as a grayhound does a hare; the mullet at last found it had no way to escape, but by running into shoal water; the seal pursued, and the former, to get more surely out of danger, threw itself on its side, by which means it darted into shoaler water than it could have swum in with the depth of its paunch and fins, and so escaped. The seal brings her young about the beginning of autumn; our fishermen have seen two sucking their dam at the same time, as she stood in the sea in a perpendicular position. Their head in swimming is always above the water, more so than that of a dog. They sleep on rocks surrounded by the sea, or on the less accessible parts of cliffs left dry by the ebb of the tide, and if disturbed by anything, take care to tumble over the rocks into the sea. They are extremely watchful, and never sleep long without moving, seldom longer than a minute; then raise their heads, and if they hear or see nothing more than ordinary, lie down again, and so on, raising their heads a little, and reclining them alternately in about a minute's time."

Common Seal (*Caloccephalus vitulinus*).

The seal-hunters in Caithness assured Pennant that their growth is so sudden, that in nine tides from their birth they will become as active as their parents. On the coast of that county immense caverns open into the sea, and run some hundred yards beneath the land. These are the resort of seals in the breeding-time, where they remain till their young are old enough to go to sea, which is in about six or seven weeks. The first of these caves, says Pennant in continuation, is near the Ord, the last near Thrumator. Their entrance is so narrow as only to admit a boat; within they are spacious and lofty. Into the mouths of these caverns the seal-hunters enter about midnight in the month of October or the beginning of November, and having rowed up as far as they can, land. Each of them being provided with a bludgeon and properly stationed, they light their torches, and make a great noise. This brings down the seals from the recesses of the cavern in a confused body with fearful shrieks and cries. The men at first are obliged to give way for fear of being overborne, but when the first crowd is passed, they kill as many as straggle behind, chiefly the young, by striking them on the nose. When the slaughter is over, they drag the seals to the boats. This is described as a most hazardous

employment; for should their torches go out, or the wind blow hard from the sea during their continuance in the cave, their lives are lost.

To the Greenlander the seal is all in all: it gives him light, food, and clothing. Mr. Farrington above quoted says of the Welsh seals, that they are taken for the sake of their skins, and for the oil their fat yields: "the former," says he, "sell for four shillings, or four and sixpence a piece, which, when dressed, are very useful in covering trunks, making waistcoats, shot-pouches, and several other conveniences." Pennant, speaking of the Caithness seals, states that those of six weeks old yield more oil than their emaciated dams: "above eight gallons have been procured from a single whelp, which sells from sixpence to ninepence per gallon; the skins from sixpence to twelve-pence." That the flesh was thought not unworthy of the tables of the great in this country is evident from the hill of fare at the 'intronization' of George Nevell, the archbishop of York; for we there find "Porpoises and Seals 12:" and, indeed, Low, in his 'Fauna Orcadensis,' states that at North Rolandshe they were taken for food, and that they made good hams. The numbers killed on the coast of Newfoundland in a good year amount to hundreds of thousands.

C. Grælandicus. This is the *Phoca Grælandica* of Müller; *P. semilunaris* of Boddaert; *P. dorsata* of Pallas; *Phoque à Croissant* of Buffon; Harp-Seal of Pennant and others; and Attersoak of Crantz.

The hair is drier, closer to the leather, and more free from wool than that of the other species; each hair flat and lustrous. A large brown oblique band, irregularly denticulated, commences nearly above the shoulders, where it joins that of the other side, and is carried along upon the sides and up to the hind legs, becoming by degrees brighter there and losing itself in the white of the belly; the posterior extremity approaches that of the other side at the root of the tail. Some small brown spots are scattered about both in the gray of the back and in the pale part of the band. The bands and spots become more and more black with age.

The females and the young have the skin of the same ground-colour, but without hands, and with unequal, well-defined, angular, brown spots, thrown as it were at hazard on different places of the upper and lower part of the body.

Cuvier, whose description this is, says that the ground-colour of the old male is gray-white, and that he is 5 feet long. The face is entirely black.

According to Crantz this species, when newly born, is quite white and woolly. In the first year it is cream-coloured; in the second, gray; in the third, painted with stripes; in the fourth, spotted; and in the fifth, wears half-moons as the sign of its maturity.

It is found in the Frozen Ocean, Greenland, Newfoundland, Iceland, the White Sea, Kamtschatka. It is rare in Britain.

Harp Seal (*Calocephalus Grælandicus*), male.

According to Fabricius this species is very numerous in the deep bays and the mouths of the rivers in Greenland. They leave the coast twice a year: at first in March, returning in May; again in June, and re-appear in September. Their young (one, rare two, at a birth) are brought forth in spring, and are suckled on the ice far from shore. They avoid the fixed ice, but live and sleep in vast herds near the floating ice-islands, among which they are sometimes seen swimming in great numbers under the guidance of one who seems to act as leader and sentinel for the whole. Their food consists of all kinds of fish, shell-fish included, but they prefer the arctic salmon. When on the feed, and one comes to the surface to breathe, he lifts his head only above the water, and quickly dives without changing his place. These seals swim in many attitudes, on their back, on their sides, as well as in the ordinary position, and occasionally whirl themselves about, as if in sport. They sleep frequently on the water, and are considered incautious, especially on the ice.

They are said to have a great dread of the toothed whales. If a grampus perceive a seal of any species hasking on floating ice, it is asserted that he does his best to upset the ice or beat the seal off with his fins, when the latter becomes an easy prey.

Crantz avers that this is a careless stupid seal, and that it is the only one which the Greenlander will venture to attack alone. He goes to hunt it in his kajak, which is in the form of a weaver's shuttle. When he perceives a seal, he endeavours to surprise it unawares with

the wind and sun in his back, that he may be neither heard nor seen. He approaches it rapidly but silently till within 4 or 6 fathoms. He then takes hold of the ear in his left hand, and with his right throws the harpoon. If it is fixed, the Greenlander throws the attached huoy overboard on the same side that the seal dives, and he dives upon the instant. The struck victim often carries the huoy under water, but, wearied and wounded, it must at last come up to breathe. The Greenlander, who is on the watch, now attacks it with his long lance till the animal is exhausted, when he releases it from its sufferings with his short lance; and then blows it up like a bladder that it may swim the easier after his kajak. This is a service of danger to the seal-hunter. If the line should be entangled, or if it should catch hold of the kajak, an oar, the hunter's hand, or his neck, as it sometimes does when the wind is high, or if the seal should make a sudden turn to the other side of the light boat, the kajak would be drawn under the waves. Then, unless the Greenlander has presence of mind and dexterity to disentangle himself, he is lost. Nor is this all the danger, for the dying seal may attack him; and if it be a female followed by young ones, she will not unfrequently turn on the pursuer, injure him, or hite a hole in his kajak and sink it.

C. discolor, Marbled Seal. This seal is a native of the coasts of France, and was at first thought to be a variety of *C. vitulinus*, or one of that species exhibiting a modification of colouring from age or sex. Baron Cuvier observes that it does not appear to be a variety of the last-named species proceeding from age and sex only; but, he adds, that its cranium does not show a sensible variation from that of the Common Seal. Dr. Hamilton states that Professor Nilsson regards it as a distinct species, giving it the name of *C. annellata*.

Marbled Seal (*Calocephalus discolor*).

A specimen of this seal was kept for some time in the Jardin des Plantes, Paris. In the same inclosure with it were two little dogs, and they amused themselves by mounting on the seal's back, harking, and even hiting it: the seal however took it in good part, and seemed pleased with them, though it would sometimes give them slight blows with its paws, as if more to encourage their play than repress their liberties. When the little dogs made their way out of the inclosure, the seal tried to follow them, not deterred by the rough and stony ground. In cold weather they all three huddled kindly and warmly together. If the dogs snatched the fish from the seal's mouth when he was feeding, he bore it patiently: but he exhibited very different conduct to another seal, who shared his mess; for they generally had a fight over their meal, the combat ending, as usual, in the defeat of the weakest.

Stenorhynchus.—Muzzle prominent; teeth composed of a long median, rounded, cylindrical tubercle, curved backwards, and separated from two other tubercles which are rather smaller, one anterior and one posterior, by deep notches. Claws very small.

Skull of *Stenorhynchus leptonyx*.

Dental Formula:—Incisors, $\frac{4}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5}$ = 32.

Two species only of this genus appear to be known, *S. leptonyx*, *S. phoca leptonyx*, De Blainv., the Small-Nailed Seal; and *S. Weddellii*, Less., the Sea-Leopard. Of the natural history of the first-named species, which is a native of the Falkland Islands and New Georgia, little or nothing seems to be known; and the accounts of the habits

Teeth of *Stenorhynchus*.

of the latter are very meagre, though there is a very accurate description by Dr. Hamilton in the 'Naturalist's Library' ('Mammalia,' vol. viii.). It has been observed in the South Shetlands.

Sea-Leopard (*Stenorhynchus leopardinus*).

Pelagius (F. Cuv.).—Muzzle enlarged and elongated at its extremity; chanfrein very much arched; upper incisors notched transversely at their extremity; lower ones simple; molars thick and conical, having before and behind small rudimentary points only.

Dental formula:—Incisors, $\frac{4}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-6} = 32$.

P. Monachus; *Phoca Monachus*, Herm.; Phoque à Ventre Blanc of the French, the Monk Seal. Hair short, smooth, and shining; dark-brown, mixed with gray on the neck and head, above; white below. No external ear. Whiskers smooth and strong. Length from 7 to 10 or 12 feet.

It is a native of the Adriatic; coasts of Sardinia.

This appears to be the *Phoca bicolor* of Shaw, and *P. leucogaster* of Péron. It is the species which afforded Buffon and F. Cuvier their interesting descriptions, and is supposed to be that whose skin was always carried everywhere (semper et ubique) by the emperor Augustus as a protection against lightning. (Suet., 'Octav. Aug.' 90.) The Romans generally seem to have considered seal-skins in the same light. Pliny, in his chapter headed 'Quæ non feriantur fulmine,' says, "Idco pavidī altiōres specus tutiōsimos putant: aut tabernacula ē pellibus belluarum, quas vitulos marinos appellant, quoniam hoc solum animal ex marinis non percutitur." ('Hist. Nat.' li. 55.)

Stenmatopus (F. Cuv.).—Head surmounted by a peculiar organ (whence the name of the genus), the nature of which is not well known

Molars with simple roots, short and wide, and striated only on their crown; muzzle narrow and obtuse.

Skull of *Stenmatopus*.

S. cristatus; *Phoca cristata*, Gmel.; *P. leonina*, Fabr. It is remarkable for possessing, about two inches from the extremity of the upper jaw, on the superior surface, a cartilaginous crest, which rises, increasing rapidly in height as it passes backwards, about 7 inches high at its posterior or vertical edge, which is separated into two planes by an intervening depression an inch deep. The superior edge is slightly convex, and the whole structure is an elongation of the septum of the nose, the true nostrils opening on each side of it by an oblong figure. This crest runs into the hood or sac-like appendage of the head. This hood is strongly muscular, with an aggregation of circular fibres round its external orifices, which are two, situated at the lower anterior part of the head. The females and young have the crest in a very rudimentary state. The length of this species is 8 feet.

Dental Formula:—Incisors, $\frac{4}{2}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5} = 30$

Teeth of *Stenmatopus*.

It is found on the coasts of Greenland and of North America down to the United States.

This species, which especially haunts the open sea, is said to visit the land in April, May, and June chiefly. They are found for the most part on large ice-islands, where they sleep without precaution: and occur in great numbers in Davis's Straits, where they are stated to make two voyages a year, in September and March. They depart to bring forth their young, and return in June very lean and exhausted. In July they proceed again to the north, where they appear to procure plenty of food, for they return in high condition in September. The Crested Seal is said to be polygamous, and to have its young on the ice. Its bite is formidable, and its voice is stated to resemble the bark and whine of a dog. When surprised by the hunter it weeps copiously. Among themselves they have fierce encounters, and inflict deep wounds in the conflicts with their claws and teeth.

It is one of the species most generally pursued, and together with the Rough Seal (*Calcephalus hispidus*), furnishes the greatest number of skins brought to Great Britain. The natives clothe their women with the skins of the young, and cover their boats and houses with the skins of the old ones. They head their hunting-spears with the teeth, and blow up the stomachs into fishing-buoys.

*Stenmatopus cristatus.*

Macrorhinus (F. Cuvier).—Differing widely from that of the other seals. Incisor teeth curved like the canines, but smaller; canines strong and well developed; molars with simple roots, larger than the crowns, which last resemble a pedunculated mamilla.

Teeth of *Macrorhinus*.Skull of *Macrorhinus*.

M. proboscideus. This is the *Phoque à Trompe* of Péron; *Phoca proboscidea*, Desm.; *Elephant Marin* of the French; *Sea-Elephant* and *Elephant-Seal* of the English; *Bottle-Nose* of Pennant; and *Miouroung* of the Australians.

Dental Formula:—Incisors, $\frac{4}{2}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5} = 30$.

This species is remarkable for the nose of the male being prolonged into a kind of proboscis, which respires violently when the animal is excited, or is elongated in the form of a tube about a foot long, when it is preparing for attack and defence. When the animal is in a stato

NAT. HIST. DIV. VOL. IV.

of repose, the nostrils are shrunk, and the proboscis flaccid, giving the face a larger appearance. The female has no proboscis.

It is found in the southern hemisphere, both in the Atlantic and Southern Oceans, between 35° and 55° S. lat., Kerguelen's Land, South Georgia, Juan Fernandez, South Shetland, and the Falklands.

Elephant Seal (*Macrorhinus proboscideus*). Males.Elephant Seal (*Macrorhinus proboscideus*). Female.

This enormous animal, which, to use the expression of Mr. Lizars, "compared with any ordinary seal three or four feet long, appears like an elephant when compared to a sheep," owes its name to its size and bulk, most probably, quite as much as to the proboscis with which the male is furnished. These seals are fond of wallowing in fresh-water swamps, and resort to lakes and rivers, whose waters they drink with apparent pleasure. They sleep both afloat and on the sands of the shore: when a flock reposes in the latter situation, some of them keep watch, and if alarmed, down they go to the sea. Those who have seen them in progress describe their gait as very singular, their motion being a kind of crawling, during which their body trembles like a great bag of jelly. At every 15 or 20 paces they halt, as if from fatigues. If any one gets before them, they stop, and if urged to motion by repeated blows, appear to suffer much, and the pupil of the eye, which is ordinarily bluish-green, becomes blood-red. Notwithstanding their unwieldiness however, they have been known to ascend low downs of 15 or 20 feet elevation, in order to reach small ponds of water. The cry of the female and the young is said to resemble the lowing of an ox, but the hoarse gurgling singular voice of the male, strengthened by the proboscis, is described as being audible to a great distance, and as wild and frightful. To obtain shelter from the heat of the sun, when lying on the shore by day, they cover themselves, by the aid of their paws, with the moist sand. They perform a sort of migration in order to avoid the extremes of heat and cold, leaving the south in the beginning of winter for more temperate climes, and retiring southward again in summer. About a month afterwards, the females bring forth one, very rarely two, according to Péron; generally two, according to Anson. The young weigh about 70 lbs, and are between four and five feet long at their birth, the male, even at that early period, being larger than the female. At this time it is stated that the mothers are all collected near the shore, surrounded by the males, who prevent them from returning to sea till the period of suckling is past, during which operation the female lies on her side. The young grow so rapidly that they are said to double their original dimensions in eight days, and at the end of the third year they have attained a length of from 18 to 25 feet and upwards, when they increase principally in fatness.

x

At this period the proboscis appears in the male. Six or seven weeks elapse before the young are conducted to sea, to familiarise them with which the whole troop abandon the shore, swimming about for three weeks or more, when they return to the coasts for the purpose of breeding. The young males stay with the females till their proboscis is developed, announcing that they have arrived at maturity. During the breeding season, bloody battles take place among the males, in which they are often severely wounded, but rarely killed, while the females calmly wait the issue, and receive the conqueror. The period of gestation is said to be nine or ten months.

They are a harmless race, never attacking man unless in defence of themselves and their young. One of Anson's sailors lost his life by exasperating a mother, in whose presence he skinned her young one. Their disposition is however gentle and affectionate; and a young one, petted by an English seaman, became so attached to his master from kind treatment for a few months, that it would come to his call, allow him to mount upon its back, and put his hands into its mouth. Their length of life is estimated at 25 or 30 years.

Their tongues, when salted, are considered savoury and wholesome, but the flesh is black, oily, and indigestible. The heart, though tough and hard, is sometimes eaten, but the liver appears to be unwholesome. The skin, though not valued for its fur, is extensively used for carriage and horse harness, on account of its thickness and strength. But the oil is the great object for which the animal is hunted.

Arctocephalus (F. Cuvier).—Head with a narrow retracted muzzle. The four intermediate incisors of the upper jaw separated in their middle by a deep notch; the lower incisors notched from before backwards. Molars with a single root, less thick than the crown, which consists of a tubercle, furnished at its base before and behind with a smaller tubercle. External ears.

Skull of *Arctocephalus*.

Dental Formula:—Incisors, $\frac{6}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{6-6}{5-5} = 36$.

Teeth of *Arctocephalus*.

A. ursinus. This is the *Otaria ursina* of Desmarest; *Phoca ursina* of Linnaeus; *Ursus marinus*, Sea-Bear, of Steller; L'Ours Marin of Buffon; the Ursine Seal of some authors.

It is the size of a large bear; girth at the shoulder 5 feet, near the tail 20 inches. Fur brown, acquiring a grayish tint at the point of the hairs in old age. External ears one inch eight lines long, conical, erect, covered with short hair, and opening by an oblong slit, which is shut in the water. Nails very slender and minute. Length $7\frac{1}{2}$ feet.

It is found on the islands on the north-west point of America, Kamtchatka, and the Kurile Islands.

When these migratory seals appear off Kamtchatka and the Kuriles early in the spring, they are in high condition, and the females are pregnant. They remain on or about the shore for two months, during which the females bring forth. They are polygamous, and live in families, every male being surrounded by a crowd of females (from 50 to 80), whom he guards with the greatest jealousy. These families, each including the young, amounting to 100 or 120, live separate, though they crowd the shore, and that to such an extent on the islands off the north-west point of America, that it is said they oblige the traveller to quit it and scale the neighbouring rocks. Both male and female are very affectionate to their young, and fierce in their defence; but the males are often tyrannically cruel to the females, which are very submissive. If one family encroaches on the station of another, a general fight is the consequence. They will not, in fact they dare not, leave their stations, for if they did they must encroach on that of some other family. Steller relates that he had been beset by these seals for six hours together, and was at last obliged to climb a precipice to get rid of the infuriated animals, at the imminent peril of his life. They have their war-notes and several other intonations. When amusing themselves on the shore, they low like a cow, chirp like a cricket after a victory, and when they are wounded cry like a whelp. They swim very swiftly, and are as great a terror to other seals as the Sea-Lion is to them.

The skin, which is very thick, is covered with hair, like that of the common seal, but a great deal longer, standing erect, and very thick. The skins of the young are highly prized for clothing; and Steller speaks of a garbment which he had made for himself from one, when he was in Behring's Island, with grateful remembrance.

Ursine Seal (*Arctocephalus ursinus*).

Platyrrhynchus (F. Cuvier).—Incisors pointed; molars with no secondary point, except at their anterior part. Cerebral region very much elevated, and the muzzle much more enlarged than in *Arctocephalus*. The complete number of teeth the same as in that genus. External ears.

Skull of *Platyrrhynchus*.

If a number of species have been confounded under the name of Sea-Bear, there have been several honoured with the name of Sea-Lions, and among them the Elephant-Seal above-noticed. M. Lesson enumerates three species of *Platyrrhynchus*:—1, *P. leoninus* (*Otaria jubata*, Desm., the Sea-Lion of Steller and Pernetty); 2, *P. molossinus*, Less. (*Otaria molossina* of the Zoology of La Coquille, Lesson, and Garnot); and 3, *P. Urania* (*Otaria Guérin* of Quoy and Gaimard). To the first of these he assigns the Antarctic islands, such as the Falklands and Tierra del Fuego, adding that Steller found it in the northern hemisphere at the Kuriles; for the second and third the Falklands are the only locality given. ('Manuel.')

Dr. Hamilton also records three species:—1, The Sea-Lion of Steller (*Phoca jubata*, Gmel.); 2, the Sea-Lion of Forster (*Leo marinus*, Buff.); and 3, the Sea-Lion of Pernetty (*Platyrrhynchus leoninus* of F. Cuvier). To the first of these he assigns the eastern shores of Kamchatka and the Kurile Islands, and as far as Matsmai, adding that they abound in Behring's Island, and that Steller also saw them in abundance on the coasts of America in July; he assigns the southern hemisphere to the second, and the Falkland Islands to the third.

P. marinus, the Sea-Lion of Forster, has a thick skin; hair reddish, yellowish, or dark brown; no fur, or short woolly hair under the long hair; a mane on the neck of the male reaching to the shoulders; head small in proportion to the body, which is everywhere equally thick-looking, as Buffon describes it, like a great cylinder, more suited for rolling than walking; ears conical, about 6 or 7 lines long, cartilage firm and stiff, but yet rather curled at the margin; upper lip overhanging the lower, both furnished with long coarse black whiskers, which become white with age. Length from 10 to 14 feet; the females shorter and more slender.

Sea Lion of Forster (*Leo marinus*).

Captain Cook states that it is not at all perilous to go among these animals, for they either fled or stood still. The only danger was in going between them and the sea; for if they took fright at anything they would come down in such numbers that the person in the way would be run over. When he and his party came suddenly upon them, or waked them out of their sleep, they would raise up their heads, snort and snarl, and look fierce, as if they meant to devour the intruder; but when the men advanced the Sea-Lions always ran away. He states that the male is surrounded by from twenty to thirty females, and that he is very attentive to keep them all to himself, heating off every male that attempts to come to his flock. Others again had a less number, some no more than one or two; and here and there was seen one lying growling in a retired place, suffering neither males nor females to come near him. These he judged to be old and superannuated.

Forster relates that the rocks along the shore in New Year's Harbour were covered with multitudes of these Sea-Lions. He says that they were often seen to seize each other with an indescribable degree of rage, and that many of them had deep gashes on their backs, which they had received in the wars. The younger active Sea-Lions, with all the females and the cubs, lay together. When undisturbed, they were often observed caressing each other in the most tender manner, and their snouts often met together as if they were kissing. The same author states that they come on shore on those uninhabited spots to breed, and that they do not feed during their stay on land, which sometimes lasts for several weeks; they then grow lean, and swallow a considerable quantity of stones to distend the stomach. He adds that the stomachs of many of them were found entirely empty, and those of others were filled with ten or twelve round heavy stones, each of the size of two fists.

Halichoerus (Nilsson).—Head very flat; muzzle very deep. Molar teeth of the upper jaw consisting of a simple point without tubercles; those of the lower jaw with a rudimentary tubercle before and behind the principal point. The number of incisors given in Mr. Bell's vignette

('British Quadrupeds') is six in the upper jaw, and the same number apparently belong to the lower. No external ear.

Dental Formula:—Incisors, $\frac{6}{6}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5} = 36$.

H. griseus is the Gray Seal. This is the *Phoca Gryphus* of Fabricius; *Phoca barbata* of Fleming; the Long-Bodied Seal of Parsons. Its coat is white and silky, the hair two inches long, passing into a grayish lead-colour on the back. Wool under the hair short and white. Length from 7 to 8 feet. It is found in the seas of the North of Europe, Baltic, coasts of Pomerania, and the south coast of Ireland.

Professor Nilsson states that in the Baltic it is solitary; but Mr. Ball says that on the south coast of Ireland (Cork and Waterford) he has often seen this seal in small parties, and he learned from the fishermen that they had noticed as many as thirteen congregated on a rock. The same author has heard them in a cave baying like large dogs.

The comparatively small cerebral development and great expanse of the bones of the face, compared with that of the cranium, indicate a form inclining from the true Seals to the Walrus. All that is known of the habits of the Gray Seal tends to the conclusion that it is less susceptible of domestication and less intelligent than the other Seals.

The group of animals to which the Walrus belongs differs in many points from the Seals. Though the general structure of the skeleton resembles that of the Seals, there is a striking difference in the cranium and the teeth. In the adult lower jaw there are neither incisors nor canines, and the lower jaw itself is compressed anteriorly so as to fit between the two enormous tusks (canines) of the upper jaw, which are sometimes two feet long and proportionably thick, and directed downwards. The great alveoli, or sockets for containing these formidable teeth, produce the characteristic form of the skull of the Walrus, and make the anterior part of the upper jaw present an immense convex muzzle, the nostrils having an upward direction, and not terminating at the snout. All the molars are cylindrical, short, and truncated obliquely. Between the two canines are two incisors similar to the molars, but Cuvier observes that the greater number of authors have not considered them as incisors, although they are implanted in the intermaxillary bone; and between them, besides, in young individuals, are two small and pointed teeth.

Skull and anterior portion of jaw of Walrus. Skull in profile. Anterior portion of lower jaw seen from above.

The stomach and the intestines are nearly the same as those of the Seals. ('Règne Animal.')

Mr. MacGillivray found in the cranium of a young Walrus, in the Museum of the Royal College of Surgeons in Edinburgh, three incisors on each side of the upper jaw; the first or inner very small, the second a little larger, and the third or outer both disproportionately large, being equal to the largest molars. There were two very small incisors on each side in the lower jaw. The incisors are obliterated in adults.

There is a general resemblance between the organisation of the Walrus and that of the Seal; but the development of the brain is not so great in the former as it is in the latter, and the Walrus appears not to be gifted with so high a degree of intelligence as the Seal, though it is far from stupid.

Trichechus is the generic name for the Walrus. It has the following characters:—Head well proportioned, round, obtuse, eyes small and brilliant, upper lip remarkably thick, covered with pellucid whiskers or hristles as large as a straw. Two very large canines (in the upper jaw only) directed downwards. Nostrils large, rounded, placed on the upper part of the snout. No external ears.

In adults, according to Mr. MacGillivray, from whom the formula is taken, the incisors are obliterated, except the lateral pair of the upper jaw; the fifth grinder also disappears, and sometimes the fourth.

T. Rosmarus, the Walrus, Sea-Horse, Morse, and Sea-Cow of the British; Morse, Vache Marine, Cheval Marin, and Bête à la grande Dent of the French. It is the Horse-Whale or Whale-Horse (Hval-Roe) of Oether the Norwegian, who, about the year 890, made his report of it to Alfred, as having in its teeth bones of great price and excellency, some of which he brought to the king on his return from his voyage beyond Norway; also Rosmar of the Norwegians; Morse or Morsh of the Russians; and Morsk of the Laplanders.

The neck is short, body very bulky, broadest round the chest, and diminishing towards the very short tail. Hair close; colour, according to Fabricius, varying with age, the young being black, then becoming brown, and gradually paler and paler, till the animal in old age becomes white. Limbs very short. Inside of the flippers defended by a horny kind of coat, or callous, produced, in all probability, by climbing over ice and rocks. Length from 10 to 15 or even 20 feet in the case of the largest hulla. Girth 8 or 10 feet, and upwards. Length of the tusks when cut out of the skull generally from 15 to 20 inches, sometimes 30 inches, and their weight from 5 to 10 lbs.

It is a native of the Icy Sea and Northern Ocean, Spitzbergen, Nova Zembla, Hudson's Bay, Gulf of St. Lawrence, &c. Rare on the north coasts of Britain.

Dental Formula:—Incisors, $\frac{6}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5} = 31$.

Molars and Tusk of Walrus. (F. Cuvier.)

The contents of the stomach of a walrus noticed by Sir E. Home, consisted entirely of the *Fucus digitatus*, and Schreber affirms that it is not at all carnivorous. Fabricius and Crantz are of opinion that walrus feed on shell-fish and marine vegetables which adhere to the bottom of the sea, and that one of the uses of their tusks is to root up their food from the spot to which it is fixed. Buffon states that they live on fish, like the seals, especially on herrings and the smaller fishes. The Rev. Dr. Scoresby found in their stomachs shrimps, a kind of crawfish, and the remains of young seals. Upon the whole of this evidence, the conclusion would be that the Walrus is omnivorous. The molar teeth certainly appear to be more adapted for bruising the long branches of sea-weeds (*Fucus digitatus*), which Mr. Fisher informed Sir Everard Home filled the stomach of the animal that he examined, than for dividing fish or flesh; and the probability is, that though the Walrus does not abstain entirely from carnivorous habits, marine plants form the bulk of its food. The tusks must be a great help as ice-hooks or grapplings in assisting the animal to climb upon the ice from the sea. Though they swim so rapidly, that, according to some authority, it is as difficult to follow them with boats in rowing as the whale itself, their progress on land is awkward and

tedious. Martens compares their gait to a kind of jerking, probably like that of the Seals, but he says they can make considerable springs, and can advance pretty rapidly with the help of their teeth.

They appear to be monogamous, and consequently are exempt from the terrible combats which are the result of the jealousies of the polygamous seals. The female is said to bring forth her young, one only at a birth, either on shore or on the ice. When born the young is about the size of a year-old pig. Till taught by fatal experience, the Walrus seems to be a fearless animal, and to be undisturbed by the face of man; but he soon learns his lesson of distrust. Still the animal is not incautious, for Captain Cook never found the whole herd asleep, some being always on the watch. These, on the approach of the boat, would rouse those next to them, and the alarm being thus gradually communicated the whole herd would presently awake. In the North Pacific Ocean he got entangled with the edge of the ice, on which lay innumerable sea-horses. They were lying in herds of hundreds, huddling one over the other like swine, and were roaring and braying very loud; and indeed in the night or in foggy weather they gave the voyagers notice of the vicinity of the ice before it could be seen. They were seldom in a hurry to get away till after they had been once fired at, when they would tumble over each other into the sea in the utmost confusion. Vast numbers of them would follow the boats and come close up to them, but the flash in the pan of a musket sent them down instantly. Before they were put upon their guard by persecution as many as 300 or 400 were killed at a time. That they are not without courage or sympathy for their wounded companions there is ample testimony. When Martens wounded one others speedily surrounded the boat, and whilst some endeavoured to pierce it with their tusks, others raised themselves out of the water and endeavoured to hoard her. Captain Phipps, afterwards Lord Mulgrave, relates that when near a low flat island opposite Waygat's Straits, in 1773, two of the officers went in a boat in pursuit of sea-horses. They fired at one and wounded it. The animal was alone when it was wounded, but diving into the sea it brought back a number of others. They made a united attack upon the boat, wrested an oar from one of the men, and were with difficulty prevented from staving or oversetting her; but a boat from the Carcase joining that from the Racehorse, they dispersed. Captain Phipps adds that one of that ship's boats had before been attacked in the same manner off Moffen Island. Sir Edward Parry encountered about 200 in Fox's Channel, lying piled as usual over each other on the loose drift-ice. A boat's crew from both the *Fury* and the *Hecla* went to attack them, but they made a desperate resistance, some with their clubs mounted on their backs: and one of them tore the planks of a boat in two or three places. Their parental affection is great. The boats from the *Resolution* and *Discovery* were hoisted out to attack sea-horses in Behring's Straits. Captain Cook states that on the approach of the boats to the ice all the walrus took their clubs under their fins, and endeavoured to escape with them into the sea. Several whose young were killed and wounded, and were left floating on the surface, rose again and carried them down, sometimes just as the people were going to take them into the boat; and they might be traced bearing them to a great distance through the water, which was coloured with their blood. They were afterwards observed bringing them up at times above the surface, as if for air, and again diving under it with a dreadful bellowing. The female in particular whose young had been destroyed and taken into the boat, became so enraged that she attacked the cutter, and struck her tusks though the bottom of it.

That the Walrus is capable of a degree of domestication, in youth at least, appears from the testimony published by John De Laet, who gives no bad wood-cut of a full-grown animal and a young one, and relates that "Elius Everhardus Vorstius, M.D. et Professor," saw a cub ten weeks old, according to those who had brought it from Nova Zembla, about the size of a mastiff (*canis Britannici majoris*), which followed its master (*magno nisu et grunnitu*) for its food, consisting of a mash of oatmeal or millet (*pulmentarium ex avena miliove*), which it ate slowly (*et suctu magis quam deglutendo*). The tusks had not yet projected from the mouth, but tubercles were perceived in the upper lip. There were two heads of adults, and those who showed them said that with the tusks they ascended rocks and suspended themselves from them, and that their food consisted of the long and great leaves of some plant growing from the bottom of the sea. "Vidi hñdem," adds Vorstius, "penem ejusdem animalis osseum, rotundum, cubitum et amplius longum, crassum, ponderosum, ac solidum, in fine prope glandem longe crassiorem ac rotundiorẽ. Hujus pulvere ad calculum pellendum Muscovite utuntur."

The flesh of the Walrus is highly valued by the inhabitants of the Arctic Regions, nor does it seem to have come amiss to our northern voyagers. Cook, after stating that he procured some, being in want of fresh provision, observes that till then they had thought them Sea-Cows (*Manatus* probably), so that they were not a little disappointed, especially some of the seamen, who, from the rarity of the thing, had been feasting their eyes for some days. Nor would they, continues Cook, have been disappointed now, nor know the difference, if they had not had some on board who had been in Greenland, and declared what animals these were, and that no one ate them. Notwithstanding this however, Cook and his crew lived upon them as long as they lasted, and there were few on board who did not prefer

them to salt meat. Sir Edward Parry remarks that the flesh was found tolerably good, affording a variety amid the ordinary sea-fare. But the tusks, the skin, and the oil, are the parts and products for which the Walrus is more particularly hunted. The ivory of the first is highly esteemed, and is used in Europe for artificial teeth. The skins make excellent carriage-braces, and are very useful about shipping, making very good wheel-ropes, &c. The oil is more valued than that of the whale, though not more than 20 or 30 gallons are afforded by one animal.

It is not at all improbable that some of the stories of Mermen and Mermaids have taken their origin from those who have seen walruses or seals with their heads lifted out of the water. The former especially, in such a situation, bear a strong resemblance to the human head before their tusks have grown, and when seen at some distance.

Walrus (*Trichechus Rosmarus*). (Bell.)

The following is Dr. J. E. Gray's arrangement of the family Phocidae in his 'Catalogue of Specimens of Mammalia in the British Museum':—

a. *Stenorynchina*.

1. *Leptonyx Weddellii*, the Sea-Leopard.

b. *Phocina*.

2. *Phoca vitulina*, the Seal.
3. *P. Grælandica*, the Atak or Harp-Seal.

c. *Trichecina*.

4. *Halichærus gryphus*, the Gray Seal.
5. *Trichechus Rosmarus*, the Morse or Walrus.

d. *Cystophorina*.

6. *Morunga proboscidea*, the Sea-Elephant.

e. *Arctocephalina*.

7. *Otaria jubata*, the Sea-Lion.
8. *Arctocephalus ursinus*, the Sea-Bear.

PHENISO'MA. [TANAGRINÆ.]

PHENIX, a genus of Palma, which has been so named from one of its species, the Date-Tree, having been called so by the Greeks: this name is thought by some to be derived from Phœnicia, because dates were procured from thence. The genus is common in India and in the north of Africa, and one of the species grows in Arabia, the lower parts of Persia, and along the Euphrates to Syria. The genus is characterized by having flowers dioecious, sessile, in a branched spadix, supported by a simple spathe; calyx urceolate, 3-toothed; corolla 3-petalled; stamens 3 or 6; filaments very short, almost wanting; anthers linear; (female) calyx urceolate, 3-toothed; corolla 3-petalled, with the petals convolute; pistil with three ovaries, distinct from each other, of which one only ripens; stigmas hooked; drupe 1-seeded; seeds marked on one side with a longitudinal furrow; albumen reticulate; embryo in the back of the seed; palms with stems of a moderate height and ringed, or marked with the seams of the fallen leaves; fronds or leaves pinnate; pinnæ or leaflets linear, with the spadix bursting among the leaves, surrounded with an almost woody 2-edged sheath; flowers yellowish-white; fruit soft, edible, of a reddish-yellow colour.

P. dactylifera, the Date-Tree, or Date-Palm, is one of the best known and probably the earliest known of the palms, and though belonging to a family which abounds and flourishes most in tropical regions, itself attains perfection only in comparatively high latitudes. It is no doubt the species to which the name *Palma* was originally applied, as we may infer from its being common in Syria, Arabia, the

lower parts of Persia, as well as Egypt and the north of Africa, whence it has been introduced into the south of Europe, and cultivated in a few places, not only as a curiosity, but on account of its leaves, which are sold twice in the year, in spring for Palm Sunday, and in September for the Jewish Passover; and also, from the name not being applicable to the other species known to the ancients, as it is considered that the bunches of dates were likened to the fingers of the hand, as appears from the present specific name, *dactylifera*, from the Greek δάκτυλος, a finger. It is the Palm-Tree of Scripture, and was emblematic of Judæa, as we see in coins with the inscription of *Judæa capta*. It is found in oases in the desert, and round Palmrya, which is supposed to have been named from its presence. This appears indeed to be only a translation of the Oriental name, which is Tadmor, supposed to be a corruption of Tamar (from 'Tamar,' a Date), a city built in the desert by Solomon. The Date-Tree is therefore a subject of classical as well as of scriptural interest, besides its fruit forming a large portion of the food of a great part of the Arab race, and also a considerable article of commerce.

The Date-Palm being dioecious, that is, the stamens and pistils, or the male and female parts being not only in different flowers, but even on different plants, the crops entirely fail, or the fruit is worthless and unfit for food, if fertilisation is in any way prevented. To ensure this, the Arabs have long been in the habit of hanging the clusters of male flowers on the trees which bear only female ones, and therefore the Date-Tree is one of those which led to a knowledge of the sexes of plants.

The extensive importance of the Date-Tree is, says Dr. Clarke, one of the most curious subjects to which a traveller can direct his attention. A considerable part of the inhabitants of Egypt, Arabia, and Persia subsist almost entirely on its fruit. They make a conserve of it with sugar, and even grind the hard stones in their hand-mills for their camels. In Barbary they form handsome heads for paternosters of these stones. From the leaves they make couches, baskets, hags, mats, hrushes, and fly-traps; the trunk is split and used in small buildings, also for fences to gardens, and the stalks of the leaves for making cages for their poultry. The threads of the web-like integument at the bases of the leaves are twisted into ropes, which are employed in rigging small vessels. The sap is obtained by cutting off the head of the palm and scooping out a hollow in the top of the stem, where, in ascending, it lodges itself. Three or four quarts of sap may be obtained daily from a single palm, for ten days or a fortnight, after which the quantity lessens, until, at the end of six weeks or two months, the stem is exhausted, becomes dry, and is used for firewood. This liquor is sweetish when first collected, and may be drunk as a mild beverage, but fermentation soon takes place, and a spirit is produced, which is distilled, and forms one of the kinds of aruk (arrack), or spirit of eastern countries. Such being the importance and multiplied uses of the Date-Tree, it is not surprising that in an arid and barren country it should form so prominent a subject of allusion and description in the works of Arab authors, and that it should be said to have 300 names in their language. Many of these are however applied to different parts of the plant, as well as to these at different ages.

P. sylvestris is a species common in the arid parts of India, and there commonly called Khujjoor by the natives, and the Date-Tree by Europeans, which it resembles in appearance. In its parts of fructification it is like the following species, but differs in growing to be a tree, with a tall pretty thick trunk and large yellowish or reddish fruit. It yields Tarri, or palm wine, commonly called Toddy. The mode of obtaining this is by removing the lower leaves and their sheaths, and cutting a notch into the centre of the tree near the top, from which the liquor issues, and is conducted by a small channel, made by a hit of the palmyra-tree leaf into a pot suspended to receive it. This juice is either drank fresh from the tree, or boiled down into sugar, or fermented for distillation, when it gives out a large portion of spirit, often called Paria Aruk. Mats and baskets are made of the leaves.

Sugar has always been made from this species, and accounts of it have been given by Drs. Roxburgh and Buchanan Hamilton. Date-sugar is not so much esteemed in India as that of the cane, and sells for about one-fourth less. It has sometimes been imported in considerable quantities into this country, but is not distinguished from the cane sugar. Dr. Roxburgh calculated, 40 years ago, that about 100,000 lbs. were made annually in all Bengal. At the age of 7 or 10 years, when the trunk of the tree is about 4 feet high, it begins to yield juice, and continues productive for 20 or 25 years. The juice is extracted during the months of November, December, January, and February, during which period each tree is reckoned to yield from 120 to 240 pints of juice, averaging 180 pints. Every 12 pints, or pounds, is boiled down to one of goor, or jagari, and four of goor yield one of good sugar in powder, so that the average produce of each tree is about 7 or 8 lbs. of sugar annually.

P. furinifera is a dwarf species of this genus, which is a native of dry ground or sandy hills, not far from the sea on the Coromandel Coast. It flowers in January and February, and the fruit ripens in May. The leaflets are wrought into mats for sleeping on, and the common petioles are split into three or four, and are used for making baskets. The small trunk is generally about 15 or 18 inches long,

and about 6 inches in diameter. It incloses in its substance a large quantity of farinaceous matter, which the natives use for food in times of scarcity. To procure this meal, the small trunk is split into six or eight pieces, and dried and beaten in wooden mortars till the farinaceous part is detached from the fibres; it is then sifted, to separate them; the meal is then fit for use. The only further preparation which this meal undergoes is the boiling it into a thick gruel, or canji. It seems to possess less nourishment than common sago, which is obtained in a similar manner from another palm, and is less palatable when boiled, but it has saved many lives in times of scarcity.

PHŒTHORNIS. [TROCHILIDÆ.]

PHOLADARIA, Lamarck's name for a family of Conchiferous Mollusca, consisting of the genera *Pholas* and *Gastrochena*.

PHOLADIDÆ, a family of Conchiferous Mollusca, embracing the genera *Pholas*, *Pholadites*, *Xylophaga*, and *Teredo*. It has the following characters:—Shell gaping at both ends, thin, white, brittle, and exceedingly hard; armed in front with rasp-like imbrications; without bioge or ligament, but often strengthened externally by accessory valves; hinge-plate reflected over the umbones, and a long curved muscular process beneath each; anterior muscular impression on the hinge-plate; pallial sinus very deep. Animal eluh-shaped or worm-like; foot short and truncated; mantle closed in front, except the pedal orifice; siphons large, elongated, united nearly to their ends; orifices fringed; gills narrow, prolonged into the exhalant siphon, attached throughout, closing the branchial chamber; palpi long; anterior shell-muscle acting as a substitute for a ligament.

The *Pholadidæ* perforate all substances that are softer than their own valves. The burrows of *Pholas* are vertical, quite symmetrical, and seldom in contact. The Ship-Worms (*Teredines*) also make symmetrical perforations, and, however tortuous and crowded, never invade each other, guided either by the sense of hearing or by the yielding of the wood. The burrow has frequently a calcareous lining, within which the shell remains free. *Teredina* cements its valves to this tube when full grown; the opening of the burrow, at first very minute, may become enlarged progressively by the friction of the siphons, which are furnished with a rough epithelium, but it usually widens with much more rapidity by the wasting of the surface. As the timber decomposes the shelly tubes of the *Teredo* project; and as the beach wears away the *Pholas* burrows deeper. (Woodward.)

Pholas.—Animal more or less thick and elongated, rarely shortened; mantle reflected on the dorsal part, for the purpose of tying together

Shell of *Pholas dactylus*.

- 1, Accessory valves: a, anterior pair; b, central piece; c, posterior piece.
- 2, Exterior view of shell, side view.
- 3, Internal view of valve: a, spoon-shaped process.

the valves and the accessory pieces; anterior aperture rather small; foot short, oblong, and flattened; siphons often elongated and united into a single very extensible and dilatable tube; mouth small, with very small labial appendages; branchiæ elongated, narrow, slightly unequal on each side, united on the same line nearly throughout their length, and prolonged even into the siphon.

Shell delicate, milky white, rather transparent, covered sometimes with a thin epidermis, oval, elongated, inequilateral, gaping posteriorly, and especially at the antero-inferior part; umbones hidden by a callosity; hinge toothless, ligament doubtful; a flat, recurved, spoon-shaped process enlarged at its extremity, elevating itself within each valve below the umbo; muscular impressions very distinct, the posterior one large, oblong, elongated, always very visible, the anterior one small, rounded, but little distinct, both more or less approximated to the edge of the shell, particularly the anterior edge, and joined by a pallial impression, which is long, narrow, and deeply excavated backwards.

Many accessory pieces or none (!); sometimes a calcareous tube enveloping all the parts, but leaving an aperture backwards. (Rang.)

M. Rang remarks that there are some species of *Pholades* which seem to lead to *Teredo*. These shells inhabit stones, madrepores, wood, and sometimes mud or sand (vase). When the reflux of the sea leaves them, and the animals are disquieted, they eject through their siphon to a considerable distance the water contained in their mantle, and which bathes the gills. ('Manuel de l'Histoire Naturelle des Mollusques.')

Dr. Leach divided the Linnæan *Pholades* into several genera, but as his distinctions consisted principally in the number of the accessory valves, Mr. G. B. Sowerby has not adopted any of his genera; they may, according to Mr. Sowerby's opinion, appear to be calculated for divisions of the genus, but are not sufficiently strong for generic distinctions. Mr. Sowerby admits indeed that some species (*Pholas clavata*, Lam., for instance) may, on account of their being closed at both ends, be distinguished generically, because this circumstance implies a difference in the habits of the animals by which they are formed: this character therefore, he remarks, has been seized by Dr. Leach, and upon it the doctor founded his genus *Marteria*, an example which Mr. Sowerby says he should have been induced to have followed had he been convinced of its necessity.

M. Ch. des Moulins has formed a genus of *Pholades* which he calls *Jouannetia*.

M. Rang speaks highly of the discovery of this genus by M. des Moulins, and having studied it with that naturalist, he pronounces it to be very distinct from the *Pholades*, and its place to be clearly fixed between them and the *Teredines*, to which it leads so naturally by its valves. *Jouannetia*, he observes, has no enveloping calcareous tube, as sometimes happens to the *Pholades*, &c.; and though only one species is yet known (*Jouannetia semicaudata*, fossil, from the faluns of Méridien, in the interior of madrepores, &c.), he does not think that a similar tube ever exists, if the amplitude and disposition of the scutcheon, which appears to him to take its place, is a generic character.

Mr. Swainson makes the *Pholida* the first family of his tribe *Macrotrachia*, and thus characterises that family:—"Shell bivalve, sedentary, generally perforating, opening at one or both ends; the valves often prolonged into a shelly tube, sometimes of great length, representing the *Tubulibranchia*."

Under this family he assembles several forms, and makes it consist of the following genera and sub-genera:—

1. *Aspergillum*; including the sub-genera *Aspergillum*, *Clavagella*, and *Fistulana*.
2. *Gastrochina* (*Gastrochena*), Lam.
3. *Pholadomya*, Sow.

Pholas dactylus (animal and shell); the lower or ventral parts are presented to the spectator.

a, mantle; b, foot; c, tube; d, shell.

Animal of a *Pholas* (Jolan—*Pholas clavata* (1), Lam.), from Adanson—side view.

a, tube; b, mantle; c, foot.

4. *Pholas*, Linn., with the sub-genera *Pholas*, Linn.; *Pholidæa*, Leach; *Martesia*, Leach; and *Xylophaga*, Sow.

5. *Teredo*, Linn., with the sub-genera *Teredo*, Linn., and *Teredina*. ('Malacology,' 1840.)

The geographical distribution of the *Pholades* is very wide, and their habit of boring hard substances, such as indurated mud or clay, wood, and stone, renders them, as well as other terebrating testaceans, an object of anxious interest to those who construct submarine works. The Breakwater at Plymouth was soon attacked by the *Pholades*, and in Dr. Goodall's fine collection, which has since been sold, there was a specimen from the Breakwater perforated by these testaceans. Wood is also attacked by this genus, and submarine piles are consequently exposed to their ravages. To counteract their operations in the latter substance, nails closely driven into the submerged part of the timber, as in the pile which support the pier at Southampton, seem to be the best safeguard hitherto applied. When unmolested, the young *Pholades* excavate burrows in the substance which chance has opposed to them, or to which choice—for it is not improbable that the young shell-fish may in some cases have the faculty of making the selection of the material in which it is to pass the whole of its life—has directed it.

The accompanying cuts will convey some notion of their ravages upon the substances which they penetrate:—

Pholas striatus in wood.

A block of stone perforated by *Pholas dactylus*.

Pholas (Xylophaga) dorsalis in wood.

The mode in which the operation of boring is conducted has been frequently discussed. From the observations of M. Cailliaud it would

appear that the valves are quite equal to the task of boring limestone. [LITHOPHAGIDÆ; CLAVAGELLA; GASTROCHÆNA.] Mr. G. B. Sowerby, in his description of *Pholas acuminata*, found by Mr. Cuming at Panama in limestone at low water, notices one specimen in that gentleman's collection as demonstrating a fact of considerable importance to geologists: it is in argillaceous limestone, very much resembling lias, and, in forming the cavities in which it resides, it has, by such chemical processes as in Mr. Sowerby's opinion frequently takes place, absorbed a much greater quantity of the rock than could be retained or converted; this is again deposited at the upper part of the cavity, and thus the rock is recomposed. ('Zool. Proc.,' 1834.)

Pholas has been found at depths varying from the surface to 17 fathoms, and *Xylophaga* from the surface to 45 fathoms.

The species are numerous, and some are very abundant on our own coasts. "Of these," says Mr. G. B. Sowerby, "*Pholas crispata*, *P. dactylus*, *P. candida*, and *P. parva*, are the most common; several others are described by Turton in his 'British Bivalves,' of which we are quite convinced the *P. lamellata* is only the young of *P. papyracea*: we are not acquainted with his *P. tuberculata*. Much confusion appears to prevail in regard to several very distinct species: among these we believe the *P. papyracea* of Turton is the *P. striata* of Montagu; the *P. clavata* of Lamarck is the *P. striata* of Linnaeus, but not of Montagu."* The number of living species of *Pholas* noted by M. Deshayes in his Tables is 15, and of these one, *P. candida*, is recorded as living and fossil. Woodward, in his 'Manual of the Mollusca,' gives 25 recent species of *Pholas* and 25 fossil. Forbes and Hanley give the following as British species:—*P. dactylus*, *P. parva*, *P. crispata*, *P. candida*, *Xylophaga dorsalis*, *Pholadidea papyracea*.

The following cuts, with those previously given, will show the variety of form put on by the shells of this genus:—

Pholadidea dorsalis.

a, enlarged view of interior; b, dorsal view, natural size; c, ventral view, natural size.

This species, which is found in cylindrical cavities eaten (!) in wood (see cut in previous column), bears some resemblance to *Teredo*, but is without the shelly tube, nor has it the posterior hiatus.

Pholas (Pholadidea) papyracea.

a, side view; b, dorsal view; c, cup-shaped membrane.

Teredo is the name given by Linnæus to a genus of Testaceous Molluscs, highly interesting on account of the ravages which one of the species commits upon submerged wood.

Linnæus, in the twelfth edition of the 'Systema Naturæ,' placed the genus among his *Vermes Testacea*, between *Serpula* and *Sabella*.

Cuvier, in his last edition of the 'Règne Animal,' makes *Teredo* one of the genera of his *Enfermée*, the fifth family of his *Acephalous Testaceans*, arranging the genus between *Pholas* and *Fistulana*.

The following are its characters:—

Animal very much elongated, vermiform, with a very delicate mantle, open in front and at its lower part for the passage of a mammilliform foot; tubes separated, very short, especially that for the dejections; mouth small; labial appendages short; anus situated at the extremity of a small tube floating in the cavity of the mantle; branchiæ rihand-like, united on the same line throughout their length, and a little prolonged in the siphon; a muscular ring at the point of junction of the mantle and the tubes, in which is implanted a pair of pediculated corneo-calcareous appendages or palmules, playing laterally one against the other.

Shell rather thick, very short, annular, equally open before and behind; equivalve, inequilateral, angular, with triangular valves, trenchant in front, and only touching each other by the two opposite edges; no hinge; an elongated, nearly straight, subbiliform, spoon-shaped process; a single slightly-marked muscular impression.

* Zoologists sometimes make the word 'Pholas' masculine, sometimes feminine. Linnæus makes it masculine, and so it should be considered.

Tube cylindrical, straight or flexuous, closed with age at the buccal extremity, so as to envelop the animal and its shell; always open at the other, and lining the cavity into which the animal has introduced itself.

Such is M. Rang's definition of *Teredo*, excluding *T. gigantea* (*Septaria*), of which he gives the following definition, observing that it closely approximates to the *Teredines* and *Fistulane*:—

Animal unknown. Shell unknown. Tube calcareous, thick, solid, in the shape of a very elongated cone, and irregularly flexuous, furnished internally with small incomplete annuliform septa; terminated at one of its extremities by a convexity, and at the other by two slender and separated tubes.

The number of species of *Teredo* (exclusive of *Septaria*) recorded by Lamarck in the 'Animaux sans Vertèbres' (1818) were two, *T. navalis* and *T. palmulatus*; of the latter, Lamarck, who had seen neither its tube nor its shell, says that it probably only differs from *T. navalis* in its greater size, its longer palmules having been more easily observed.

Messrs. Forbes and Hanley record three as true British species—*T. Norragica*, *T. navalis*, *T. Megotaca*; and three as doubtful—*T. bipinnata*, *T. malleolus*, and *T. palmulata*. Woodward gives 14 as the number of recent species, and 25 fossil.

For our early knowledge of the nature and structure of the *Teredo* we are indebted to three investigators, Pierre Massuet, Jean Roussel, and Godfrey Sellius. The work of the last-named author was a very remarkable production, and he was the first to recognise the molluscan nature of this animal. The study of these animals was neglected in this country till it was taken up by Sir Everard Home. He wrote a paper entitled 'Observations on the Shell of the Sea-Worm found on the Coast of Sumatra, proving it to belong to a Species of *Teredo*, with an account of the Anatomy of the *Teredo Navalis*.' Sir Everard remarks that the internal structure and economy of *Teredines* were so little known, and so much of what was said of them by Sellius was so vague, that it became necessary to acquire an accurate knowledge of the common *Teredo navalis*, before any adequate idea could be formed of the new species, which he names *Teredo gigantea*.

On examining the shell of *T. navalis* while in the wood, Sir Everard found its external orifice very small, just large enough, in fact, to give a passage to the two small tubes. The greatest thickness observed was 1/24th of an inch. The canal in the wood at its termination, and for an inch in length, was not lined with shell, but smeared over with a dirty green-coloured mucus, which was also spread upon the last-formed portion of shell. According to Mr. Hatchett's analysis, the shell of *T. navalis* was perfectly similar to that of *T. gigantea*, being devoid of phosphate of lime, and composed of 97 parts of carbonate of lime and 3 parts of animal matter.

While the animal was in the shell alive and undisturbed, what is termed the head was in contact with the end of the canal in the wood; but on laying the head bare, it was drawn in for an inch into the shell. The body of the animal filled the area of the shell completely, but appeared much smaller when taken out, in consequence of the sea-water which it contained having escaped. The largest of the worms examined, which were of different lengths, measured 8 inches. Many of them were alive 24 hours after being removed from their shell, and in these the heart was seen to palpitate. The blood in the vessels going to the head was red, as also the parts near the liver; but this colour disappeared soon after death.

The head of the worm was inclosed between the two concave boring shells, so that what Sir Everard calls this face was the only part exposed. These shells were united together on what is termed the back part of the head by a very strong digastric muscle, having a middle tendon from which the fibres go off in a somewhat radiated direction, partly for insertion into the concave surface of each shell, and partly into a long semicircular process projecting from the posterior part of each shell. The two inclose the œsophagus and other parts surrounding it. The double muscle was inclosed in a smooth shining fascia. When first exposed it was of a bright red.

On the opposite side of the head the shells were united by a ligament from which they were readily separated; at this part were two small tooth-like processes, one from the narrow edge of each shell, where they were joined together.

From the middle of the exposed part of the head projected a kind of proboscis; which in the living animal had a vermicular motion: its extremity was covered by a cuticle not unlike the cornea of the eye. On removing this, the cavity immediately beneath it was found to contain a hard brown-coloured gelatinous substance, like a Florence flask, with the large end uppermost in form. Sir Everard remarks that as this proboscis has no orifice, there is reason to believe that it adheres to the wood, acting as a centre-bit, while the animal is at work with the shell, and thus the canal in the wood is perfectly cylindrical. The mouth was nearly concealed by the projection of the proboscis, but, when exposed, presented a very distinct round orifice between the proboscis and the large digastric muscle.

"The body of the worm," proceeds Sir Everard, "is inclosed in one general covering, extending from the base of the boring shell, with which it is firmly connected to the root of the two small tubes, which appear out of the wood. It terminates in a small double fold forming a cup, on the inside of which are fixed the long small stems

of two opercula, which become broad and flat towards their other extremity. These, when brought together, shut up the shell, and inclose the two contracted tubes within it: not one operculum corresponding to each tube, but in a transverse direction. In the *T. gigantea*, the opercula are similarly situated, each shutting up one-half of the bifurcation. At the base of this cup the general covering is thick and ligamentous, for about one-fourth of an inch in length, where the stems of the opercula are connected with it; and at one spot of this thickened part there is an adhesion to the cylindrical shell, which is the only part of the animal connected with it. There is a depression in the shell pointing out this spot. The double fold of the outer covering, that forms the cup, contains the sphincter muscle, which closes the orifice by bringing the opercula together. The general covering is composed of two membranes, the outer the strongest, and made up of circular fibres, the inner much finer, having no fibrous structure. On the back of the animal, this covering is firmly connected to the parts underneath, and is there strongest. On the belly it forms a cavity, and is thinner. It is everywhere sufficiently transparent to show the different viscera through it."

In this paper Sir E. Home examines in detail the anatomy of these creatures, and left little further to be known on that point.

With regard to *T. gigantea*, he observes that, when arrived at its full growth, it closes up the end of its shell, and so does *T. navalis*. Sellius believed that the animal by this act formed its own tomb, since it could no longer destroy the wood in which it was contained. Sir Everard however remarks that in *T. gigantea* death is not a consequence of seclusion from the substance in which it is imbedded. In some of Mr. Griffith's specimens the shell was just covered in, and the part close to the termination extremely thin, whilst in others it was increased twenty-fold in thickness. In others again the shell had not only become thick, but the animal had receded from its first inclosure, and had formed a second three inches up the tube, and afterwards a third two inches further on, and had made the sides thicker and thicker, so as to diminish the canal in proportion to the diminution of its own size.

Animal of *Teredo navalis* out of the shell.

1, the opercula are wanting, and the tubes retracted. 2, the opercula in their situation, and the tubes protruded. *a a*, the boring-shells; *b*, the proboscis; *c*, the mouth; *d d*, the contents of the abdomen seen through the transparent external covering; *e e*, breathing organs seen in the same way. ('Philosophical Transactions.')

Shell and Tube of *Teredo navalis*.

G. L. Sowerby.

Sir Everard considers these facts as proving that *Teredo gigantea*, when arrived at its full growth, or whenever it is prevented from

increasing in length, closes up the end of its shell, and lives a long time afterwards, furnished with food from the sea-water. *Teredo navalis*, he observes, closes up its shell in the same manner: it must therefore, after that period, be supplied with food entirely through the medium of sea-water. The Teredines, he adds, turn round in the shell, to which they are not attached, and with which their covering only has a slight connection at one particular spot, to prevent the external tubes from being disturbed. This motion, Sir Everard observes, is for the purpose of boring.

Some of the Teredines examined by Sir Everard Home were sent from Sheerness in the wood alive, and they lived in salt-water for three days after being brought to town. Sir Everard observed that when the surface of the wood was examined in a good light, while only an inch in depth in the water, the animal threw out sometimes one tube, at others two small tubes. When one only was protruded, the other almost immediately followed it. One of them was about three-quarters of an inch long; the other only half that size. When the largest was exposed to its full extent, there was a fringe on the inside of its external orifice of about twenty small tentacula, scarcely visible to the naked eye: these were never seen except in that state; for when the tube was retracted, the end was first drawn in, and so on, until the whole was completely inverted: and therefore in a half-protruded state it appeared to have a blunt termination with a rounded edge. The smaller tube was not inverted when drawn in. "These tubes," says Sir Everard Home in continuation, "while playing about in the water appeared at different times to vary in their directions, but usually remained at the greatest convenient distance from each other. The largest was always the most erect, and its orifice the most dilated; the smaller one was sometimes bent on itself with its point touching the wood. In one instance, where a small insect came across the larger one, the point of the smaller turned round and pushed it off, and then went back to its original situation. In several instances the smaller one appeared to be the most sensible; since by touching the larger one gently it did not retract; but on touching the smaller one they both were instantly drawn in. Indeed whenever they were retracted they always were drawn in together. When the worm was confined within the shell the orifice was not to be distinguished in the irregular surface of the wood, which was covered with small fuci. The worm appears commonly to bore in the direction of the grain of the wood, but occasionally it bores across the grain to avoid the track of any of the others; and in some instances there was only a semi-transparent membrane as a partition between two of them."

T. navalis has been found at depths ranging from the surface to ten fathoms.

It is said, probably with truth, that *T. navalis* was introduced into Europe from warmer climates. However that may be, it now unfortunately swarms in our seas. The ravages of this apparently insignificant animal are terrible. Ships, piles, all submarine wood-works, are ruinously affected by it: small as it is, it threatened the submersion of Holland by its destruction of the dykes. The living specimens which formed the subject of Sir Everard Home's observations were furnished from one of the royal dockyards. The rapidity of its growth and the destructive celerity with which it works are hardly credible. A piece of deal, after a submersion of forty days, was riddled by them, and some had attained considerable size. Those from the dockyard at Plymouth, examined by Montagu, were in piles which had been recently taken up to be replaced with new; they had not, according to the information given to Montagu, been under water above four or five years, but they were greatly perforated, though they were sound solid oak when they were driven. The only effectual way of preventing the attacks of this animal upon piles appears to be by covering all that part which is continually beneath the surface with short broad-headed nails. The action of the sea-water on the nails produces a strong coating of rust, said to be superior to a copper sheathing.

Wood perforated by *Teredines navalis*.

T. gigantea. Rumphius, in his 'Amboinsche Raritätzkammer,' gives two figures, here copied, of a species of tubular shell found in shallow water among mangrove-trees. He describes the ground whence they were brought, and the mode in which the large end of the shell is closed, so as to leave little doubt that it was *T. gigantea*, though the separation of the two tubes through which the parts of the animal pass out is different from the specimens brought home by Mr. Griffiths. This difference however, as the latter observes, may have been connected with the situation in which the animal was found, namely, shallow water among the mangroves.

NAT. HIST. DIV. VOL. IV.

connected with the situation in which the animal was found, namely, shallow water among the mangroves.

Teredo gigantea. (Rumph.)

Teredo gigantea.

1, the small or upper extremity of the shell, the external covering broken away and showing the termination of the tubes, one of which is broken; 2, a longitudinal section of that part of the shell where the double tubes are formed; 3, the shell complete, or nearly so, the exception being the imperfect state of the upper extremity. ('Philosophical Transactions.')

Mr. Griffiths relates that a short time after a very violent earthquake that occurred in Sumatra in the year 1797, which produced "a most tremendous" inundation of the sea, did great damage, and caused the loss of many lives, these shells were procured in a small sheltered bay with a muddy bottom, surrounded by coral reefs, on the island of Battoo. More than twenty specimens were brought to Mr. Griffiths, but not one was complete: a portion of the shell with the apex nearly perfect, and another with the opposite closed extremity nearly so, were however procured. The length of the longest of Mr. Griffiths's shells was 5 feet 4 inches, and the circumference of the base 9 inches, tapering upwards to 2½ inches. There were other good ones of smaller size. The large specimen was nearly perfect, having a small part of the lower extremity entire. Most of the shells had adhering to them, about one foot or more from the top, the small cockcomb oyster, small serpulæ, &c.; consequently, Mr. Griffiths observes, they must have been protruded that distance from the hard mud; but the water being thick and discoloured, the people of Battoo had not taken notice of them antecedent to the earthquake. The specimens were milk-white on the outside and within were tinged with yellow. Mr. Griffiths remarks that the large end of the shell is completely closed, and has a rounded appearance; at this part it is very thin. The small end, or apex, is very brittle and divided by a longitudinal septum running down for 8 or 9 inches, forming it into two distinct tubes, inclosed within the outer one, whence the animal throws out tentacula. Mr. Griffiths goes on to describe the substance of the shell as composed of layers having a fibrous and radiated appearance, covered externally with a pure white crust, and internally as having a yellow tinge; and the external surface as frequently interrupted in a transverse direction by a sudden increase of thickness, which, he observes, probably indicates different stages in the growth of the shell, although they are at unequal distances, sometimes at 6 inches, sometimes at 4 inches, in the same shell. Many of the shells, he adds, are nearly straight, others crooked and contorted.

Teredo gigantea.

1, a transverse section of shell, giving a front view into the orifices of the double tube, and showing the thickness of the shell at that part; 2, transverse section of shell at the thickest part after it had been polished, showing the structure, and giving a front view of the orifices into the double tube. ('Philosophical Transactions.')

PHOLADOMYA, a genus of Conchiferous *Mollusca*, which is thus characterised:—Shell very thin, rather hyaline, transverse, ventricose; inside pearly; posterior side short, sometimes very short, rounded; anterior side more or less elongated, gaping; upper edge also gaping a little. Hinge with a small rather elongated triangular pit, and a marginal lamina in each valve, to the outer part of which is attached the rather short external ligament. Muscular impressions two; these, as well as the muscular impression of the mantle, in which there is a large sinus, are indistinct. (O. B. Sowerby.)

The genus *Pholadomya* is a most interesting form, for the knowledge of which we are indebted to Mr. O. B. Sowerby, who described it from a recent species brought from the island of Tortola by Mr. Nicholson, and in the possession of Mrs. Mawe, from whom it passed into Mr. Broderip's collection, and consequently is now in the British Museum.

The discovery of this recent species led at once to the more perfect knowledge of several fossils, whose genus, as Mr. Sowerby observes in

his 'Genera' (No. xix.), was before exceedingly doubtful, inasmuch, that from a consideration of their external appearance alone, authors had been induced to place them in several genera, to none of which they really belonged—as for instance those named *Cardita* (l) *producta*, *C. obtusa*, *C. lyrata*, *C. deltoidea*, and *C. margaritacea*; and *Lutaria* *lyrata*, *L. ovalis*, *L. ambigua*, and *L. angustata*. These occur in several rocks of the Oolitic Series, particularly the Cornbrash, Inferior Oolite, and Fuller's Earth; as well as in the Lias, the London Clay, and the Sutherland Coal-Field; also in the dark-coloured clay at Alum Bay.

Professor Owen gives the following description of the animal:—"Pholadomya presents all the family characters of the *Inclusa*, or *Enfermes*, but differs generically from all those, the organisation of which has hitherto been described, by the presence of a fourth aperture leading to the interior of the mantle, that is to say, besides the linear slit for the protrusion of the narrow foot at the anterior part of the ventral aspect of the mantle and the two siphonic tubular passages, there is, at the under or ventral part of the base of the united siphons, a small round aperture, which is continued upon a truncated pyramidal papilla projecting into the pallial cavity, forming a valvular obstruction to the exit of fluids, but admitting their entry. This doubtless relates to some curious and peculiar feature in the economy of the mollusc: the foot is compressed, half an inch long, three lines broad; the siphonic tube two inches long, half an inch in diameter, bifid at the extremity; the labial appendages short; the two branchiæ of each side conjoined, and those of the right united to those of the left side along their posterior fourth. More of the anatomy I have not at present worked out; but there is enough, I think, here stated to serve as an answer to M. De Blainville's question."

P. candida (G. B. Sowerby) may be given as an example.

The shell is transversely oblong, very short posteriorly, rounded; median part marked with divaricated, decussate striae, which are decurrent from the umbo; anteriorly elongated, subquadrate.

It is a marine species, and most probably inhabits deep water. The specimen from which Mr. Sowerby characterised the genus was thrown upon the beach at Tortola after a hurricane.

This is the only living species, but several fossil forms from the Coal, Oolite, and Lias have been found.

Pholadomya candida.

a, valves shut, the umboes towards the spectator; b, inside view of valve, showing the impressions and the umbo worn through.

PHOLARITE, a Mineral, a Hydrated Silicate of Alumina. This substance occurs in small pearly scales, which are usually convex. These are white, soft, and friable, and they adhere to the tongue.

It occurs in the department of Allier in France, in the Coal Formation of Fins.

PHOLAS. [PHOLADIDÆ.]

PHOLIDOPHORUS, a genus of Fossil Fishes. [FISH.]

PHONEMIUS, a genus of Foraminifera.

PHONOLITE. [CLINKSTONE.]

PHONYGAMA, a genus of Birds belonging to the family Corvidæ.

PHORCYNIA. [ACALEPHÆ.]

PHORMIUM, a genus of Plants of the natural family of *Liliaceæ*, tribe *Agapantheæ* of Endlicher, *Asparagææ* of Lindley, contains only a single species, which is remarkable for its useful product, so well known under the name of New Zealand Flax, and which is found indigenous in New Zealand and Norfolk Island.

P. tenax has a coloured tubular perianth, of which the tube is very short, and divides into six segments, of which the three inner are the longest; stamens six, inserted into the base of the tube, ascending, exerted; capsule oblong, 3-cornered; seeds numerous, compressed; embryo in the centre of the seed, longer than half the albumen, with its radicle next the umbilicus. The root is tuberous, fleshy, and bitter tasted; the leaves are numerous, all radical, linear-lanceolate, five or six feet long, and from an inch and a half to two inches broad, 2-rowed, equitant at the base, leathery, and very tough. Its flowers are numerous, showy, yellow-coloured, arranged on a tall branched panicle.

The leaves of this plant yield a very beautiful and a very strong fibre, which has been imported in considerable quantities under the name of New Zealand Flax. It was expected to be much more useful than it has proved to be, in consequence of its having the defect of breaking easily when made into a knot. Being a plant of high southern latitudes, it was supposed that it might easily be grown in different parts of Europe. The French have attempted to cultivate it near Cherbourg, Toulon, and other places, and it has been introduced into Ireland, the moist insular climate of which is probably favourable to its growth. It grew remarkably well for a number of years in the Chelsea Botanic Garden, but was killed by the severe winter of 1837-38. Its cultivation has also been attempted in Australia, but has not yet succeeded to any extent.

PHORUS. [TROCHIDÆ.]

PHOS (De Montfort), a genus of Turbinate Gastropodous *Mollusca*.

PHOSPHATITE, a name proposed for the native Phosphate of Lime derived from organic sources, and usually called *Coprolites*. The latter term conveys an impression which is evidently wrong, with regard to large quantities of the phosphate of lime now obtained for agricultural purposes. In that which is obtained from the Red Crag fragments of bones of large size are constantly present, and it is questionable if any portion of this phosphate has ever been excrementitious matter. Hence the impropriety of the term *coprolite*. The more probable origin of these masses seem to be that they are the debris of a huge sepulchre of *Cetacea*, sharks, and other animals, which was formed previously to the existence of the beds in which these remains are now found. After deposition in this sepulchre, the animal matter of the bones was gradually washed away, and the large quantities of phosphate of lime found in the water-worn nodules of the Red Crag are thus accounted for. [COPROLITES.]

PHOSPHORESCENCE. [LUMINOSITY IN ORGANIC BEINGS.]

PHOSPHORITE, a name for the native Phosphate of Lime obtained in Spain. [APATITE.]

PHOTOZITE, a name for Manganese Spar. [MANGANESE.]

PHIRAGMATURUS. [IOUANIDÆ.]

PHIRAGMITES, a genus of Plants belonging to the natural order *Graminaceæ*. *P. communis*, the Reed, is a plant formerly regarded as a species of *Arundo*, but now separated from that genus on account of its lower floret being male while the others are hermaphrodite, and its rachis being fringed with long silky hairs. It is a tall plant with annual stems and a perennial root, and is found exclusively in places overflowed even during summer. In such situations it is found abundantly in Great Britain, and occurs all through Europe, is common in Siberia, Japan, North America, and even Australia, forming thick coverts, and yielding an abundance of stout durable grass of great value for the purpose of thatching the roofs of buildings. This is undoubtedly the *Φαραμύτης* of the Greeks. A second species is said to grow in Egypt, and a third in the island of Mauritius; the two latter species are however little known.

PHIRAGMO'CERAS. [ORTHOCERATIDÆ.]

PHRO'NIMA, Latreille, a genus of Amphipodous *Crustacea*. It has two very short setaceous antennæ composed of a small number of joints. Four first feet (*mâchoires extérieures* of Latreille) in the form of small compressed arms, terminating in a point, and dentated below: the two interior the smallest, and annexed to the head.

P. sedentaria (*Cancer sedentarius*, Forsk.; *Cancer gammarellus sedentarius*, Herbst.), has a transparent body, which is nacreous and dotted with reddish. Length not exceeding an inch.

It lives at some distance from the coast, and keeps, according to M. Risso, in the interior of the body of *Radiata* belonging to the genera *Pyrosoma* and *Berë*. Found in the Mediterranean and near Luray in Zealand.

P. Cuvos is smaller than the preceding, and very white. Found near Nice, in the interior of *Meduse* (*Equeora* and *Geronia* of Péron and Lesueur). (Risso.)

PHRO'SINE, Risso, a genus of Amphipodous *Crustacea*, namely, those furnished with four antennæ. The two superior antennæ are

large and spoon-shaped; two lower antennæ, setaceous and very small. The ten feet properly so called monodactyle, formed of five flattened joints: the first pair short, delicate, and hooked; the second a little shorter than the third; the fourth very large, with its first joint wide and oval, the two following triangular, the fourth oval and spiny, and the last long, pointed, arched, and falciform; the fifth pair shorter than the preceding, but of the same form. (Desm.)

P. semilunata has an oblong body, yellowish anteriorly, red posteriorly; the head is provided with two small horns, which form a sort of crescent; eyes small. Total length seven to eight lines.

This species is rather rare in the neighbourhood of Nioc, where it appears in the spring at the season of reproduction. It inhabits deeps on a sandy bottom. Eggs transparent.

P. macrophthalma has an oblong violet-red body, with a transparent head; no horns. Found on *P. Pyrosoma*, in February and July: at the latter period, the female is loaded with a quantity of very small globular eggs. (Risso.)

PHRYGANEÆ. [NEUROPTERA.]

PHRYNOCEPHALUS. [DRACONINA.]

PHRYNOSOMA. [IOUANIDÆ.]

PHYCIS, a genus of Fishes belonging to the family *Gadidae*. It has an elongated body; two dorsal fins, the first short, the second long; ventral fins with a single ray only at the base, afterwards divided; chin with one barbule.

P. furcatus, the Forked Hake, the Hake-Dame, the Common Fork Beard, is a rare fish on the British coasts. It has been taken most frequently in Cornwall. It is about two feet in length, but not very good eating.

(Yarrell, *British Fishes*.)

PHYLLASTREPHUS. [MERULIDÆ.]

PHYLLIDIA. [INFEROBRANCHIATA.]

PHYLLIDIANS (Lamarck), a family of Gastropodous *Mollusca*, including the genera *Phyllidia*, *Chitonellus*, *Chiton*, *Patella*, *Patelloidea*, and *Siphonaria*. [CHITONIDÆ; PATELLIDÆ.]

PHYLLITE, a name for *Ottrelite*. [OTTRELITE.]

PHYLLIDIUM is that organ which in the greater part of the Australian Acacias, or Wattle-Trees, stands in the place of leaves. [LEAF.]

PHY'LLODOCE, a genus of Plants belonging to the natural order *Ericaceæ*. It has a 5-parted calyx, an ovate corolla with a contracted 5-toothed mouth, 10 stamens inclosed, slender glabrous filaments longer than the anthers, short truncate cells opening by pores at the apex. The seeds are compressed and shining. The species are small evergreen shrubs, natives of the north of Europe, Asia, and North America.

P. carulca has linear leaves with denticulated margins, glandular hairy peduncles; calycine lanceolate-acute segments; anthers three times shorter than the glabrous filaments. The stem is from 4 to 5 inches high, determinately branched, naked below, densely hairy above. The flower is large, pale, bluish-red; the peducles terminal, aggregate, and simple. The plant is a native of Perthshire and the north of England. There are three other species of *Phyllodoce*, which are natives of North America.

(Babington, *Manual of British Botany*.)

PHY'LLODUS, a genus of Fossil Fishes. [FISH.]

PHY'LLOPA. [BRANCHIOPODA.]

PHY'LLOTODA (Latreille), a section of Entomostracous *Crustacea*. [ENTOMOSTRACA.]

PHY'LLOSO'MA, a family of *Crustacea* called by Milne-Edwards Double-Cuirassed (*Bicuirassés*). It is composed of forms which are very remarkable for their rounded shape and the transparency of their teguments. The carapace is large, lamellar, extended like a leaf horizontally above the base of the antennæ and a more or less considerable portion of the thorax. The thorax is equally depressed, so as to resemble a thin blade or plate placed horizontally, and to the existence of these two bucklers, so to speak, they owe the name (*Bicuirassés*) given to them by Latreille. The ophthalmic ring is but little if at all distinct from the interior border of the carapace, and it is from this border also that the antennæ spring. The eyes are very large and projecting. The antennæ spring below and behind their peduncle, on the same transversal line, and are directed forwards; those of the first pair are bifid at the end, and the conformation of those of the second pair varies. The mouth is situated very far from the base of the antennæ, and is found towards the anterior third or the middle of the lower surface of the carapace; it has the form of a rounded tubercle, and is composed essentially of a large upper lip, a pair of hooked mandibles which want a palpiiform stem, a membranous and bilobed lower lip, and a pair of jaws; sometimes there are to be found a second pair of jaws and even jaw-feet applied against the mouth, but in general those organs are rudimentary and thrown rather far backwards. The great flattened blade or plate, which constitutes the thorax, commences immediately behind the mouth, and presents no annular divisions; in general it reaches a good deal beyond the carapace, and gives insertion to the feet by its lateral borders, so that those organs are very distant from the median line. The number of feet consists of from seven to eight pairs, but those of the first pair, and sometimes those of the last, are very short, whilst the others are very long; all are very slender, and lead, towards a third

of their length, to a large flabelliform appendage, which is analogous to the external branch of the thoracic feet of the Mysians, but which takes its origin much farther from the body. The abdomen is slender, and sometimes rudimentary; in general, nevertheless, it is terminated by a fin composed of five blades disposed in a fan-shape, as in the family of the Caridoids. The false feet are always more or less rudimentary.

These Crustaceans do not present any organs which can be considered as branchiæ; some naturalists give this name to the ciliated appendages which represents the palp of the thoracic feet, but without resting this conclusion on any fact; and M. Milne-Edwards is disposed to believe that respiration is carried on by means of the general surface of the body. ('Histoire Naturelle des Crustacés.')

M. Milne-Edwards, whose definition of this family we have above given, makes it consist of two genera only, *Phyllosoma* and *Amphion*. He observes that the *Phyllosomata* are easily recognised by their foliaceous carapace, which leaves part of the thorax exposed. In *Amphion*, the carapace hides the thorax entirely.

Phyllosoma (Loach).—This, one of the most remarkable genera known, is composed of animals whose body is so much flattened, that there is scarcely an interval between the teguments of the upper and lower surfaces, so that it is difficult to comprehend how the viscera are there lodged. This lamellar body is divided into three distinct parts; the head, the thorax, and the abdomen.

The head has the form of a delicate disc or of an ordinary oval leaf, and only adheres to the thorax by its central portion, so that the borders all round are free. This species of buckler is wide and horizontal; at its anterior extremity it gives insertion to the eyes and to the antennæ. The eyes spring near the median line, and are globular; they are carried on slender, cylindrical, and very long peduncles.

The thorax is lamellar like the carapace, and constitutes a second buckler, the anterior portion of which only is covered by the first of those foliaceous discs. It is in general wider than it is long, and striated transversely, but it presents no trace of a division into rings. The feet are inserted all round the disc. The disposition of the abdomen varies: sometimes it is elongated, divided into very distinct rings, and perfectly distinct from the thorax which covers its base; sometimes it is confounded with the buckler, and only seems to be a prolongation of it.

The nervous system of the *Phyllosomata* presents a remarkable mode of conformation; the mass formed by the cephalic ganglion is situated near the base of the antennæ, and communicates with the thoracic ganglions by means of two very long chords. The thoracic ganglions are not united on the median line, but communicate with each other by transversal commissures: there are nine pairs. The abdominal ganglions are very small, and amount to six pairs. The intestine seems to be straight, and in the interior of the cephalic buckler are to be perceived a great number of vessels which diverge laterally.

The species are found in the seas of warm countries. M. Milne-Edwards remarks, that were it not for the beautiful blue of their eyes, they would not be perceived as they float on the surface of the water, so transparent are their bodies. The seas of Africa and India, Australia and New Guinea furnish the greatest number of species. M. Milne-Edwards divides the genus into the three following natural groups:—

1. Ordinary *Phyllosomata*.

Abdomen very distinct from the thorax, large, divided into rings, and terminated by a well-developed caudal fin.

The *Phyllosomata* of this division approach, more than the others, the Caridoids and the Amphions, for their abdomen, though flattened, much resembles that of the Shrimps (*Salicoides*).

P. commune has the cephalic plate less than the thoracic plate, covering the base of the second pair of feet (or external jaw-feet), elongated, and narrowed forward. External antennæ styliform, much longer than the ocular peduncles, and composed of five joints (without reckoning the peduncle that supports them, and which is only a prolongation of the border of the carapace), of which the third is very small, the fourth shorter than the ocular peduncle, and the last nearly half the length of the preceding, and not convex.

It inhabits the seas of Africa and India.

Phyllosoma commune.

P. claricorne, from the seas of Africa and Asia, is another example of this section.

Phyllosoma claricorne.

The other two sections consist of those *Phyllosomata* whose abdomen is intimately united with the thorax, without well distinguished divisions, and terminated by a very small caudal-fin.

2. Short-Tailed *Phyllosomata*.

Abdomen in general rudimentary and lodged in the middle of a great notch on the posterior border of the thorax.

P. laticorne and *P. brevicorne*, the eyes and antennæ of which are represented below, are examples of this section.

a, Eyes and Antennæ of *Phyllosoma laticorne*; b, Eyes and Antennæ of *Phyllosoma brevicorne*. The first of these species is found in the Indian Seas, and the second in the seas of Africa and Asia.

3. Broad-Tailed *Phyllosomata*.

Abdomen large, triangular, and occupying the whole length of the posterior border of the carapace.

P. spinosum (Azores) and *P. Mediterraneum* (Mediterranean), &c., are examples of this section.

Amphion (Milne-Edwards).—M. Milne Edwards states that the *Crustacea* which he has designated under the name of *Amphion* approach nearer to the *Phyllosomata* than any of the other Stomatopoda, but in some respects they resemble also the genera *Alima* and *Mysis*; and he is of opinion that they establish the natural passage between these animals. Their cephalic buckler or carapace is foliaceous, like that of the *Phyllosomata*, whilst the form of the abdomen and the caudal-fin is that of *Mysis*.

The only species known, *Amphion Reynaudii*, was taken at sea in the Indian Ocean by M. Reynaud, naval surgeon. Its length is about an inch, and its teguments, with the exception of those of the abdomen are diaphanous.

(*Histoire Naturelle des Crustacés.*)

PHYLLOSTOMA. [CHEIROPTERA.]

PHYSA. [LIMNÆADÆ.]

PHYSALIA. [ACALEPHEÆ.]

PHYSALIS (from *ψύσα*, a bladder, in reference to the inflated calyx), a genus of Plants belonging to the natural order *Solanaceæ*. It has a 5-toothed calyx; a campanulate rotate 5-lobed corolla; converging anthers opening longitudinally; a capitate stigma; smooth 2-celled berry, covered with the angular membranous inflated calyx. The species are annual or perennial herbs, rarely shrubs.

P. somnifera has several shrubby branched stems, round and downy. The leaves are in lateral pairs, short-stalked, ovate, downy, and from two to four inches long. The flowers are axillary, subsessile, small, crowded, and of a greenish-yellow or white. The berry is red and smooth, and about the size of a pea. This plant is the *Στρέχνος* *ἰκνωτικός* of Theophrastus ('Hist. Plant.,' 9, 12); and the *Στρέχνον* *αλικάκιστον* of Dioscorides (4, 72). It is a native of rocky places in the south of Europe and the East Indies. It is reputed to be narcotic, diuretic, and alexipharmic. The leaves steeped in oil are in India applied to inflammatory tumours, and they are used in a similar way in Egypt. Kunth recognised this plant in Egyptian mummies.

P. Alkekengi, the Winter Cherry, is an herbaceous downy plant, with a perennial creeping root; ovate deltoid leaves; spotless flowers, ovate coloured calyx, and subulate segments. It is a native of Europe on

exposed hills, and of Japan. The corolla is a dirty white; the calyx reddish-yellow, inclosing a red berry. The fruit of this plant was well known to the ancients, and is described by Dioscorides. In this country however the fruit is seldom eaten, and the plant is cultivated chiefly on account of its appearance. In Arabia and Armenia, Spain, and Germany however the berries frequently supply the place of other eatable fruits. They have a subacid and not unpleasant flavour, but the persistent calyx with which they are invested is very bitter. Ray speaks of these berries as a preventive of gout, and others have extolled them as diuretics, and recommended them in the treatment of dropsy.

P. pubescens, Downy Winter Cherry, is a native of North America and the East Indies. The whole plant is densely clothed with down. The corolla is yellow, marked with five roundish brownish-violet spots at the throat. The berries are yellowish when ripe; they are called Gooseberries, and are used as a substitute for them in many parts, and when preserved with sugar make an excellent sweetmeat. It is the Camara of Brazil.

(Lindley, *Flora Medica*; Burnett, *Outlines of Botany*; Fraas, *Synopsis Plantarum Floræ Classicæ*.)

PHYSALITE. [TOPAZ.]

PHY'SALUS. [ACALEPHE; CETACEA.]

PHYSE'TER. [CETACEA.]

PHYSIC-NUT. [JATROPHA.]

PHYSIOLOGY (φυσιολογία, from φύσις, nature, and λόγος, discourse) is the science which treats of the phenomena of living bodies. Its several departments are considered in separate articles, in which a complete system may be found. The reader is referred to the articles VITALITY, DIGESTION, ABSORPTION, CIRCULATION, HEART, RESPIRATION, NUTRITION, SECRETION, GLAND, BONE, SKELETON, ARTICULATION, MUSCLE, LARYNX, NERVOUS SYSTEM, BRAIN, the several organs of the SENSES, REPRODUCTION, and the articles on the anatomy and special physiology of the individual organs of animals and plants, which are referred to in each of the preceding.

PHYSOGRADA. [ACALEPHE.]

PHYSONE'MUS, a genus of Fossil Fishes. [FISH.]

PHYSPERMUM (from φύσα, a bladder, and σπέρμα, a seed, in reference to the tegument not adhering to the seed when young), a genus of Plants belonging to the natural order *Umbelliferae*. It has a 5-toothed calyx; obovate petals, with an inflexed point; the fruit laterally compressed; the carpels reniform, globose, didymous, with five filiform slender equal ridges, the lateral within the margin; the interstices with single vittæ. The species are perennial herbs. The flowers white.

P. Cornubiense has triternate radical leaves; wedge-shaped leaflets deeply toothed; the stem-leaves ternate, lanceolate, and entire; the stem from one to three feet high, erect, round, striated, minutely scabrous, bearing a few small ternate leaves with linear-lanceolate segments; the umbels are terminal; the carpels longer than broad; the coat loose. It is a native only of Cornwall, in bushes and hedges; in great plenty in the neighbourhood of Bodmin. Cattle are so fond of this plant that they will eat it down to the ground. The root contains a yellow resinous juice. There are but few species of this genus.

(Babington, *Manual of British Botany*.)

PHYSSO'PHORA. [ACALEPHE.]

PHYTELEPHAS (from φυτόν, a plant, and ἑλέφας, ivory), a genus of Plants belonging to the natural order *Pandanææ*, of Brown, and originally referred by Lindley to the order *Cyclanthaceæ*, but in his 'Vegetable Kingdom' he places it with the Palms. Under this name it was first described by Ruiz and Pavon, in their 'Systema Vegetabilium Floræ Peruvianæ.' It was also described by Willdenow under the name *Elephantusia*, but the former name is now generally used. The substance called Vegetable Ivory consists of the seeds of species of *Phytelephas*.

This genus is characterised by possessing pinnated fronds and an erect stem. The flowers are arranged on a spadix inclosed in a universal spathe, and are of two sorts, the one containing both stamens and pistils, the others only pistils. The spadix is crowded with flowers, and the stamens are very various; the style is divided into 5 or 6 deep segments; there is no visible calyx or corolla; the fruit consists of quadrilocular drupes, which are aggregated into a large muricated coriaceous head. The seeds are about the size of a pigeon's egg, and of an oblong-ovate triangular shape. When young they contain a crystalline liquor without odour or taste, which is regarded as a refreshing drink by travellers. In the process of growth however this once opaline liquid becomes milky and opaque, acquiring some taste and odour, and at last it is converted into a substance in many instances whiter and harder than ivory. If the liquid of the seed is kept long, even when it is clear, it becomes sour, thus indicating that although clear and tasteless it contains some carbonaceous principle, as well as water. There are two species of *Phytelephas*, yielding seeds of the same kind: the *P. macrocarpa* has a low stem and large fruit, whilst the *P. microcarpa* has little or no stem and small fruit. These plants, which have an external character something between a palm and a cypas, occur in South America, in the valleys of the Peruvian Andes, and especially on the borders of the river Magdalena. The natives of these districts have used the seeds from time immemorial, for the purposes of making buttons, heads to walking-sticks, and various

trinkets; but it is only within a recent period that they have been used for these purposes in Europe. They are now extensively used, as far as their size will permit them, for the manufacture of almost all the articles for which ivory had been in use before; and, as they can be made at a cheaper rate, their sale is at present somewhat extensive. In the use of the nuts for turning, considerable difference is found in their quality; some are comparatively oily and soft, and work up with ease, whilst others are so brittle as to be unmanageable in the lathe. They do not answer so well as ivory for the construction of delicate articles, as they are much more easily fractured; and although at first these seeds are whiter than ivory, they are not found to retain their colour so well.

It might at first appear difficult to account for the germination of these plants, as the albumen, which is destined to nourish the young plant, is as hard as ivory; but this is provided against by the hard albumen absorbing water, and thus not only becoming soft and capable of being used by the embryo, but it also loses its whiteness. It retains these properties when dry. The embryo is small compared with the size of the seed, of a sweet taste, and lies inclosed in a little bag at one end of the seed, the presence of which is indicated by a slight swelling on the external part of the seed. When the seeds are brought into this country they are contained in a soft external tegument of a light colour, and about the eighth of an inch in thickness, with a dark mark indicating the point of attachment. This covering is easily removed, and the seed underneath is of a dark brown colour, from a membrane which is closely attached to the albumen. In some cases this is of a reddish colour, especially on the smaller seeds, and these are probably the produce of the smaller species of the plants. When the seed is cut completely through, an irregular cavity is found in the centre. This should be attended to in working it.

(Ruiz and Pavon, *Systema Vegetabilium Floræ Peruvianæ*; Cooper, *Paper On Vegetable Ivory*, in *Microscopical Journal*, No. 16.)

PHYTEUMA (a name adopted by Dioscorides), a genus of Plants belonging to the natural order *Campanulaceæ*. It has a 5-parted calyx; a rotate corolla with 5 long linear segments; free anthers; and filaments dilated at the base.

P. orbiculare, Round-Headed Rampion, has the heads of its flowers globose, those of the fruit oblong, the leaves crenate-serrate, the lower ones cordate-ovate, stalked, the upper ones linear, lanceolate, sessile. It is a native of the mountains of Europe and of England in chalky soil. The flowers are of a deep blue colour.

P. spicatum, Spiked Rampion, is distinguished by having the heads of its flowers oblong, those of the fruit elongated, cylindrical; the lower leaves cordate-ovate, the upper ones linear-lanceolate, sessile; the flowers are white, cream-coloured, or blue. It is a native of the temperate parts of Europe, and of Sussex in England. *Campanula Rapunculus* is likewise known as the Rampion.

(Babington, *Manual of British Botany*.)

PHYTO'CRINUS. [ENCRINITES.]

PHYTOLACCA; a genus of Plants the type of the natural order *Phytolaccaceæ*. The species are tropical or subtropical herbaceous plants, with erect or occasionally twining stems, a thickish, turnip-

Phytolacca decandra.

1, an expanded flower; 2, the pistil; 3, a ripe fruit; 4, the same, cut through transversely; 5, a vertical section of a seed.

shaped root, alternate undivided broad leaves, and leafless erect racemes of flowers, succeeded by deep purple fruits. They have a 5-parted calyx; no corolla; from 5 to 30 stamens inserted into a fleshy disc; and the pistil consists of several unilocular distinct carpels united at the base or along the whole inner angle. The fruit is an umbonate depressed berry, with solitary seeds whose embryo is turned round nearly albumen.

P. decandra, a species found wild in Virginia, where it is called P'ocan, whence the vulgar name of Poke applied to this species, has a root which acts as a powerful emetic, but its exhibition is attended with narcotic effects; its berries are also reported to possess the same quality; they stain an intense purple colour, and are said to be employed in Portugal as a means of improving the appearance of inferior red wines. Notwithstanding the acidity of its leaves, this plant, when very young, is said to be eaten in the United States as asparagus; and Dr. Royle relates that he found *P. acinosa*, a Himalayan species, employed in the same manner in the north of India, to be very palatable when boiled.

PHYTOLACCACEÆ, a natural order of Plants belonging to the class Exogena. According to most writers they are regarded as apetalous plants, and allies of the Chenopodiaceous and Polygonaceous orders, from which their distinct ovaries chiefly distinguish them; but Endlicher, in his arrangement of plants, probably influenced by the form of their embryo and by the plurality of the carpels, considers them as related on the one hand to the Caryophyllaceæ and on the other to the Malvaceæ orders. Notwithstanding the apparent difference between these two stations it is probable that both are correct, and that *Phytolaccæ* are really plants connecting *Chenopodiaceæ* and *Caryophyllaceæ*. If so, they furnish a new proof of the badness of the fundamental divisions proposed for Exogens by both De Candolle and Jussieu. With the exception of *Phytolacca*, no plants of this order appear to be of much importance to man; their properties seem to be generally acid.

PHYTOSAU'RUS, Jaeger's name for a genus of Fossil Saurians. Two species are recorded, *P. cubicondon* and *P. cylindricodon*, both from the Dolomitic Sandstone (Keuper Formation).

PHYTOTOMA. [MUSOPHAGIDÆ.]

PHYTOZOA'RIA (Ehrenberg), a name for the animals included in the families *Rotifera*, *Infusoria*, and *Rotatoria*. [ROTIFERA; INFUSORIA.]

PIA MATER. [BRAIN.]

PIAIAU, or PIAUHAU, the name assigned to certain Cotingas (*Ampelis*, Linn.), whose bill is more strong and more pointed than the ordinary Cotingas. [MUSCICAPIDÆ.]

PIAUZITE, a kind of mineral resin or wax insoluble in alcohol.

PICA. [CORVIDÆ.]

PICATHARTES. [CORVIDÆ.]

PICIDÆ, a family of Scansorial Birds. The order *Picæ* of Linnæus is thus characterised:—Bill (cuneus sarricus) cultrated, with a convex back. Feet walking, short, rather strong. Body 'tenaciussculm,' impure. Food 'quisquilia.' Nest in trees; the male feeding the incubating female. Monogamy. Order analogous to the *Primates*.

This order seems to be the most arbitrary in the ornithological system of Linnæus, for under it birds of very discordant habits are collected. The Woodpeckers, the Crows, the Trogons, the Orioles, the Cuckoos, the Kingfishers, the Humming-Birds, are there associated with others in the following succession:—

Genera:—*Pittacus*, with its three sections; *Ramphastos*, *Buceros*, *Buphaga*, *Crotophaga*, *Corvus*, *Coracias*, *Oriolus*, *Gracula*, *Paradisca*, *Trogon*, *Bucco*, *Cuculus*, *Yunx*, *Picus*, *Sitta*, *Todus*, *Alcedo*, *Merops*, *Upupa*, *Certhia*, and *Trochilus*.

Brisson had previously arranged the Wrenneck, the Woodpeckers, and the Jacamar in the first section (bill straight) of his thirteenth order of birds—thone, namely, with four toes, two before and two behind.

Latham's *Picæ* consist of even a more heterogeneous group than that assembled under the *Picæ* of Linnæus.

The fourth order of Birds, in the Method of Lacépède, consists of those which have the bill straight and compressed, and under it two genera only, *Gallula* (Jacamar) and *Picus*, are arranged. The Count's third and fifth orders are formed respectively of the genera *Bucco* and *Yunx*.

The first family (*Cuneirostres*, or *Sphenoramphes*) of M. Duméril's third order (Grimpeurs, or Climbers) comprises the genera *Picus*, *Yunx*, *Gallula*, *Crotophaga*, and *Cuculus*.

The *Pici* form M. Meyer's third order, and are divided into two sections:—

1. With stiff feathers. Genera—*Picus*, *Certhia*.
2. With soft feathers. Genera—*Yunx*, *Sitta*, *Tichodroma*.

Illiger's *Scansores* consist of the *Pittacini*; the *Serrati*; the *Amphiboli*; the *Sagittilingues*; and the *Syndactyli*. The *Sagittilingues* embrace the genera *Yunx* and *Picus*.

The great genus *Picus* is placed by Cuvier in his third order, Grimpeurs, between *Gallula* and *Yunx*.

The *Zygodactyli* are the first tribe of the *Sylvicola*, the second order of birds according to the method of M. Vieillot: the second family of that order, the *Macrogloues*, consist of the genera *Picus* and *Yunx*.

The *Zygodactyli* are the fifth order in M. Temminck's arrangement; and the genera *Picus*, *Gallula*, and *Yunx* constitute the second family of that order.

The Cuckoos and the Woodpeckers form the *Zygodactyles* of M. De Blainville.

Mr. Vigors separates the Parrots [PITTACIDÆ] and Woodpeckers from the other families of *Scansores* [SCANSORES], associating them together in consequence of their affinity in the essential characteristics of the tribe; and, in his view, they compose its normal groups, as Climbers par excellence, differing however as to the mode in which they climb: the Parrots using the foot chiefly in grasping the object which assists them in their ascent, and in conjunction with the bill; while the *Picidæ* rely upon the strength and straightness of the hind toes in supporting them in a perpendicular position on the sides of trees, in which posture they are also assisted by the strong shafts of the tail-feathers.

The Proglosses of M. Latreille are arranged between the *Cuculides*, and the *Grandirostres* (Toucan and Araçari); the Proglosses consists of the genera *Yunx*, *Picoides*, and *Araçari*.

In the method proposed by M. De Blainville in 1815 and 1821, and developed by M. Lherminier in 1827, the Woodpeckers (*Picus*) stand between the Toucans and the Hoopoes, in the first sub-class (Normal Birds).

In the Projet of M. Lesson the *Picidæ* comprise the genera *Yunx*, *Picoides*, *Picus*, and *Picumnus*, and are placed between the *Cuculides* and the *Ramphastidæ*, forming the fourth family of the first tribe (*Zygodactyles*) of *Insectores*, or *Oripseurs*.

Mr. Swainson is of opinion that the structure of the *Picidæ* constitutes them the most perfect of all the climbing birds, for nature has rendered their whole organisation subservient to this particular power. The feet, he observes, although very short, are unusually strong; the nails are broad and crooked, and the toes placed in pairs, that is, two forward and two backward.

Foot of Woodpecker.

As an additional and powerful support in their rapid and perpendicular ascent up the trunks of trees, their tail-feathers, he remarks, terminate in points, and are uncommonly hard, so that being pressed against the bark, they assist the bird in its progress or in keeping its position. The bill, destined for the laborious operation of penetrating the wood or stripping off the bark of forest-trees, is beautifully adapted for the purpose, being wedge-shaped, furnished with regular-sided angles, and in one species (*Picus principalis*) nearly of the colour and consistency of ivory, whence it has been termed the Ivory-Billed Woodpecker. Mr. Swainson then calls attention to the worm-like tongue barbed at the point, and capable of being protruded to a great length.

Bill of Woodpecker.

In the College of Surgeons in London, are several preparations illustrative of the structure of the muscles of the base of the tongue in these birds. The end attained by the arrangement of these muscles is the rapid and extensive protrusion of the tongue in the transfixion of the insects which constitute the food of the Woodpecker, and which are dislodged from their hiding-places under the bark of trees.

Head of Woodpecker, showing the mechanism of the tongue. (Yarrell.)

by means of its powerful bill. For the more effectual retention of the stronger insects, it may be observed that the horny sheath at the tip of the tongue is barbed; the tongue is also lubricated by a glutinous secretion, abundantly furnished by the two large submaxillary glands, which may be seen extending from behind the angles of the lower jaw along the under side of the rami to the symphysis.

This mechanism enables the bird to introduce the tongue into holes and crevices, and under the loose bark of trees, to the destruction of insects there harboured. A similar conformation, directed to a different end, exists in the Humming-Birds. [TROCHILIDÆ.]

Mr. Yarrell observes, that another anatomical peculiarity remarkable in the skeleton of the Woodpecker, but admirably adapted to the habits of the bird, is the small size of the keel of the breast-bone. "Moderate powers of flight," says this observing zoologist, "sufficient to transport the bird from tree to tree, are all that it seems to require; large pectoral muscles with a deep keel to the breast-bone would to this bird be an inconvenience. The advantage of a narrow shallow keel is immediately apparent, on looking at a representation of the skeleton in a climbing position; the low keel, allowing the bird to place its body close to the tree, brings its centre of gravity in a perpendicular line before the points of support, and thus materially diminishes the labour of, and the strain upon, the muscles of the legs and thighs. The descending position of the bones of the tail indicate the mode by which the stiff points of the tail-feathers are brought into contact with the surface of the bark of the tree to form an accessory prop." ("British Birds.")

Skeleton of Woodpecker. (Yarrell.)

In the opinion of Mr. Swainson the divisions of this family are strongly marked; because, as some few intervening forms are wanting, the circle is, in one sense, incomplete. Thus the Nuthatches (*Sitta*), he observes, although clearly approximating to the Woodpeckers, are not directly united to them; neither does the intervention of the Wryneck, with its worm-like tongue, or of *Oxyrhynchus*, with its acute bill, do more than indicate the broken links of the chain. The absolute connection between the true Woodpeckers (*Picinae*) and the sub-family of Barbets (*Buccinae*) is, he thinks, unquestionably established by two very singular little birds; one being the Minute Woodpecker of Linnæus (*Athenurus*, Sw.), the other a Barbet (*Picumnus*, Temm.).

The true Woodpeckers (*Picinae*, Sw.) are, Mr. Swainson observes, typically represented by the great ivory-billed species already noticed. The upper and lower ridge of the bill in this bird exactly correspond, he remarks, in their inclination towards the tip, rendering the organ a perfectly straight wedge. This construction is, he points out, rendered still more perfect by a ridge, forming a strongly carinated line, which runs parallel to the culmen, and is situated nearly half way between that and the external margin of the upper mandible. Mr. Swainson then draws attention to the crests in these birds—short, rigid, and turned upwards; but their chief generic distinction rests, in his opinion, on the structure of the feet, the hinder external toe being manifestly longer than that in front: this peculiarity is, he observes, even extended to such aberrant species as have one of the small toes wanting—the two northern species *Apternus tridactylus* and *A. arcticus*, for instance. To this group therefore he restricts the generic name of *Picus*, which includes in his arrangement all the British species excepting *P. viridis*.

In the next group, *Chrysomitris*, he finds a diminution of the typical excellences; the bill, as in the Common Green Woodpecker, is still

nearly straight, but the lateral ridge is close to the culmen, and the hind toe is either of equal length or slightly shorter than the fore toe: the crest, though still short, is less rigid, and not so much developed. Mr. Swainson remarks that the colours of these birds are always gay; green and soot-black predominate, and most of the typical species have the quills of a beautiful golden hue, whence the generic name above stated.

The third genus, *Malaccolophus*, Sw., is described to be highly elegant: the bill is no longer straight, the culmen being more arched than the lower ridge or gony, and the latter particularly short, owing to the prolonged advancement of the chin, which occupies full one-half of the lower mandible. The lateral ridge of the upper mandible is as in the last genus; but the anterior toe is longer than the hind toe; the crest is long, formed of loose feathers, and, like the rest of the plumage, particularly soft, whence the generic name.

Colaptes (Sw.) is distinguished from *Malaccolophus* by the greater curvature and compression of the bill, and by the disappearance of the ridge on the upper mandible; thus, in Mr. Swainson's opinion, assimilating the group to the *Tenuirostres*, and exhibiting the weakest structure among the Woodpeckers.

Melanerpes (Sw.), the fifth and last genus, may, Mr. Swainson thinks, be not unaptly called Swallow-Woodpeckers, for they resemble those birds in their migratory habits, their long wings, and their black glossy plumage, destitute in the typical examples of spots or bands.

Mr. Swainson concludes his observations on the *Picidæ* by stating that the other genera, whose climbing habits have induced naturalists to place them with this family, are *Yuncæ* and *Oxyrhynchus*: the first of these types belongs exclusively to the Old World; the latter, in Mr. Swainson's opinion, seems to be the representative of it in America.

The following is Mr. Swainson's systematic arrangement:—

Picidæ.—Bill straight, more or less conic. Toes placed in pairs.

Sub-family:—*Picinae* (*Picinae* ?), the True Woodpeckers. Bill wedge-shaped. Tongue vermiform.

1. *Picus*, Typical-Woodpeckers.—Bill perfectly wedge-shaped, cylindrical; the culmen straight; lateral ridge removed from the culmen. Versatile (outer posterior) toe always longer than the anterior (outer fore toe).

Sub-genera:—*Picus* (America and India); *Hemicircus* (India); *Dendrobates* (Africa, except two species from Tropical America); *Apternus* (Arctic Regions); and *Dendrocopos* (Universal).

2. *Chrysomitris*, Green-Woodpeckers.—Versatile and anterior toes of equal length. Lateral ridge nearest to the culmen, which is sharp, and either quite straight or very slightly bent. Bill depressed or widened at the base. Colour green banded or spotted with black. Sub-typical genus.

Sub-genera:—*Dendromus* (Africa and India); *Chloronerpes* (Tropical America); *Dryotomus* (America and Europe); *Chrysomitris* (Tropical America).

3. *Malaccolophus*, Rasorial-Woodpeckers.—Versatile toe shorter than the anterior, culmen curved. The lateral ridge (except in the typical group) wanting. Tarsus shorter than the versatile toe. Hind head with a crest of very soft feathers.

Sub-genera:—*Brachylophus* (Old World only); *Hemilophus* (India only). Typical:—*Malaccolophus* (Tropical America only); *Meiglyptes* (India); *Chrysotomus* (India only).

4. *Colaptes*.—Tarsus lengthened and equal to the versatile toe; which latter is shorter than the anterior. Bill broader at its base than it is high; the sides compressed; the culmen considerably curved from its base; the lateral ridge either obsolete or entirely wanting. Nostrils partially defended by feathers.

Sub-genera:—*Geocolaptes* (Africa only); *Colaptes*.

5. *Melanerpes*.—Bill straight, more or less cylindrical; base wide; the ridge of the culmen slightly bent, but not very prominent; the sides rounded; the lateral ridge slight, and placed near but not close to the culmen. Gony very long, as in the typical group. Nostrils nearly concealed. Wings long; the first quill spurious or very small; the second nearly as long as the third. Toes various. Habits gregarious and migratory. Colours black varied with white and red. The fissirostral type (America only).

Sub-genera:—*Centurus*, *Leuconerpes*, *Melanerpes*, *Tripsurus*. Sub-family: *Buccinae*, Barbets [BARBETS]. Bill surrounded with long bristles. Tail short, soft.

Yuncæ. [YUNX.]

The *Picidæ*, in Mr. Swainson's arrangement, are placed between the *Psittacidæ* and the *Certhiade*.

Picus martius, Linu. (genus *Dryocopus*, Boie; *Dryotomus*, Sw.). This is the Pic Noir of the French; Picchio Grande, Picchio Nero, and Picchio Corvo of the Italians; Schwartz Specht and Fichten- und Nordischer-Baumhacker of the Germans; Swarte Specht of the Netherlands; Great Black Woodpecker of the English.

The whole plumage deep black, except that, in the male, all the upper part of the head is of a lively red; the female, on the contrary, has only a small space of that colour on the occiput. Very old males have the belly and abdomen tinged with reddish; part of the tarsus

feathered; iris yellowish-white; naked circle which surrounds the eye and feet black; bill bluish-white, black at the point. Length from 16 to 17 inches.

Young males have the upper part of the head marked with red and blackish spots; iris whitish-ash colour. The older the male grows the more vivid does the red on the head become.

This bird is found in the north of Europe and Siberia principally: Norway, Sweden, Poland, and Russia possess it, and it inhabits the Swiss mountains and those of Savoy and the Tyrol. It is rare in France and Germany. There is no record of its appearance in Holland. Prince Bonaparte mentions it as occurring very rarely in the neighbourhood of Rome, in the winter only, in the deep sub-Apennine woods. Sir W. Jardine, in the 'Naturalist's Library' (1839), says Mr. Jenyns, the latest writer on our British Fauna, in 1835 writes thus:—"No specimens however known to have been certainly killed in this country exists in any of our museums, and there is strong reason to doubt the reality of its claims to a place in the British Fauna." The authority previous to this rests with the works of Drs. Latham and Pulteney.

Great Black Woodpecker (*Picus (Dryocopus) martius*).

Upper figure, female; lower, male. (Gould.)

Mr. Yarrell, in his interesting 'British Birds,' states, that the Great Black Woodpecker was added to the catalogue of the birds of these islands by Dr. Latham, who said that he had been informed that the species had occasionally been seen in Devonshire and the southern parts of the kingdom. Mr. Yarrell refers also to Dr. Pulteney's catalogue of the Dorsetshire birds, where the Great Black Woodpecker is noticed as having been more than once killed in that county—one in particular said to have been shot in a nursery at Blandford, and another at Whitechurch; and he then quotes Montagu's supplement for the following passage:—"Lord Stanley assures us that he shot a *Picus martius* in Lancashire; and we have heard that another was shot in the winter of 1805 on the trunk of a tree in Battersea Fields." Mr. Yarrell then goes on to state that the specimen of the Black Woodpecker, formerly in the collection of Mr. Donovan (who was

well known to give very high prices for rare British-killed birds, for his own use in his 'History of British Ornithology'), was affirmed to have been shot in this country; and, at the sale of Mr. Donovan's collection, this specimen was purchased by the Earl of Derby, and is now at Knowsley. Mr. Yarrell further states that he has been told of two instances of the Black Woodpecker having been killed in Yorkshire, and that it is also recorded to have been killed in Lincolnshire. "A few years since," says Mr. Yarrell in continuation, "a communication was made to the Zoological Society of London, that two examples of the Great Black Woodpecker had been at that time killed in a small wood, near Scole Inn in Norfolk; and, still more recently, a pair were frequently seen in a small preserved wood, near Christchurch in Hampshire. It was hoped that they would have remained to go to nest; but the birds, disturbed by being too frequently watched, left the wood. Lastly, I may add, that Sir Robert Sibbald, in his 'Scotia Illustrata,' claims *Picus martius* as a bird of Scotland, including it in his 'Historia Animalium in Scotia.'" ('British Birds.')

Mr. Gould thus describes the habits of the Great Black Woodpecker:—"We need hardly say that it is on the bark of trees more exclusively that the Woodpecker finds its food, and to this end are its powers and organs adapted. If we examine the toes of the present species, which are to be taken as illustrative of form in the whole of the family (with the exception of a single limited group), we find them long and powerful, furnished with strong claws, admirably adapted for grasping or clinging to the rough inequalities of the bark; besides this they are placed in pairs, so as in some measures to antagonize; but not, as generally stated, two before and two behind, for one pair is lateral and diverges from the other at an acute angle, so as to be applied to the convexity of the tree, and thus render the grasp close and firm. The tail is composed of stiff feathers; the shafts of which taper gradually from the base of the extremities, which, curving inward when pressed against a tree, not only form a fulcrum for the support of the body, but by their elasticity tend to propel it forwards. This provision, the more needed from the posterior situation of the legs, is admirably calculated for ascending; and having explored the bark by a spiral course, the woodpecker flies off to the next tree to repeat the same process. The flight of the present species is undulating, seldom protracted to any extent, but limited to a transit from tree to tree in the seclusion of its native woods. Its food consists of the larvae of wasps, bees, and other insects; in addition however it devours fruits, berries, and nuts with avidity. The female selects the hollows of old trees, in which she deposits two or three eggs of an ivory whiteness."

Mr. Hewitson saw this species in two instances only in Norway, and at a distance. The birds were so wild that to approach them was impossible. The same observing ornithologist says that on the wing the Black Woodpecker looks like a crow, and that its notes resemble a loud hoarse laugh.

P. viridis (Genus *Gecinus*, Boie; *Brachylopus*, Swainson). This is the Pic Vert and Pic Vert of the French; Pico Verde, Picchio Verde, and Picchio Pollastro, of the Italians; Grün Specht, and Fichten-, Laub-, Grüner- und Grünlicher-Baumhacker, of the Germans; Wedknar, Gronspik, and Grongjoling of the Swedes; Groenspet of the Danes and Norwegians; Deteu and Detela of Scopoli; Green Woodpecker or Woodspite, Rain-Bird, Rain-Fowl, High-Hoe, Hewhole, Awl-Bird, Pick-a-Tree, Yappingale, Yaffil, Yaffle, Yaffler, Woodwall (!), Whet-Hle, Popinjay, and Poppinjay, of the English; Cnocell y Coed and Delor y Derw of the Welsh.

Male.—Top of the head, occiput, and moustaches brilliant red; face black, upper parts a beautiful green; rump tinged with yellowish; quills regularly marked with whitish on their external bars; tail shaded with brown and striped transversely; base of the lower mandible yellowish; iris white, feet greenish-brown. Total length about 13 inches.

Female with less red on the head and less black round the eyes the moustaches black.

The young at their departure from the nest have a little red upon the head, the rest yellowish ash-colour; all the green paler, and marked on the back with ashy spots; the moustaches formed by some black and whitish spots; the rest of the lower parts greenish-white with transverse brown bands; iris blackish-ash.

Varieties.—Pure white with the head yellowish; the plumage whitish, with the ordinary colours weakly developed; often more or less variegated with white.

Belon seems to confound the Great Black Woodpecker and the Green Woodpecker: his description and figure indicate the latter, but over the cut in 'L'Histoire de la Nature des Oyseaux' (folio, 1555), he writes, "Dryocolaptos, Pipra, Pipo, Chloreaus in Grec, *Picus martius* major, *Picus arborarius* et *Arborum Cavator* in Latin, Pic mart, Pic verd, ou Pic laulne en François;" and below he gives the description of the *Δρυκολάπτης* from the ninth chapter of the ninth book of Aristotle ('Hist. Anlm.), where the Greek zoologist states that the *Δρυκολάπτης* does not perch on the ground, but strikes the oaks to make the worms and insects (*σκύριες*) come forth. Now the Green Woodpecker frequently alights on the ground for the purpose of feeding on emmetts. In the 'Portraits des Oyseaux,' &c. (4to, 1557), over the same figure, is printed "Grec., *Δρυκολάπτης*; Latin, *Picus*

maximus, *Picus martius*, *arborarius*; Italien, Pico, Pichio; François, Pic, Picmart, Pic verd, Pic iaulne, Picumart;" and below it:—

"Le Pic verd iaulne à la Turtrelle a guerre,
Et au Corbeau et au rouge Pic verd.
De plume iaulne il a le corps couvert,
Et ses petits en un trou d'arbre enseerle."

Green Woodpecker (*Picus (Gecinns) viridis*).

Upper figure, adult male; lower, young bird, (Gould.)

This bird is found on the European continent, but not common in Holland, from Scandinavia and Russia to Spain, Provence, and Italy; the wooded districts of Greece; England generally, where there are woods. Not recorded as having been found in Ireland.

This species obtains its food both upon trees and on the ground; its flight is short, undulating, and rather laborious. "When seen moving upon a tree," says Mr. Yarrell, "the bird is mostly ascending in a direction more or less oblique, and is believed to be incapable of descending unless this action is performed backwards. On flying to a tree to make a new search, the bird settles low down on the hole or body of the tree, but a few feet above the ground, and generally below the lowest large branch, as if to have all its work above it, and proceeds from thence upwards, alternately tapping to induce any hidden insect to change its place, pecking holes in a decayed branch, that it may be able to reach any insects that are lodged within, or protruding its long extensible tongue to take up any insect on the surface; but the summit of the tree once obtained, the bird does not descend over the examined part, but flies off to another tree, or to another part of the same tree, to recommence its search lower down nearer the ground."

A very large proportion of the food of this species is derived from ants and their eggs. Every person who has lived in the country must frequently have seen this gay-coloured woodpecker on its feed at some ant-hill. Mr. Yarrell states that he has seldom had an opportunity of examining a recently-killed specimen, the beak of which did not indicate by the earth adhering to the base, and to the feathers about the nostrils, that the bird had been so at work. Bechstein says that in the winter it will take bees from the hive, and that in the house it is

fed on ants, ants' eggs, and meat. Of its manners in captivity the German ornithologist says that the beauty of its plumage is all that can be said of it; for it is so fierce, quick, and stubborn, that it can only be kept chained. It is curious, he adds, to see it crack nuts.

Buffon laments over the hard lot of this bird, always condemned to labour for its existence; and hears in its wild laughing cry exclamations of wretchedness. An animal can hardly be unhappy while obeying an instinct which is associated with enjoyment; and so differently has the sound fallen upon other ears, that it has conveyed the idea of mirth. But Buffon had strange fancies about the happiness and unhappiness of animals.

The nest is generally formed in an elm or ash tree; and when the birds are excavating the hole on which they have pitched for its place, they are said to carry their chips to a distance, for fear their presence on the spot should lead to discovery. The eggs, which are smooth, shining, pure white, are deposited on the bare loose decayed wood, and are from five to seven in number.

Besides the laughing note, which is repeated more frequently and loudly before rain, a low jarring sound is uttered by the adults, and is supposed to be a sexual call. Mr. Yarrell states that the young are fledged in June, and creep about at a short distance from the hole where they were hatched before they are able to fly, and that he has known the young birds taken from the tree and brought up by hand to become very tame and utter a low note not unlike that of a young gosling.

P. major (Genus *Dryobates*, Boie; *Dendrocopus*, Swainson).—This is the Grand Pic Varié and Pic Varié ou Epeiche of the French; Picchio Cardinale Maggiore, Picchio Varia Maggiore, and Picchio Rosso Maggiore of the Italians; Der Bunt Specht, Fichten-, Kieffer-, Laubholz- und Bergbut-Specht, and Grosser Baumhacker, of the Germans; Gylleurena of the Swedes; Hakke-Speet of the Danes; Great Black and White Woodpecker, Greater Spotted Woodpecker, Witwall, Whitwall, Wood Pie, and French Pie (the last in Gloucestershire), of the English: Delor Fraith of the Welsh.

Male.—A transverse whitish band on the forehead; top of the head black; on the occiput a red space; a large black band originates at the angle of the bill, surrounds the temples, and forms a junction with itself upon the nape in one direction, whilst in another it advances, enlarging as it proceeds, upon the breast; back and wings deep black; temples, a patch on the side of the neck, scapulars, middle wing-coverts, and lower parts, pure white; white spots on the two halves of the quills; abdomen and tail-coverts crimson; lateral tail-feathers terminated with white, with some black spots; four middle tail-feathers black; iris red. Length about 9½ inches.

The female has no red on the occiput.

Young before the Moulting.—Forehead gray; all the top of the head of a fainter red than in the adults, interspersed occasionally with a few black feathers; occiput black; black of the plumage generally tinged with brown; white of the lower parts tawnyish, and interspersed with small blackish points.

After the first moult the red on the top of the head disappears, to give place to the black; and the occiput, which is black in the young, becomes red in the adult males. By this peculiarity in the change of the livery the young of this species may infallibly be distinguished from those of *P. leuconotus* and *P. medius*.

The distribution of this bird is extensive, more so perhaps than that of any other European Woodpecker. Denmark, Norway, Sweden, and Russia; Europe generally to Italy inclusive; common in Smyrna (Strickland); England (rarer northward), Scotland, and Ireland.

Mr. Gould observes that the group to which this species belongs, although they occasionally descend to the ground, are far more arboreal in their habits and manners than the Green Woodpeckers represented by the *P. viridis*, *P. caniceps*, and several others from the Himalaya Mountains. "They exhibit," says Mr. Gould in continuation, "great dexterity in traversing the trunks of trees and the larger decayed limbs in quest of larvae and coleopterous insects which lurk beneath the bark, and to obtain which they labour with great assiduity, disengaging large masses of bark, or so disturbing it by repeated blows as to dislodge the objects of their search. Besides searching trees of the highest growth, they are observed to alight upon rails, old posts, and decayed pollards, where among the moss and vegetable matter they find a plentiful harvest of spiders, ants, and other insects; nor are they free from the charge of plundering the fruit-trees of the garden, and in fact commit great havoc among cherries, plums, and wall-fruit in general. Their flight is rapid and short, passing from tree to tree, or from one wood to another, by a series of undulations. In their habits they are shy and reclusive; and so great is their activity among the branches of trees, that they seldom suffer themselves to be wholly seen, dodging so as to keep the branch or stem between themselves and the observer." ('Birds of Europe.')

The editor of Pennant's 'British Zoology' states that this species puts the point of its bill into a crack or the limb of a large tree, and makes a quick tremulous motion with its head, thereby occasioning a sound as if the tree was splitting, which alarms the insects, and induces them to quit their recesses: this, the editor says, it repeats during the spring in the same spot every minute or two for half an hour, and will then fly to another tree, generally fixing itself near the top for the same purpose. The noise, he adds, may be distinctly heard for

half a mile; and he remarks that the bird will also keep its head in very quick motion while moving about the tree for food, jarring the bark, and shaking it at the time it is seeking for insects. Bechstein says that the food of this species consists of insects, beech-mast, acorns, nuts, and the seed of pines and firs; and that, in order to crack nuts, it fixes them in the clefts of the trees. Temminck makes the food to consist of "hannetons" (*Melolonthæ*), bees, grasshoppers, ants, perforating and other larvæ."

The eggs, which are glossy-white, and from four to six in number, are deposited at the bottom of a hole in a tree upon the decayed wood.

The favourite localities of the Greater Spotted Woodpecker are large woods and well-timbered parks. It has been seen, but not so abundantly as the next species, in Kensington Gardens.

Greater Spotted Woodpecker (*Picus (Dryobates) major*).

Upper figure, male; lower, female. (Gould.)

Pennant and others have placed the Middle Spotted Woodpecker, *P. medius*, among the British birds; but there is no safe record of its having been ever seen in this country. The mistake has arisen from the captors supposing the crimson-headed young of the Greater Spotted Woodpecker to be the Middle Spotted Woodpecker, which when in perfect plumage has the top of the head red. The last-named species is now withdrawn from the British catalogue.

P. minor, Linn. This is Le Petit Epeiche and Le Petit Pic of the French; Picchio Sarto Minore, Picchio Piccolo, Picchio Cardinale Minore, and Picchietto Cardinale, of the Italians; Gras-Specht, Garten und Gras Bunt-Specht, Kleiner Bunt-Specht, and Kleiner Baumhacker, of the Germans; Kleinste Bonte Specht of the Netherlanders; Lilla Hackspetten of Nilsson's Scandinavian Fauna; Lesser Spotted Woodpecker, Lesser Spotted Woodspite, Hickwall, and Crauk-Bird, of the English; Delor Fraith Beiaf of the Welsh.

Old Male.—The whole of the forehead, region of the eyes, sides of the neck, and under parts, tarnished white; five longitudinal black lines on the breast and flanks; top of the head red; occiput, nape, upper part of the back and wings, black; on the rest of the upper parts black and white bands; a black band goes from the angle of the bill on the sides of the neck; lateral tail-feathers terminated with white and streaked with black; iris red. Length 5½ inches.

Female.—No red; white of the plumage clouded with brown, with a greater number of spots and black stripes than in the male; the black of the upper parts is also less perfect.

Lesser Spotted Woodpecker (*Picus minor*).

Lower figure, male; upper, female. (Gould.)

This, the least of the European Woodpeckers, but by no means the smallest of the family, is pretty generally distributed over Europe from Scandinavia, and as far east as Siberia, to Italy. It is common in England, and Sir Robert Sibbald claims it as a Scotch bird under the name of *Picus varius minor*, a designation by which it was known to Ray and the earlier writers. In Ireland it does not seem to have been noticed.

Woods, orchards, nursery gardens, and well-timbered parks, are the haunts of this pretty little bird. "In England," says Mr. Gould, "it is far more abundant than is generally supposed; we have seldom sought for it in vain wherever large trees, particularly the elm, grow in sufficient numbers to invite its abode: its security from sight is to be attributed more to its habit of frequenting the topmost branches than to its rarity. Near London it is very common, and may be seen by an attentive observer in Kensington Gardens, and in any of the parks in the neighbourhood. Like many other birds whose habits are of an arboreal character, the Lesser Spotted Woodpecker appears to perform a certain daily round, traversing a given extent of district, and returning to the same spot whence it began its route. Besides

the elm, to which it is especially partial, it not unfrequently visits orchard-trees of large growth, running over their moss-grown branches in quest of the larvæ of insects which abound in such situations. In its actions it is very lively and alert. Unlike the Large Woodpecker, which prefers the trunks of trees, it naturally frequents the smaller and more elevated branches, which it traverses with the utmost ease and celerity. Should it perceive itself noticed it becomes shy, and retires from observation by concealing itself behind the branch on which it rests; if however earnestly engaged in the extraction of its food, its attention appears to be so absorbed that it will allow itself to be closely approached without suspending its operations. When spring commences it becomes clamorous and noisy, its call being an oft-repeated note so closely resembling that of the Wryneck as to be scarcely distinguishable from it. At other times of the year it is mute, and its presence is only betrayed by the reiterated strokes which it makes against the bark of trees." ('Birds of Europe.')

The four or five eggs are deposited in a hole in a tree generally suited to the size of the bird (whereby larger intruders are excluded), and sometimes very deep. They are of a delicate flesh-colour before they are blown, being so transparent that the colour imparted by the yolk is visible; when blown they are of a shining white.

P. tridactylus (Genns, *Picoides*, Lacép.; *Tridactylia*, Stephens; *Dendrocopus*, Koch; *Apternus*, Sw.). This is the Northern Three-Toed Woodpecker of Edwards; *P. hirsutus* of Vieillot; Dreizehiger Specht and Berg und Alpen Dreizehiger Specht of the Germans; Tre-taig Hackspette of Nilsson's Scandinavian Fauna; Picchio a Tre-Dita of the Italians.

Three-Toed Woodpecker (*Picus tridactylus*).

Lower figure, male. (Gould.)

Male.—Forehead variegated with black and white; top of the head golden-yellow; occiput and cheeks lustrous black; a black moustache is prolonged upon the breast; behind the eyes a narrow white stripe, and a larger one below; front of the neck and breast pure white; upper part of the back, sides of the breast, flanks, and abdomen trans-

versely streaked with black and white; wings tarnished black, with some white spots on the quills; part of the upper part of the tarsus covered with feathers; upper mandible brown, lower whitish to the point; iris blue. Length nine inches.

The old male has the yellow of the head more vivid and more white on the lower parts, but the white is always transversely striped with black.

Female.—Top of the head lustrous or silvery-white, variegated with fine black streaks.

This bird inhabits the vast forests in the mountains of the north of Europe, Asia, and America. It is very abundant in Siberia, and common in the Swiss Alps, but rare in France and Germany, where it only passes accidentally; it is never seen in Holland. Such is M. Temminck's account, who adds, in the fourth part of his 'Manual,' that it is never or very rarely found on the summits of the Alps, and that it never passes the elevation of 4000 feet above the level of the sea. It inhabits, he adds, exclusively the forests and valleys at the foot of the Alps, and is very common in Switzerland. Mr. Gould states that it is by no means uncommon in the northern parts of the European continent, the vast forests of the mountainous parts of Norway, Sweden, Russia, and Siberia, forming its principal habitat; that it is also found among the Alps of Switzerland, is but an accidental visitor in France and Germany, and has never been taken, he believes, in the British Islands. Sir John Richardson says that this bird exists in all the forests of spruce-fir lying between Lake Superior and the Arctic Sea, and that it is the most common woodpecker north of the Great Slave Lake.

Insects and their larvæ and wild fruits form the food of this species, which lays four or five pure white eggs in the hole of a tree.

Two other European Woodpeckers (four-toed), namely, *P. canus* and *P. leucnotus*—the first a good deal resembling the Green Woodpecker, and the second not unlike the Greater Spotted Woodpecker—are unknown as inhabitants of the British Islands.

The European Woodpecker seems to have been known to the ancients. Aristotle ('Hist. Anim.' viii. 3), after treating of insectivorous birds, says that there are other insect-eaters (*σκινοφάγα*), as the Greater and Lesser *Pipra* (*Pipo* in Bekker's text), and that some call both these *δρυκολάπτης*, that is, tree-pocker or piercer. These birds, he adds, resemble each other, and have the same voice, but the greater has the loudest. They both obtain their food by flying to the trees. The *Kolids*, or *Kelēds* (Bekker, whose text is the only good one), also, which is the size of the turtle-dove, but whose colour is green entirely. This, Aristotle says, is a great excavator of trees, on which it gets its living, and its voice is very loud. This bird occurs especially in the Peloponnesus. Aristotle then mentions another insectivorous bird, which is called *κνιπολόγος* (gnat or insect catcher), and hollows trees; but this, from its small size and colour, can hardly have been any known woodpecker. In the ninth chapter of the ninth book, Aristotle states that the *Dryocolaptes* does not sit on the ground, but pecks the oaks to make the worms and insects come forth, which it afterwards catches with its tongue, which is broad and large. It runs very quickly upon the trees.

Aristotle mentions three of these *Dryocolaptes*, one smaller than a *Cottophus* (Blackbird probably), which has red spots; a second of the same size as a *Cottophus*; and a third not much less than a hen. It has its nest on trees, especially on the olive-tree, and feeds on emmets and worms which come out of the trees. To get at the worms he hollows out the tree so much, they say, as to cause it to fall. A tame one having adjusted an almond in a chink of wood, broke it at the third stroke and ate the kernel.

Aristotle also mentions the strong and compact bill of the *Dryocopus* in the first chapter of the third book ('De Partibus Anim.').

Pliny appears to use the term *Picus martius* as a general name for all woodpeckers. ('Nat. Hist.' x. 33; xi. 37; xxvi. 4; xxvii. 10; xxx. 16).

P. squamatus. Top of the head and occiput scarlet; above and below the eye a yellowish-white streak; a black line extending from the base of the lower mandible along the sides of the neck; the upper surface of a bright green; quill-feathers and tail dull olive-black, barred with white; throat and breast grayish-green; abdomen and under surface of a still lighter tint, marked with black scales closely and regularly disposed; bill yellowish-white, horn-brown at the base; tarsi brown. Length 12½ inches.

It is found in Asia, in the Himalaya Mountains.

Mr. Gould, from whom the above description is taken, observes, in his 'Century,' that there appears to be a natural group of the Woodpeckers, intermediate between the genus *Colaptes*, whose habits confine them entirely to the ground, and the typical *Picida*, who gain their subsistence almost wholly from the bark of trees. In this intermediate division—of which, he remarks, our own *P. viridis* and the *P. canus* of the continent may be considered as the types, and which are the only species found in Europe—the present species, as well as *P. occipitalis*, also a Himalayan bird, may be classed; all these birds being found, like the typical Woodpeckers, to frequent trees as a resort for food, while at the same time they equally subsist, like the ground-feeding species, on ants and other insects which they obtain on the surface of the ground.

Mr. Gould further states that the locality of *P. squamatus*, as well

as *P. occipitalis*, is believed to be confined solely to the higher parts of the mountains.

Picus squamatus. (Gould.)

P. Shorii. Upper part of the head and elongated crest of the head and rump rich scarlet; a white line, extending from the base of the upper mandible to the occiput, edges the scarlet of the head; a black band originates behind the eye below this white line, passes through the ear-coverts to the back of the neck, and there spreads as far as to the back; cheeks and sides of the neck white, separated from the throat and forehead by a wavy black line passing from the gape to the sides of the chest; base of the lower mandible bordered by a brownish mark; throat white; back orange passing into various tints of scarlet on the shoulders and wing-coverts, and on the rump into bright scarlet; quills, tail, and upper tail-coverts black; under surface dirty brownish-white, with black scale-like marks; bill and tarsi black. Length 12 inches.

It is also found in the Himalaya Mountains.

This three-toed woodpecker exhibits a close affinity with *P. tiga* (Horsf.), an inhabitant of the Indian Archipelago, as well in colouring as in the absence of the hinder toe, which in both birds is represented only by a rudimentary tubercle. Few, if any, of the tribe surpass it in brilliancy of plumage.

P. Cafer (Genus *Trachyphonus*, Ranz; *Cucupicus*, Less.; *Polysticta*, Smith). This is the Promecop of Le Vaillant; *Trachyphonus Vaillantii*, Ranz; *Micropogon sulphuratus*, Latreille; and *Polysticta quopapa*, Smith. This form has been arranged by Mr. G. R. Gray as the last of the sub-family *Buconinae*.

The generic characters of *Trachyphonus*, are as follows:—Bill of the length of the head, convex above, pointed, recurved or arched longitudinally, upper mandible thicker than the lower; nostrils oval, basal, furnished with bristles; tarsi slender; third quill longest; tail rounded.

The birds of this genus are Woodpeckers which seek their food on the ground, and under the bark and in the moss which grows on trees, and indeed the old zoologists termed the species which we have selected as an example a *Picus*. It differs however considerably from the typical Woodpeckers, which has led to its separation, and the generic names applied to it by modern zoologists.

P. Cafer (*T. Cafer*), has the head, belly, and rump yellow; upper coverts of the tail orange; forehead black; two black scanty pointed aigrettes; a large black collar variegated with white, bordered above with a small narrow white edging varied a little with brown below; back of the neck and back brown, each feather terminated with white. Tail rounded, brown, striped with grayish-white; bill black at the point. It inhabits Caffraria.

Picus Shorii. (Gould.)

This species inhabits the forests, and lives on insects and their larvæ which harbour in the moss that grows on trees and under their bark.

Picus (Trachyphonus) Cafer.

P. pileatus (Genus *Dryolomus*, Sw.). This is the Larger Red-Crested Woodpecker of Catesby; Pileated Woodpecker of Pennant and others; Pileated Woodpecker, or Log-Cock of the Anglo-Americans; Moh-keechah Cannashoes of the Cree Indians; Thedd-Dilleh of the Chipewyans.

Male.—Top of the head, occipital crest, and maxillary stripe bright

scarlet. Line bounding the crest laterally from the eye, a band from the nostrils to the side of the nape, thence along the neck to the sides of the breast, the concealed bases of all the quill-feathers, a spot covered by the spurious wing, the chin, throat, and inner wing-coverts pure white. A bar across the orbit and to the middle of the nape, and the rest of the plumage, pitch-black, purest on the quills and tail. Some of the ventral feathers are fringed with gray, and two or three of the greater quills are tipped exteriorly with brownish-white. Bill blackish-gray above, pale horn-colour beneath. Irides golden-yellow. Legs bluish-black.

The female has a yellowish-brown forehead, with darker shafts and a blackish maxillary stripe. Length of a male killed in the winter, 57° N. lat., near the Rocky Mountains, 20 inches.

This bird is not unfrequent in well-timbered forests, from Mexico to Canada, at least to 50° N. lat. (Nuttall.)

Catesby says that these birds (besides insects which they get from rotten trees, their usual food) are destructive to maize by pecking boles through the husks that inclose the grain, and letting in the wet. Sir Jobu Richardson states that the stillness of the primeval shades which it frequents is often invaded by the stroke of its powerful bill, which excels the woodman's axe in the loudness of its sound, and still more in the rapidity with which its blows are urged; nor does it, he adds, fall far short in the quantity of chips it produces. Like other Woodpeckers, it is, he says, extremely industrious, seemingly never a moment idle, flying from tree to tree, and plying its head like a hammer the instant that it alights.

"From the tall trees which cast their giant arms over all the uncleared river lands may often be heard his loud, echoing, and incessant cackle, as he flies restlessly from tree to tree, presaging the approach of rainy weather. These notes resemble ckerck rek rek rek, rek, rek, uttered in a loud cadence, which gradually rises and falls. The marks of his industry are also abundantly visible on the decaying trees, which he probes and chisels with great dexterity, stripping off wide flakes of loosened bark, to come at the burrowing insects which chiefly compose his food. In whatever engaged, haste and wildness seem to govern all his motions; and by dodging and flying from place to place as soon as observed, he continues to escape every appearance of danger. Even in the event of a fatal wound, he still struggles with unconquerable resolution to maintain his grasp on the trunk to which he trusts for his safety, to the very instant of death. When caught by a disabling wound, he still holds his ground against a tree, and strikes with hitherness the suspicious hand which attempts to grasp him, and, resolute for his native liberty, rarely submits to live in confinement." Nuttall further states that this species is without much foundation charged at times with tasting maize, but in winter he observed the bird in South Carolina occasionally making a hearty repast on holly and similar berries.

The female lays about six snow-white eggs in the cavity of a tree. Two broods are said to be produced in a season.

P. principalis. This is the Largest White-Bill Woodpecker of Catesby; Ivory-Billed Woodpecker and Large Log-Cock of the Anglo-Americans.

Black with a gloss of green. Fore part of the head black, the rest of the crest crimson, with some white at the base. A stripe of white proceeding from a little below the eye, down each side of the neck, and along the back (where the two are about an inch apart) nearly to the rump. Tail black, tapering from the two exterior feathers, which are three inches shorter than the middle ones, the feathers concave below. Legs lead-colour. Bill an inch broad at the base, of the colour and consistence of ivory, and channelled. Tongue also white. Iris vivid yellow. Length about 20 inches; alar extent about 30 inches. (Nuttall.)

It is found in Brazil, Mexico, the Southern States, seldom seen to the north of Virginia, and but rarely in that state.

Catesby says that these birds "subsist chiefly on ants, wood-worms, and other insects, which they hew out of rotten trees, nature having so formed their bills, that in an hour or two they will raise a bushel of chips, for which the Spaniards call them 'Carpenteros.' He adds that their bills are much valued by the Canada Indians, who make coronets of them for their princes and great warriors by fixing them round a wreath, with their points outward. The Northern Indians, he tells us, having none of these birds in their cold country, purchase them of the southern people at the price of two and sometimes three buckskins a bill.

Nuttall states that it is a constant resident in the countries where it is found, in the warmer regions, breeding in the rainy season, and that the pair are believed to be united for life.

Wilson, whose 'American Ornithology' is known to every lover of the subject and of nature, wounded one of these birds. His narrative is painful. The Woodpecker did not survive his captivity more than three days, during which he manifested an unconquerable spirit, and refused all sustenance. When he was taken he uttered cries almost like those of an infant; and no sooner was he left alone for an hour, than he so worked, that he nearly made a way through the wooden house in which he was confined. He severely wounded Wilson whilst the naturalist was sketching him, and died with unabated spirit. This unconquerable courage most probably gave the head and bill of the bird so much value in the eyes of the Indians.

Largest White-Bill Woodpecker (*Picus principalis*).

Picus chilensis. (Coquille.)

The four or five white eggs are generally deposited in a hole in the trunk of a cypress tree at a considerable height, at which both the male and the female have laboured, to enlarge and fit it for the purposes of incubation, till it is some two or more feet in depth. About the middle of June the young are seen abroad. Besides the usual arboreal insects, this woodpecker, it is said, is fond of grapes and other berries; but Indian corn, other grain, or any orchard fruit, it does not touch, according to good authorities.

P. Chilensis. Somewhat with little bars of brown and whitish except on the lower part of the back and rump, where a single colour predominates, forming a large patch of pure white; bill black; a gray hood, pencilled with very bright gray, covers the head; cheeks rusty, and throat whitish; all the upper part of the body, wings, and even the great quills, rusty brown barred with small whitish bands; shafts of the quills golden yellow, and their internal part fulvous brown, with a white border or a single spot of the same colour towards the middle; breast, abdomen, and flanks whitish, dotted with brown; colour of each feather yellowish-white, while the middle is occupied by a circle of brown deepest upon the breast. Tail-feathers stiff and wedge-shaped, brown above with a slight fulvous tint brightest below; the two external and the two internal ones are pencilled with whitish sinuous bands upon their edges. Colour of the tarsi greenish; that of the claws approaching reddish. Total length more than eleven inches. (Lesson.)

It is found in the woods of the province of Concepcion in Chili. M. Lesson killed many individuals upon the peninsula of Talcahuano.

The Chilians call this bird *Carpeutero*, a name generally applied by the Spaniards to the Woodpeckers, both in Europe and America.

PICKERINGITE, a name given in America to the Magnesia Alum occurring near Iquique, South America.

PICRIS, a genus of Plants belonging to the natural order *Compositæ*, and the sub-order *Cichoraceæ*. It has an involucre of one row of equal scales, with unequal, linear, often spreading scales at the base; the receptacle is dotted; the fruit terete, transversely striated, constricted, or slightly beaked above; the pappus in two rows, feathery, external row subpilose.

P. hieracioides, the only British species, has rough leaves, with forked and hooked bristles, lanceolate leaves, dentate or sinuated, the upper leaves somewhat clasping; the head solitary, terminating the stem and branches; the outer involucreal scales lax, oblong, bristly on the keel, glabrous on the margin. The fruit constricted just below the pappus. The flowers are a bright yellow colour. This species is found on dry banks in Great Britain.

(Babington, *Manual of British Botany*.)

PICROLITE, a Mineral which occurs massive, with a thin fibrous radiated structure. Colour leek- or yellowish-green. Fracture splintery. Hardness 3.5 to 4. Opaque, or translucent on the edges. Lustre slight, but somewhat pearly. Before the blow-pipe it colours borax green, the colour disappearing on cooling. This mineral is found at Taberg and Nordmorkeu in Sweden, traversing beds of magnetic iron-ore. It is stated also to have occurred at Reichenstein in Silesia. The following is its analysis by Klaproth:—

Silica	40.04
Carbonic Acid	4.70
Magnesia	33.80
Protoxide of Iron	8.28
Water	9.08

—100.90

PICROSMINE, a Mineral which occurs crystallised and also massive. Its primary form is a right rhombic prism. Fracture indistinct, uneven. Hardness 2.5 to 3. Nearly opaque. Lustre dull, vitreous. Colour greenish-white, or sometimes dark green or even blackish. Streak white and dull. Specific gravity 2.58 to 2.66. Before the blow-pipe it gives out water, but does not melt; it becomes black, and then white and opaque, and acquires a hardness = 5.

The massive varieties have a thin and fibrous structure; fracture splintery, granular to compact.

It is found in the iron-mine of Engesburg near Presnitz in Bohemia. According to Magnus it consists of—

Silica	54.88
Magnesia	33.34
Protoxide of Iron	1.30
Protoxide of Manganese	0.42
Water	7.30

—97.33

PICTITE. [TURNERITE.]

PICUMNUS. [PICIDEÆ.]

PICUS. [PICIDEÆ.]

PIG. [SUIDEÆ.]

PIG-NUT. [PICUMNUS.]

PIGEON. [COLUMBIDEÆ.]

PIGEON PEA is the seed of the plant called by Linneus *Cytisus Cajan*, and by De Candolle *Cajanus bicolor* and *Cajanus flavus*. It is a kind of pulse highly esteemed by all classes of the natives of India, and is by them regarded as holding the third rank among such articles of food.

PIGMENT. In certain parts of the animal organism we meet with definite and well-marked colorations, not dependent on any peculiar

arrangement of fibres, &c., but on the presence of pigment-granules of various colours. These granules are usually inclosed in cells, termed pigment-cells. In all races of men we find a most remarkable development of these cells on the inner surface of the choroid coat of the eye, where they form several layers known as the *Pigmentum Nigrum*. They are probably always mingled with the epidermic cells, giving rise in the dark races to the deep colour of the skin; and presenting themselves in the white races in the form of freckles, the areola round the nipple, &c. The pigment-cells are usually flat and laterally compressed into the polygonal form. The granules in their interior are extremely minute, retain their dark colour under high magnifying powers, but exhibit various forms. In the choroid membrane of the human eye their form is very regular (fig. 1); in the adult no nucleus can be

Fig. 1.

Cells from the choroid coat of an adult.

seen, a structure which is obvious in corresponding cells from the fetus (fig. 2). [EYE.] The pigment-cells have not always a simple

Fig. 2.

Similar cells from a fetus at the third month.

rounded or polygonal form; they sometimes present remarkable stellate prolongations and other singular shapes, which we have attempted to depict in fig. 3, representing pigment-cells from a frog: a, b, c, d, e,

Fig. 3.

and g (fig. 3), are representations of various pigment-cells from its choroid coat, while f is introduced to exhibit the stellate shape in which these cells occur on the skin of that animal. The nucleus is sufficiently obvious in one of the cells in a, c, d, e, and g.

Little is known of the chemistry of the animal pigments. Scherer has made three analyses of the black pigment from the eye of the ox, from which he concludes that it consists of—

Carbon	58.284
Hydrogen	5.918
Nitrogen	13.768
Oxygen	22.030

—100

From these analyses it appears probable that the black pigment contains a larger amount of carbon than any other constituent of the animal body. The absence of these cells in the tissues produce those varieties of animals called *Albinoes*. [ALBINOS.]

PIGOTITE, a Mineral consisting of an organic acid called mudic-acid and ammonia.

PIKE. [ESOX.]

PIKE, SEA. [CENTROPOMUS.]

PILCHARD. [CLUPEIDÆ.]

PILE-WORT. [RANUNCULUS.]

PILE'OLUS. [NERITIDÆ.]

PILEOPTSIS, Lamarck's name for a genus of *Mollusca* (*Capulus* of De Montfort), which name has the priority, whose place in the system was long doubtful.

The form was arranged by Linneus under his genus *Patella*, with the name of *Patella Ungarica*.

Lamarck divided his genus *Pileopsis* into two sections: the first consisting of those species whose shell was without any known support (*Pileopsis*, Lam., *Capulus*, Montf.); the second consisting of those species whose shell had a known support (*Hippomyx*, DeFrance).

Hipponyx (DeFrance).—Animal oval or subcircular, conical, or depressed; bead globular, carried at the extremity of a sort of neck, on each side of which is a tentacle convex at its base, and terminated by a small conical point; eyes placed on the tentacular convexity; mouth with two small labial tentacles; foot very delicate, thickened towards its borders, which lessen and enlarge like those of the mantle, to which it bears a complete resemblance; branchia situated above the origin of the back; anus at the right side of the cervical cavity; oviduct terminated in a large tubercle at the root of the right tentacle.

Shell conoid or depressed, the apex not spiral; aperture with irregular edges; cavity deep, with a muscular impression in the form of a horse-shoe; a rounded lamellar support, or an impression on the body serving as the resting-place of the animal, presenting also a muscular impression of a horse-shoe shape. (Rang.)

The number of living species given by M. Deshayes in his tables is six; in the last edition of Lamarck the number is three:—*H. acuta*, *H. foliacea*, and *H. suturalis* of M. Quoy; the first from the seas of Australia, and the last two from the island of Guam in the archipelago of the Marianne Islands. To these, according to his own showing, *Patella Australis* should be added; and also the *Patella mitrata* of Linnæus.

The genus is marine, and has been found attached to stones and shells at depths varying from the surface to 16 fathoms.

H. acuta has the shell solid, ovate, thickly striated longitudinally, the margin crenulated, violaceous; the vertex long, acute, and straight; white internally.

It is found in the seas of Australia.

Pileopsis (Lam., *Capulus*, Montf.).—Animal conical, slightly spiral at the summit, furnished with a distinct bead which has a proboscis terminating the mouth; in front of the anterior border of the foot is a double membrane forming numerous folds; the tentacles are nearly cylindrical, stout, obtuse, and carry the eyes on small convexities a little above their external base; foot large, but very anterior and delicate; mantle simple and without ornament; branchial cavity open anteriorly; branchia composed of many narrow and longitudinal laminae, which adhere by a single transversal line to the plafond; orifice of the anus towards the right side of that cavity.

Shell irregular, conical, with the apex more or less inclined or spiral, directed backwards; aperture rounded, with simple, irregular, and continuous borders; cavity deep, offering a muscular impression in form of a horse-shoe, open anteriorly. (Rang.)

This genus, like *Hipponyx*, is entirely marine, and has been taken adhering to shells and stones at depths ranging from the surface to 20 fathoms. The Pacific, the East and West Indies, and the coasts of Europe, are the localities principally known.

The number of living species recorded by M. Deshayes in his tables is seven, and of these one, *Pileopsis Ungarica*, is noted as recent and fossil (tertiary): the number given in the last edition of Lamarck is six, to which, as we have seen, *Patella Galathea* and *P. tricotata* are to be added.

P. Ungarica has the shell conico-acuminate, striated; the vertex

uncinate and revolute; aperture rather wider transversely; rosy within. The epidermis is somewhat bony, thick, and velvety.

It is a native of the Mediterranean and the shores of the Atlantic. Abundant on our own coasts. One of the best figures we know is given by Mr. G. B. Sowerby in his 'Genera' (No. xxxviii.)

Fossil *Hipponyx* and *Pileopsides*.—Lamarck has described some fossil species among the *Patellæ* under the name of *P. Cornucopia* and *P. dilatata*; and Mr. G. B. Sowerby ('Genera') states that all the species known are from the Calcaire Grossier: (but see below).

The number of fossil species (tertiary) recorded by M. Deshayes in his tables is 12, and a 'new species' is noted as both living and fossil (tertiary). The localities for these fossils are Sicily, Italy (Sub-Ap.), Bordeaux, Dax, Touraine, and Turin. Paris is given as the locality for eight. In the last edition of Lamarck six is the number recorded, including *Hipponyx Cornucopia*.

a, external view of the upper valve; b, internal view of the same; c, inside of lower valve.

Pileopsis.—Mr. G. B. Sowerby states that he is not acquainted with many recent species, but that several are common among the fossils of the tertiary beds. M. Deshayes, in his tables, gives the number of fossil species (tertiary) as six, *P. Ungarica* being both recent and fossil (tertiary, Baden); the other localities being Sicily, Italy (Sub-Ap.), the English Crag, Bordeaux and Dax, and Touraine.

Professor Phillips records *Pileopsis* (?) *trilobus*,* *P. tubifer*, *P. striatus*, *P. neritoides*, *P. vetustus* (?), and *P. angustus*, from the Mountain-Limestone Formation of Yorkshire and other districts. ('Illustrations of the Geology of Yorkshire,' part ii.)

Mr. Murcbison, in his catalogue of the shells of the Middle Ludlow Rock, records the only imperfect specimen yet obtained from the Aymestry Limestone: the aperture appears less expanded than in the *Pileopsis vetusta* of the Carboniferous Limestone. ('Silurian System.')

PILL-BEETLE. [BYRRHUS.]

PILL-WORT. [PILULARIA.]

PILOT-FISH. [CENTRONOTUS.]

PILULARIA, a genus of Plants belonging to the natural order *Marsileaceæ*. *Marsileaceæ* are creeping plants with alternate erect leaves, having a circinate venation; the fructification consisting of globular, nearly sessile, coriaceous bodies, with three or four cells, and containing sacs including either other bodies that germinate or loose granules. [SALVINIACEÆ; SPOROCARPIUM.] According to this definition it embraces only the genera *Pilularia* and *Marsilea*. The genus *Pilularia* has solitary involucre, nearly sessile, globose, coriaceous, 4-celled; the cells containing bodies of two kinds, granules and membranes containing minute grains. Of this genus there is but one species, *P. globulifera*, which on account of the form of its fruit is called Pill-Wort or Pepper-Grass. This plant is a native of Europe, and is found in Great Britain on the extreme margin of ponds or on swampy ground covered with water during the winter and comparatively dry in the summer. It is interesting to the systematic botanist, as affording a high development in the organs of reproduction in the class of Acrogens to which it belongs. The granules contained in the cells ultimately become seeds, and have a very definite form of germination.

(Jussieu, *Mémoires de l'Académie Royale des Sciences*; Valentine, in the *Transactions of the Linnean Society*, vol. xviii.)

* *Pileopsis* is generally considered to be feminine.

PILUMNUS (Leach), a genus of Brachyurous Crustacea. This genus very much resembles the Crabs properly so called; but differs from them principally in the number of pieces in the abdomen of the male, and is removed from them still further by the mode of insertion of the external antennæ.

Pilumnus hirtellus, Leach (*Cancer hirtellus*, Linn.), is found on the coasts of England and France; generally found under stones.

(Leach, *Malac. Brit.*, t. 12; Penn., *Brit. Zool.*, vol. iv. pl. 6, lower figure.)

PIMELITE. [NICKEL.]

PIMENTA, or **PIMENTO**. [EUGENIA.]

PIMPERNEL. [ANAGALLIS.]

PIMPINELLA, a genus of Umbelliferous Plants inhabiting the meadows and mountains of Europe principally, is chiefly interesting on account of its comprehending among its species the Anise of the shops. This plant is an annual, with a smooth stem one to one and a half foot high; the lower leaves roundish, cordate, lobed, and both serrated and cut; those of the stems pinnated with wedge-shaped lanceolate segments, and the upper trifid, with the lobes undivided and linear. The flowers are small and white. The fruit is narrow, slender, rather hairy, with five filiform ridges to each mericarp. The latter is employed extensively as a carminative medicine, and for the purpose of flavouring liqueurs. The plant inhabits Egypt and the islands of the Grecian Archipelago, especially Scio.

PINACEÆ. [CONIFERÆ.]

PINE. [PINUS.]

PINE-APPLE. [ANANASSA; BROMELIACÆ.]

PINGUICULA, a genus of Plants belonging to the natural order *Lentibulariaceæ*. It has a 2-lipped calyx, the lower lip bifid, the upper one of three segments. The corolla ringent and spurred.

P. vulgaris has a subulate spur shorter than the limb of the corolla, whose segments are very unequal, oblong, obovate, rounded, separated, entire. The leaves are all radical, fleshy, and covered with minute crystalline points, pale-green; and when the plant is gathered, they curve back so as to hide the root. The flowers are purple. It is found in bogs in England.

P. grandiflora has a spur whose segments are very unequal, broadly obovate, rounded, contiguous; the middle one of the lower lip notched. This is much larger than the former species: the flowers are large, of a deep purple colour. It is found in Ireland about Kerry and Cork.

P. alpina is known by its conical spur being shorter than the unequal limb of the corolla, and curved upwards. The flower is small and yellowish. It is found in Skye and Ross.

P. Lusitanica has a cylindrical spur, obtuse, decurved, shorter than the nearly equal limb of the corolla; the capsules globose, scape downy. It is found in the western parts of this country. These species derive their common name (Butterworts) from the greasy appearance of their foliage. Like other marshy plants they have been said to produce flukes in the sheep that feed upon them. This however is attributable rather to the larvae of the fluke, which adhere to the leaves of plants in marshy districts, and are thus taken in by the animal, than to any peculiarity in the *Pinguicula*. When mixed with cow's milk, the juice of this plant acts like rennet and produces a curd; but Linneus says that when rein-deer's milk is poured on the leaves warm, and allowed to stand for a day or two, it becomes acescent, acquires consistence, neither the cream nor serum separates, and it is much esteemed by the Swedes and Norwegians.

(Burnett, *Outlines of Botany*; Babington, *Manual of British Botany*.)

PINGUITE. [IRON.]

PINITE, a Mineral which occurs in imbedded crystals. Primary form a rhomboid, but generally found in hexagonal prisms. Cleavage parallel to the lateral faces of the prism. Fracture indistinct, uneven. Hardness, scratches gypsum, is scratched by flour-spar. Colour reddish, grayish, and grayish-red. Lustre slightly resinous. Opaque. Specific gravity 2.78 to 2.98.

Before the blow-pipe on charcoal it whitens, fuses on the edges, and yields a white glass with bubbles; with borax it fuses with difficulty into a transparent glass, coloured by iron. The Saxon variety is infusible.

It is found in Saxony, France, England, in some other parts of Europe, and in North America.

According to Gmelin, the Pinite of St. Pardoux in France consists of—

Silica	55.964
Alumina	25.480
Potash	7.894
Soda	0.386
Peroxide of Iron	5.512
Magnesia, with Manganese	3.760
Water, with Animal Matter	1.410
—100.406	

PINK. [CARNATION; CARYOPHYLLACÆ; DIANTHUS.]

PINK, a name for the Minnow. [LEUCISCUS.]

PINK-UNDERWING. [CALLIMORPHA.]

PINNA. [MYTILIDÆ.]

PINNOTHERIDÆ, a family of the Brachyurous Crustacea (*Cata-*

metopes), called Pinnotherians by M. Milne-Edwards, and known by the common name of Pea-Crabs.

They are small crustaceans whose carapace is nearly circular, and whose teguments exhibit considerable softness. Their eyes are in general very small, and the disposition of their front and their antennæ varies, as also their external jaw-feet, which present remarkable anomalies. Their feet are short or of moderate length, and are in general very weak. The abdomen of the male is much narrower at its base than the corresponding part of the sternal plastron.

But it is the singular habits of these crustaceans which especially demand attention; for they ordinarily are housed between the mantle-lobes of certain *Conchifera*—*Mytilus*, *Pinna*, *Macra*, &c., for example.

M. Milne-Edwards arranges in this small group the genera *Pinnotheres*, *Doto*, *Mictyris*, *Hymenosoma*, and *Elamena*; but he acknowledges that this tribe is not so natural as might be desired, and that hereafter perhaps the necessity for subdividing it may arise.

Pinnotheres (Latreille).—Body circular and rounded above; front not soldered to the epistome; eyes very small, orbits nearly circular; internal antennæ of the ordinary form, and the fossæ which lodge them scarcely separated from each other; external antennæ short, occupying the internal angle of the orbit. Buccal frame very wide backwards, and describing a semicircle forwards. External jaw-feet placed very obliquely; their enlarged and valvular portion is formed entirely by their third joint, which is very large, whilst the second is rudimentary; the fourth joint is inserted at the summit of the preceding, and the fifth, which is tolerably developed, is articulated with the sixth by the middle of its internal border, so that it is placed nearly like the thumb of the didactylous claws. The sternal plastron is very wide, and in the male the apertures of the organs of generation occupy its last segment. The feet are moderate. The abdomen of the male is small, whilst that of the female is ordinarily very convex, and much larger than the sternal plastron. (M. Milne-Edwards.)

View of the under side of the upper part of *Pinnotheres*, eyes, jaw-feet, &c., seen from below and magnified. (Milne-Edwards.)

Mr. J. V. Thompson was the first who pointed out the interesting fact that the species, in the early stages of their existence, have a very elongated abdomen which is terminated by a fin, the carapace armed with three spiniform prolongations, very large eyes, and natatory feet; in short that it then bears the greatest resemblance to *Zoea*.

These curious animals were known to the ancients, who were not ignorant of their connection with the *Pinna*. The Greeks named them *Πιννοθήρας* and *Πιννοφύλαξ*. (Arist., 'Hist. Anim.' v. xv.) Oppian ('Halieut.' il. line 186, et seq.) treats the connection as a sort of partnership for obtaining prey. The *Pinnotheres* of Pliny ('Nat. Hist.' ix. xxxi.), described as harbouring in the empty shells of oysters, and as migrating to others when it increased in growth, appears to have been more applicable to the *Pagurus* of the moderns; but the same author, in the 42nd chapter of the same book, "De Pinna, et Pinnothere, et aquatiliu sensu," uses the terms *Pinnotheres* and *Pinnophylax* to designate the Crab which resides in the shell of the *Pinna*.

Among the moderns Hasselquist has given one of the best accounts of the habits of the genus. In a letter to Linneus, dated "Smyrna, December 16, 1749," he says, "The *Pinna muricata*, or Great Silk Muscle, is here found in the bottom of the sea in large quantities, being a foot long. The *Ὠκτώπους*, or Cuttle-Fish with eight arms, watches the opportunity, when the muscle opens her shell, to creep in it and devour her; but a little crab, which has scarcely any shell, or has at least only a very thin one, lodges constantly in this shell-fish; she pays a good rent by saving the life of her landlady, for she keeps a constant look-out through the aperture of the shell, and on seeing the enemy approach, she begins to stir, when the *Pinna* (for so the Greeks call the shell) shuts up her house, and the rapacious animal is excluded. I saw this shell-fish first at the island of Milo, and found such a little crab in all I opened: I wondered not a little what was her business there; but when I came here, I was first informed of it by the secretary of our consul, Mr. Just, a curious and ingenious man, who has travelled much, and lived long in this place. This was afterwards confirmed by several Greeks, who daily catch and eat both these animals."

M. Milne-Edwards remarks that the distinction of the species of this genus is difficult, inasmuch as that the principal differences to be remarked in the greater part of them do not exist in both sexes, and are often of the nature of those which are modified by age.

P. Pisum, the Pea-Crab. Carapace soft; front projecting in the male, not reaching beyond the curved line formed by the anterior part of the carapace in the female. Inferior border of the hands ciliated. Length: female, 4 lines; male, 2 lines.

This species is very common in *Mytilus edulis* on the coasts of England and France. Leach, 'Malac. Brit.' t. 14, f. 2, 3 (female); *P. varians* of the same work, t. 14, f. 10 and 11 (male); *P. Latreilli* of the same work, t. 14, f. 7 and 8 (young female.) (M. Edwards.)

M. Milne-Edwards is of opinion that *P. Cranchii*, Leach ('Malac.' t. 14, f. 4, 5), does not differ specifically from *P. Pisum*.

P. veterum is found in *Pinne* on the coasts of Italy, &c.

Pinnotheres veterum.

Elamena (M. Edwards) is founded on *Hymenosoma Mathæi*, figured by M. Rüppell, in his work on the 'Crustacea of the Red Sea,' and separated from that genus by M. Milne-Edwards, who thinks that it seems to establish the passage between the *Hymenosomata*, the *Oxytomes*, and the *Oxyrhynchi*.

E. Mathæi (Rüppell, 'Krahnen,' pl. v., f. 1), is found in the island of Mauritius and the Red Sea.

Hymenosoma (Leach).—Carapace very much flattened above, and nearly circular; the front very narrow and inclined. Orbits very small, and nearly circular, and the eyes must be bent back downwards rather than outwards to be hidden in them.

M. Milne-Edwards remarks that hitherto this genus has been arranged in the neighbourhood of the *Inachi*, principally on account of its narrow and pointed front; but its natural position appears to him to be in the family of the *Catamtopes*, for it is to this type that it approaches in all the important points of its organisation.

H. orbiculare is found at the Cape of Good Hope.

Hymenosoma orbiculare.

a, internal antenna; b, external antenna; c, right external jaw-foot; d, abdomen of the male; e, abdomen of the female.

Mycteris (Latreille).—Carapace extremely delicate, nearly circular, and very convex above. Front disposed nearly as in the *Ocyropodes* [OCYROPIDÆ]; but the eyes, which are short and stout, have no orbital cavity for concealment, and always remain projecting.

M. longicarpis has the carapace smooth and divided by furrows into three longitudinal portions; a small spine at the spot where the

Mycteris longicarpis.

external orbital angle is ordinarily found; anterior border of the carapace very much projecting, and furnished with hairs.

It is a native of Australia.

Doto (M. Edwards).—M. Milne-Edwards remarks that he here places, not without doubt, a small and very remarkable crustacean which Savigny has figured in the great work on Egypt, and which M. Audouin has referred to the genus *Mycteris*. It approximates to the *Ocyropodes* much in the general form of the body, in that of the feet, and in the disposition of the front, the antennæ, and the eyes; but it is distinguished from all the preceding *Catamtopes* by the conformation of the external jaw-feet and the form of the buccal frame.

D. sulcatus (*Cancer sulcatus*, Forsk.; *Mycteris sulcatus*, Audouin). has the carapace nearly square, and furrowed above; the front orbital border occupying nearly the whole of its width. Length about six lines.

It inhabits the Red Sea.

Doto sulcatus, enlarged.

a, profile view, still more enlarged, without the legs, to show the grooves; b, detail of under part of carapace.

PINNULARIA, a genus of Fossil Plants.

PINTADO. [PAVONIDÆ.]

PINTAIL DUCK. [DUCKS.]

PINUS, a genus of Gymnospermous Exogenous Plants, consisting for the most part of timber trees, inhabiting various temperate countries in the northern hemisphere. They are commonly called Pine-Trees, and are distinguished from the Firs by their leaves, always evergreen, and needle-shaped, growing in pairs, threes, fours, or fives, surrounded by a membranous sheath at their base. In reality each parcel of leaves indicates a small branch axillary to a membranous, deciduous, withering leaf. The species are generally of great beauty as objects of ornament, or of much value on account of their timber, and are in much request by the planter: on which account we give a very brief enumeration of the best known species.

Div. I. Scales of Cones truncate at apex.

a. Leaves in pairs.

* Scales of Cones spineless at apex.

1. *P. sylvestris*, the Scotch Pine. Trunk erect. Leaves 2, short, glaucous. Cones ovate, stalked, and recurved, with rugged, truncated, depressed scales. This is the most hardy and valuable of all the pines. Its timber furnishes the red deal of the carpenters, and in Scotland,

the climate of which country is particularly suited to it, the trees often acquire a great size, and highly picturesque appearance. It is however asserted that the quality of its timber is much deteriorated by being grown in warm districts. In England it is chiefly valued as a nurse to other trees, for which its hardness and rapid growth render it well adapted. It forms an excellent screen in exposed sandy situations, where no other tree will thrive. Many varieties are known, of which an account will be found in Loudon's 'Arboretum Britannicum'; of these the Pine of Haguenau, a village on the Rhine, is said to be the most important.

2. *P. pumilio*, the Dwarf Pine. Trunk prostrate, dwarfish. Leaves 2, short, stiff, glaucous. Cones ovate, spreading, sessile, with depressed truncated scales. A small mountain species from the midland parts of Europe. Its timber is of no importance; in fact, from its small size, it can scarcely be said to yield any. It is probably an alpine form of *P. sylvestris*.

3. *P. uncinata*, the Hooked Pine. Trunk erect. Leaves 2, short, dark green. Cones oval, recurved, sessile, with pyramidal, recurved, truncated, or mucronated scales. A fine alpine tree, from the Pyrenees, and other European mountains, on the upper zone of vegetation, above *P. sylvestris*. It is extremely valuable for its hardness and the great durability of its timber. The *P. Mughus* is apparently the same plant.

4. *P. resinosa*, the Red Pine. Trunk erect, lofty. Leaves 2, long, of a light somewhat glaucous green colour. Cones ovate-oblong, very obtuse, shorter than the leaves, pendulous, with rugged, rounded, truncated scales. A red-barked tree of large size from the northern parts of North America. The wood is fine-grained and of close texture, and is highly esteemed in Canada for strength and durability. In appearance the species bear some resemblance to *P. Laricio*.

5. *P. Halepensis*, the Aleppo Pine. Trunk slender, erect. Leaves 2, long, slender, light green. Cones ovate, stalked, solitary, very regular in form, with depressed truncated scales. A beautiful species, found wild in the western parts of Europe, from Genoa to Constantinople, and also throughout Syria. It grows fast, and is at once known by its fine light-green foliage; but its wood is not of much value, and it bears the climate of England with impatience.

6. *P. Bruttia*, the Calabrian Pine. Trunk erect. Leaves 2, slender, lax, pale green, very long. Cones sessile, in dense clusters, ovate, acute, very regular and even, with depressed truncated scales. A very handsome tree, inhabiting Calabria, and said to yield timber of excellent quality. It is very like the Aleppo Pine, but its cones are sessile and clustered, and it is much more hardy.

7. *P. Banksiana*, the Banks Pine. Trunk low, scrubby and straggling. Leaves 2, divaricating, oblique. Cones ovate, acuminate, horn-like, curved, erect, in pairs, gray, with rounded depressed truncated scales. An ugly tree, from the most southern parts of North America, where it is called the Scrub Pine and the Gray Pine. Its timber seems to be of little value, except for the construction of canoes, for which its lightness and toughness render it well adapted.

8. *P. Pyrenaica*, the Pyrenean Pine. Trunk erect. Leaves 2, long, fine, bright green, clustered at the end of the branches. Cones ovate, drooping, shorter than the leaves, with roundish truncated scales. A Spanish plant, inhabiting the Sierra de Segura, above the limits of the Aleppo Pine, on the Pyrenees, and elsewhere. Its timber is said to be of excellent quality and to have been used largely in the Spanish marine. It is reported to be a majestic species, and to be called by the Pyrenean peasants Pin Nazon. It is the *P. Hispanica* of some collections.

9. *P. Pallasiana*, the Pallas Pine. Trunk erect, with horizontal branches when old. Leaves 2, dark green, very long, and stiff. Cones curved, horizontal, ovate-oblong, as long as the leaves, with roundish truncated scales. A fine tree from the central parts of the Crimea, with the habits of the Pinaster. Wood resinous and durable, but difficult to form into good planks on account of being unusually knotty. The resin is stated to be very pleasant to the smell.

10. *P. Pinea*, the Stone Pine. Trunk erect; when old, flat-headed. Leaves 2, long, stiff, dark-green; when the plant is very young, small and glaucous. Cones roundish, polished, with rounded truncate scales. Seeds large, oblong, with a very short wing. An inhabitant of the southern parts of Europe and the Levant, where the wood is often used in ship-building, and the seeds, which are large and like nuts, are eaten.

11. *P. Austriaca*, the Black Pine. Trunk erect, with horizontal branches when old. Leaves 2, dark-green, glossy, straight, stiff, from 3 to 5 inches long. Cones conical, horizontal, shorter than the leaves, polished, and pale-brown. It is found among the rocks and precipices of Southern Germany, and derives its name from the peculiar dark colour of the foliage. The most sterile soil is said to suit it. The timber is reported to be valuable, but coarse; and to resist alternate dryness and moisture better than the larch.

12. *P. Laricio*, the Corsican Pine. Trunk very erect and tall. Leaves in pairs, long, deep green, distant, rather loose. Cones ovate, horizontal, shorter than the leaves, with roundish rugged truncated scales. A noble tree, from the mountains of Corsica, Greece, Turkey, and Spain. It grows faster than any other known species, and produces excellent timber, similar in quality to red deal, but more brittle and less elastic. The French use it extensively in ship-building. The tree is now becoming common in this country.

** Scales of Cones spiny at apex.

13. *P. Pinaster*, the Cluster Pine. Trunk lofty, erect. Leaves 2, long, stiff, dark green. Cones clustered, recurved, conical, shorter than the leaves, with pyramidal scales terminated by a small rigid spine. A noble species, inhabiting the most sterile sandy plains of France and Southern Europe, especially along the coast. Its timber is soft, light, coarse, and only fit for very common purposes; but it affords a large quantity of resin and tar, and is much consumed in the manufacture of lampblack. It is this species that has been so successfully employed in fixing the loose drifting sand of the barren plains of some parts of France.

14. *P. pungens*, the Prickly Pine. A large tree. Leaves 2, short, compact, pale green. Cones ovate, clustered, drooping, longer than the leaves, with hard pyramidal scales terminated by a stiff strong spine. A native of Virginia and North Carolina. The timber seems of no value. The aspect of the tree is something like that of the Scotch Pine, but it is paler. Its cones hang on the branches for many years.

15. *P. mitis*, the Yellow Pine. A fine tree. Leaves 2, long, slender, dark green. Cones ovate, pendulous, shorter than the leaves, with depressed roundish scales, armed with a small spine. Young shoots violet. A common inhabitant of the pine-forests of North America, as far north as Connecticut and Massachusetts. Its timber is of great value for domestic and naval architecture, provided the sapwood, which is very perishable, is first removed. It is regarded as a most durable timber in this country. In America it ranks next in quality to the *P. Australis*, or Southern Pine. *P. variabilis* is one of its garden names.

16. *P. inops*, the Jersey Pine. A low gnarled tree. Leaves 2, dark-green, from 2 to 3 inches long. Cones recurved, ovate-oblong, straight, longer than the leaves, with spiny spreading scales. Young shoots violet. A native of the more southern states of the American union. Its timber is of little use except for fuel. In this country it is usually a miserable-looking species, evidently unsuited to the climate. Like the Banks Pine, it is called Scrub Pine in the United States.

b. Leaves in threes.

* Scales of Cones spineless at apex.

17. *P. sinensis*, the Chinese Pine. A large tree. Leaves 3, slender, deep green, serrulated. Cones ovate, brownish, on short stalks, with flattened truncate unarmed scales. Native of China. Very little is known of it, except from Chinese drawings. It only exists in the garden of Mr. Wols, of Redleaf, near Tunbridge, where it is found to be 'tolerably hardy.'

18. *P. insignis*, the Noble Pine. Leaves 3, grass-green, a little wavy, irregularly arranged, longer than the cones. Cones ovate, bright brown, obtuse, with rounded depressed obtuse scales, the lowermost of which are longer than the others, and more or less hooked back. A beautiful species, native of California, remarkable for its bright dense grass-green foliage. Nothing is known of its native habit. It is rather too tender for the latitude of London.

19. *P. Canariensis*, the Canary Pine. Trunk stout, erect. Leaves 3, very long, rough-edged, wavy, grass-green. Cones oblong, woody, 5 or 6 inches long, with prominent large pyramidal straight-scales, terminated by a hard blunt callosity. A native of the mountains of Tenerife and Canary, where it forms large forests, and often acquires an enormous size. The timber is said to be very resinous and durable. The species is too tender for England.

20. *P. Ocote*, or *Teocote*, the Ocote Pine. Leaves 3, wavy, rough, light-green. Cones obtuse at the base, ovate, smooth, with pyramidal-angular blunt scales. A Mexican plant, of which little is known. It is found on Monte Orizaba, and near Real del Monte, and forms a tree 100 feet high.

21. *P. patula*, the Spreading-Leaved Pine. Leaves 3, very slender, spreading. Cones ovate, oblong, polished, with small angular truncated prominent scales. Native of Mexico. A lofty tree, with leaves 8 or 9 inches long. It occurs in the northern provinces of Mexico.

** Scales of Cones spiny at the apex.

22. *P. australis*, or *P. palustris*, the Southern Pine. Trunk erect, very cylindrical, and stiff. Leaves 3, very long, grass-green, clustered at the ends of the branches. Cones ovate-oblong, 7 or 8 inches long, with depressed scales, armed in the middle with a small prickle. A native of Virginia and the neighbouring states of America to the south, where it acquires the height of from 60 to 70 feet. Its timber is of excellent quality.

23. *P. Teda*, the Frankincense Pine. Trunk lofty, straight. Leaves 3, pale-green, stout, straight. Cones curved, oblong, the length of the leaves, with compressed woody prominent scales, armed with a sharp point. A tree said to acquire the height of 80 feet, in the barrens of Florida and Virginia, but not much known in England, where it seldom thrives.

24. *P. rigida*, the Pitch Pine. Trunk lofty, straight, much branched. Leaves 3, of variable lengths. Cones clustered, sessile, ovate, with rugged compressed pyramidal scales, terminated by a small hooked spine. Found in poor soil in most parts of the United States, and even inhabiting salt-marshes overflowed by the sea.

25. *P. serotina*, the Pond Pine. Trunk much branched. Leaves 3,

very long (5 or 6 inches). Cones roundish-ovate, in pairs, with prominent rounded scales, armed with a firm short brittle prickle. An obscure species. Found in America.

26. *P. ponderosa*, the Heavy-Wooded Pine. Trunk very rugged, and irregularly branched. Leaves 3, very long and strong. Cones small, oblong, with strong pyramidal scales terminated by a small recurved prickle. A large tree, with the habit of the Corsican Pine. Found in North-West America.

27. *P. Sabiniana*, the Sahine Pine. Trunk straight, erect; the young shoots covered by a glaucous bloom. Leaves 3, very long and lax, glaucous, and serrated. Cones very large, roundish ovate, with large pyramidal hooked scales. A noble Californian tree. The wood is white, soft, and not durable.

28. *P. Coulteri*, the Coulter Pine. Trunk straight, erect; the young shoots covered with a glaucous bloom. Leaves 3, very long and stiff, glaucous, and serrated. Cones very large, oblong, with long wedge-shaped rigid woody horned scales. A fine tree, from California.

29. *P. longifolia*, the Long-Leaved Pine. Trunk erect, with a coarse rugged bark, and whorled branches. Leaves very long, drooping, slender, bright-green, channelled, and serrated. Cones shorter than the leaves, oblong-ovate, woody, and rugged, with pyramidal obtuse mucronate corky recurved scales. Seeds large, eatable. An Indian species, inhabiting the valley and lower hills of Nepal.

30. *P. Gerardiana*, the Neoza Pine. Trunk lofty, with a conical head. Leaves 3, short, stiff, glaucous, obsolete serrated, with deciduous sheaths. Cones very like those of *P. longifolia*. Seeds large, eatable. A native of the coldest forests of the Himalayas.

c. Leaves in fives.

* Scales of Cones spineless at apex.

31. *P. ovocarpa*, the Egg-Fruited Pine. Leaves 5, slender, from 8 to 11 inches long. Cones roundish, ovate, polished, hard, with truncated scales. Found in the pine-region of Mexico.

32. *P. leiophylla*, the Smooth-Leaved Pine. Leaves 5, very slender, 3 or 4 inches long, rough-edged, light green. Cones ovate, 2 inches long, on a short stalk, with truncate depressed scales, a little hollowed. An inhabitant of the cold regions of Mexico.

33. *P. Montezuma*, the Montezuma Pine. Leaves 5, rather rigid, rough-edged, about 6 inches long. Cones ovate, oblong, bright-brown, about as long as the leaves, with elevated rugged truncated scales. A native of the mountains of Mexico.

34. *P. filifolia*, the Thread-Leaved Pine. Leaves 5, from 12 to 15 inches long, acutely triangular. Cones sessile, ovate-acuminate, woody, hard, curved, 9 inches long, 3 inches in diameter at the base, with lozenge-shaped pyramidal depressed scales, and a hard woody compressed callous mero in the middle. A noble pine, found in Guatemala by Mr. Hartweg.

35. *P. Acapulcensis*, the Acapulco Pine. Leaves 5, thin, short, very glaucous, as well as the shoots. Cones pendulous, ovate, acute, whorled, with pyramidal erect tapering scales, often contracted in the middle. Found in Mexico.

36. *P. pseudostrobus*, the False Weymouth Pine. Leaves 5, very fine, and glaucous. Cones ovate, whorled, horizontal, about 4 inches long, by an inch and a half in breadth over the middle, with pyramidal erect scales. A Mexican pine.

37. *P. Russelliana*, the Bedford Pine. Leaves 5, very long. Cones tapering, horizontal, a little drooping, nearly straight, from 7 to 8 inches long, about 2 inches wide near the base, and almost acute at the upper end, with pyramidal straight obtuse scales. A native of Mexico near Real del Monte.

38. *P. Devoniana*, the Devonshire Pine. Leaves 5, very long. Cones pendulous, solitary, horn-shaped, from 9 to 10 inches long, about 3 inches in diameter near the base, and tapering to 1½ inches, with rounded obtuse polished scales. It is called in Mexico *Pino blanco* or *P. real*, forming a high tree 60 or 80 feet high, between Real del Monte and Regla.

39. *P. Hartwegii*, the Hartweg Pine. Leaves 4, very slender, about 6 inches long. Cones pendulous, oblong, obtuse, clustered, about 4 inches long, with depressed truncated scales, having a projecting callosity in the middle. It is a Mexican tree, 40 or 50 feet high. The cones are of a clear grayish-brown, and of nearly the same diameter throughout.

** Scales of Cones spiny at apex.

40. *P. occidentalis*, the West Indian Pine. Leaves 5, pale green, slender, much longer than the cones. Cones ovate-oblong, obtuse, stalked, with rounded angular prominent scales, tipped by a sharp prickle. It is a native of St. Domingo.

41. *P. macrophylla*, the Long-Leaved Pine. Leaves 5, from 14 to 15 inches long. Cones straight, horizontal, ovate, tapering, solitary; 6 or 7 inches long, and about 3 inches broad at the base, with the ends of the scales strongly hooked backwards. It is a small tree from the north of Mexico.

Div. II. Scales of Cones flat, and compressed at the apex.

42. *P. Cembroides*, or *P. Llaveana*, the Mexican Cembra. Leaves 3, short, tufted, glaucous, and twisted. Cones small, roundish-ovate, hard, with elevated roundish obtuse scales. Seeds large, eatable. It

is a small Mexican tree, occurring in large forests, and producing seeds similar to those of the Stone and Neoza Pines.

43. *P. Cembra*, the Cembra Pine. Tree erect, conical. Leaves 5, with no sheath, short, stiff, glaucous-green. Cones ascending, oblong, about the length of the leaves, with thin callous-pointed scales. Seeds large, without wings. It is a tree of considerable size, inhabiting the sides of mountains in Siberia, Tartary, Switzerland, and Italy.

44. *P. Strobus*, the Weymouth Pine. Trunk erect, very long. Leaves 5, slender, bright green, without sheaths. Cones narrow, long, pendulous, from 5 to 6 inches long, with thin ovate callous-pointed scales. It is a native of Canada.

45. *P. excelsa*, the Lofty Pine. Trunk erect, very lofty. Leaves 5, bright green, distinctly glaucous on one side, with no sheath; leaves narrow, long, pendulous, stalked, from 6 to 7 inches long, with thin lax ovate callous-pointed scales. It is a fine Himalayan tree, bearing the climate of England without protection.

46. *P. Lambertiana*, the Lambert Pine. Trunk erect, very lofty. Leaves 5, rather stiff, bright green, roughish, with no sheaths. Cones very large, pendulous, from 14 to 18 inches long, with broad rounded scales. Seeds large, eatable. It is an enormous tree, found by Douglas in New Albion.

47. *P. Ayacahuite*, the Ayacahuite Pine. Leaves 5, with deciduous sheaths, slender, very glaucous on one side, sharp-pointed, from 2 to 4 inches long. Cones drooping, a foot or more long, very slender, with distant oblong-lanceolate obtuse spreading scales. It is a gigantic tree, resembling the Weymouth Pine in habit; found by Ehrenberg near Omitlan in Mexico, and by Hartweg in Guatemala.

The following species of Pine are mentioned in books:—*P. Californiana* or *P. Montereyensis*, *P. Timoriensis*, *P. muricata*, *P. tuberculata*, *P. radiata*, *P. contorta*, *P. squamosa*, and *P. turbinata*.

(London, *Arboretum et Fruticetum Britannicum*, vol. iv.; Lambert, *Monograph of the genus Pinus*.)

PIPA. [AMPHIBIA.]

PIPE-CLAY. [CLAY.]

PIPE-FISH. [SYNGNATHUS.]

PIPE-MOUTH, a Fish, the species of *Fistularia*. [FISTULARIA.]

PIPER, a genus of Plants belonging to the natural order *Piperaceae*. It has stamens varying in number from 1 to 10; stigma 3-lobed; fruit baccate.

P. Cubeba, Linn., is generally regarded as the source of the official Cubebs; but, according to Blume, *P. canicum*, Rumph., which is the *P. Cubeba* of Roxburgh, yields the greater portion of the cubebs of commerce. The fruits of both are stalked, but that of the former is larger and has more pungency than the latter. Both are common in Java, where, as in other parts of India, they are used as a grateful condiment, as common pepper is in Europe. They are also employed medicinally in the same complaints as give them repute in Europe.

The berry is small, about the size of black pepper-corns (but with a little foot-stalk, from one-third to half an inch long, hence called sometimes *P. caudatum* or *P. pedicellatum*), more or less round, of a blackish-gray or grayish-brown colour, with a thin vascular reticulated husk, which incloses a hard round oily seed. The husk has a pleasant taste; the seed a bitterish, acrid, peppery, aromatic, and camphor-like flavour.

Those which come from the islands of the Indian Archipelago are the best. A sort from the Mauritius, small, or about the size of a millet-seed, are from some unknown species. The Guinea or African cubebs is the produce of *P. Afzeli*.

Indian cubebs are frequently adulterated with black pepper, pimento berries, or the fruits of the *Rhamnus catharticus*. Genuine cubebs consist of waxy matter, two kinds of volatile oil, a peculiar resin (cubebin), balsamic resin, &c.

The volatile oil by rest deposits a camphor, which crystallizes in four-sided plates. The resin is analogous to that of copaiva, and has, like it, a peculiar influence over mucous membranes, especially those of the urino-genital organs.

P. longum, Long Pepper, a native of the East Indies, the female spike of which having attached to it the dried half-ripe berries (resembling the catkin of the birch), is used in medicine. It has nearly the same chemical composition and properties as black pepper, though feeble. It is said to contain piperin. The root is employed by the Hindoos, but it is still weaker than the fruit.

P. nigrum, Linn., Black Pepper, a climbing plant of the East Indies, and very extensively cultivated there, the plantations stretching from 96° to 115° E. long, 5° S. lat. to 12° N. lat., which limits comprise Sumatra, Borneo, the Malay Peninsula, and all countries to the east of the Gulf of Siam. The best pepper comes from Malabar, the least esteemed from Java and Sumatra. The plant is allowed to grow, trained to the stem of the *Areca Catechu*, and other trees, especially the Jack (*Artocarpus*) and *Hyperanthera Moringa* (or Horse-Radish-Tree), four years before the fruit can be collected. The berries are gathered when yet green, before they are perfectly ripe, and quickly dried on mats, by which they turn black. When plucked too young, they speedily fall into a state of powder. These are separated from the others by sieves and winnowing. In this condition it is termed black pepper. White pepper is the same fruit freed from the outer rind: for this purpose, the ripe berries are allowed to macerate in water, and the husk is removed. These are smaller, smooth, of a

grayish-white colour, varying to yellow, with a less powerful odour and taste than the black.

1, *Piper nigrum*. a, portion of the spike of *Piper aromaticum*; b, a section of its fruit; c, its embryo.

P. Belle, Linn., and *P. Siriboa*, Linn. The leaves of these two species are extensively used by the natives of the East Indies, and lately of the West, to chew along with the nut of the *Areca Catechu* and quicklime, as a restorative of the powers of the stomach and promoter of digestion. It is capable however of producing, like some other species of *Piper*, intoxicating effects, and should be used in moderation.

(Curtis, *Botanical Magazine*, t. 3132.)

PIPER, a Fish. [TRIGLA.]

PIPERACEÆ, a small natural order of incomplete Exogenous Plants, composed of climbing or creeping plants with alternate or opposite exstipulate leaves, jointed stems, and spiked naked flowers consisting of an ovary containing a single erect ovule, and of from two to an indefinite number of stamens. The fruit, when ripe, is more or less fleshy, indehiscent, and contains a single seed filled with albumen, on the outside of which, inclosed in a vitellus, is a minute embryo. Jussieu originally regarded these plants as members of the Urticaceæ order; but afterwards separated them, in which he has been followed by all botanists. There is however some difference of opinion as to their class, some regarding them as Exogens, and others as Endogens. The general properties of the order are aromatic, as in the peppers of the shops. [PIPER.]

PIPILLO. [TANAORINÆ.]

PIPING CROW. [BARITA.]

PIPIT. [ANTHUS.]

PIPPUL-TREE. [FICUS.]

PIPRA. [PIPRINÆ.]

PIPRIDÆ, the name given to a family of *Dentirostres*, by Mr. Vigors.

M. Lesson, who adopts Mr. Vigors's family, makes the *Pipridæ* consist of the genera *Rupicola* and *Calyptomena* [RUPICOLINÆ], *Pipra*, *Pardalotus*, and *Pachycephala*.

Mr. Swainson does not admit the family *Pipridæ*, but he makes the *Piprine* a sub-family of the *Ampelidæ*. [PIPRINÆ.]

PIPRINÆ, Mr. Swainson's name for the Manakins, which he makes a sub-family of the family *Ampelidæ*, Fruit Eaters, or Chatterers, and thus characterises:—Size small. Feet lengthened, slender, weak. Bill very short: the upper mandible much curved.

Mr. Swainson is of opinion that the *Piprine*, called Manakins from their diminutive size, which is seldom larger than that of a tomtit, constitute the subtypical group of this family.

Phanircircus, *Pipra* (with its sub-genus *Metopia*), *Calyptura*, and *Pardalotus*, are the genera arranged by Mr. Swainson under this sub-family.

Phanircircus (Sw.).—Size and habit of *Ampelis*. Bill small, rather weak. Wings very short, convex, rounded: the three first quills narrow, and of equal length; the fourth much shorter, and ending in a point. Tail broad, even. Feet short, strong; toes syndactyle; tarsi feathered, on their inner side only, as far as the toes; claws strong, curved. (Sw.)

P. carnifex (*Ampelis carnifex*, Linn.) is fire-red, with a bright red cap; back red-brown; breast blood-red; tail-feathers purple, termi-

nated by ruddy-black. Female reddish; abdomen ochraceous; front reddish.

The Caribs designate this magnificent bird by the names Arara and Apira. It is a native of Brazil, Guyana, and Surinam.

Phanircircus carnifex.

Pipra (Linn.).—Size very small. Bill weak; the upper mandible bent over the lower, which is flattened and nearly straight; notch small. Wings more or less rounded. Tail short, even. Toes syndactyle.

P. strigilata. Male the size of a wren; a patch or cap of fire-colour covers the head; all the upper part of the body uniform grass-green; all the lower parts yellow striated with brown; bill brownish; feet yellowish.

Female.—Not differing from the male, except in the absence of the red cap on the head.

It is found in Brazil.

P. aureola. Red; back, wings, and tail, black; throat yellow. It is found in Guyana.

Pipra aureola.

Metopia (Sw.).—Front with an elevated compressed crest. Wings lengthened, very broad. Tail broad, lengthened, rounded. (Sw.)

M. galeata (*Pipra galeata*, Licht.). Black. Frontal crest, directed forwards over the culmen of the bill, rich crimson, which colour is also continued over the head and back of the neck; feet and legs reddish-brown. It is a native of Brazil.

Calyptura (Sw.).—Bill short, strong, robust, shrike-like; the sides somewhat gibbous; the notch deep and tooth-like. Under mandible strong. Wings short, rounded. Tail remarkably small, almost concealed. Feet lengthened, slender, toes syndactyle. (Sw.)

C. cristata. Crown red; upper parts brownish or olivaceous green; rump yellow; throat and breast yellowish; abdomen brighter yellow; feet and legs black. It is a native of Brazil.

Pardalotus (Vieill.).—Bill as in *Calyptura*. Wings long, pointed; the first three quills of equal length. Tail short, even. Feet strong; lateral toes free and equal. (Sw.)

P. punctatus. Male gray above, undulated with yellow; head and wings black, dotted with white; a white line above the eye; rump

*Metopia galeata.**Calypura cristata.**Pardalotus punctatus.*

fire-red; abdomen whitish; throat yellow. The female has the head dotted with yellow points.

It is a native of Australia.

Mr. Caley states that this species is called Diamond Bird by the settlers, from the spots on its body. He adds that it is reckoned a valuable bird on account of its skin, that it is not very plentifully met with, and that it inhabits both forest-land and brushes, at least

he had seen it in both. ('Description of the Australian Birds in the Collection of the Linnæan Society,' Vigors and Horsfield, in 'Linn. Trans.,' vol. xv.)

Mr. G. R. Gray makes the *Piprinæ* the second sub-family of the *Ampelidæ*, *Pachycephalinæ* being the first; and he arranges under it the following genera:—1. *Phanircircus*, Sw. (*Pipra*, Wagl., *Ampelis*, Linn., *Querula*, Cuv.). 2. *Metopia*, Sw. (*Pipra*, Licht.). 3. *Pipreola*, Sw. 4. *Pipra*, Linn. (*Manacus*, Briss.). 5. *Pipracidea*, Sw. 6. *Iodopleura*, Sw. (*Pardalotus*, Less.). 7. *Calypturna*, Sw. (*Pardalotus*, Vieill.; *Regulus*, Licht.).

PIRE'NA. [MELANIA; MELANOPSIS.]

PIRIMETA (Leach), a genus of Brachyurous Crustacea. It is placed by M. Milne-Edwards among the Cancriniens Arqués, or those crabs which have no clypeiform prolongation on the sides of the carapace, which is much wider than it is long, arched in front, and strongly truncated on each side posteriorly.

Carapace regularly arched on its anterior moiety, and strongly truncated on each side of its posterior moiety; much wider than it is long; convex, and strongly bossed. The front narrow, and armed with three pointed teeth. The latero-anterior borders are directed very obliquely backwards and outwards, and are armed with four compressed and triangular teeth. The orbits present two teeth and two fissures above, a sharp tooth at the external angle, and a fourth at the internal and inferior angle.

P. denticulata is found on the coasts of Europe, England, and France.

*Pirimela denticulata.*

PISA. [MAIIDE.]

PISCICOLA, a name for the *Hirudo Piscium*. [ANNELIDA.]

PISCICULUS, a generic name for the Sticklebacks. [GASTER-OSTEUS.]

PISCIDIA (from 'piscis,' a fish, and 'cædo,' to kill or destroy), a genus of Plants belonging to the natural order *Leguminosæ*. It has a campanulate 5-cleft calyx, an obtuse keel, and a papilionaceous corolla. The stamens are monadelphous, with the tenth one free at the base. The style is filiform and smooth, the legume pedicellate linear, furnished with four membranous wings, the seeds separated by a spongy substance. The species are West Indian trees, with broad unequally pinnate leaves and terminal panicles of white and red flowers mixed.

P. erythrina, Dogwood, is a tree about twenty feet high. The leaflets are in pairs, from 3 to 4 together; they are oblong or obovate, rounded at the base, downy on both sides when young, but smooth when old. The racemes are compound, axillary, staminal. The flowers whitish tinged with purple. This plant possesses the peculiar property of intoxicating fish; the bark of the root is the part used. Dr. Hamilton, in a paper read before the Medico-Botanical Society of London, gives a lengthened account of this process and of the properties and uses of this plant. He says that a preparation of the root is infused into the water containing the fish, which soon rise to the top. They float perfectly insensible along, and are easily taken by the hand; they recover on being thrown into pure sea-water, and neither their flavour nor wholesomeness is in any degree impaired. The same gentleman made a series of experiments on himself as to the effect of a tincture of this plant. Labouring under an attack of severe toothache, he took a powerful dose of the tincture, which was succeeded by a profound sleep and entire relief from pain on awaking. As a topical application to carious teeth he found it equally successful, and came to the conclusion that the tincture of the Dogwood is more powerful than that of opium. The root-juice is used to poison the arrows with which birds are shot in the Antilles. It is said to be an effectual remedy for mango in dogs: it is also reputed to possess tanning qualities. It is one of the best timber-trees in Jamaica; the wood is coarse, heavy, resinous, and almost imperishable, lasting equally well in or out of water; hence it makes excellent piles for docks and wharfs.

P. Carthaginensis is a native of Jamaica, Guadeloupe, and Carthage, on the mountains. It closely resembles the former species, and is scarcely distinguishable from it.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

PISCIS. [FISH.]

PISIDIA. [PORCELLANIDÆ.]

PISIDIUM. [CYCLADIDÆ.]

PI'SODUS, a genus of Fossil Fishes.

PI'SOLITE, or *Pea-Stone*, a variety of carbonate of lime, which occurs in globules from one-eighth to half an inch in diameter, imbedded in a calcareous cement; they usually consist of concentric lamellæ, in the midst of which is generally a grain of sand.

PISSODES. [CURCULIO.]

PISSOPHANE, a Mineral occurring amorphous. Colour pistachio, asparagus, or olive green. Fracture conchoidal. Harness 1·5. Very fragile. Lustre vitreous. Transparent. Specific gravity 1·93 to 1·98. It is found at Garnsdorf, near Saalfeld. Its analysis, by Erdmann, gives:—

Sulphuric Acid	12·593
Alumina	35·228
Peroxide of Iron	9·769
Water	41·695

—99·285

PISTACIA, a genus of Plants belonging to the natural order *Anacardiaceæ*. It has decolous, apetalous flowers. The male flowers with the raceme amentaceous, with 1-flowered bracts; calyx 5-cleft; stamens 5; anthers subsessile, 4-cornered. Female flowers with the raceme more lax; calyx 3-4-cleft; ovary 1-3-celled; stigmas 3, rather thick. Drupe dry, ovate, with a somewhat bony nut, usually 1-seeded and 1-celled. Seeds solitary, each without albumen.

P. vera, a small tree, or large bush, from 15 to 20 feet high; its leaves are alternate, unequally pinnate, without stipules, and consist of from 3 to 5 oval blunt leathery smooth leaflets. The flowers are small, and arranged in short branched racemes from the old wood; some are male and others female; the latter are succeeded by dry drupes about the size of an olive, of a reddish colour, with a very thin rind, a brittle 2-valved shell, and contain a single almond-like seed with a green embryo. The tree is originally from Asia Minor, but is now naturalised all over the South of Europe, where the fruit is in request for confectionary and for the dessert, under the name of Pistachio Nuta.

Pistacia vera.

1, a male flower; 2, a female; 3, a ripe fruit; 4, a seed cut transversely.

P. Terebinthus is a native of Syria and the Greek Archipelago, a smaller plant than the last, but much like it.

P. Lentiscus is a bush found on the coasts of the Mediterranean. The leaves are evergreen, equally pinnate; leaflets 8 to 12, usually alternate, with the exception of the two upper, which are opposite, oval, lanceolate, obtuse, often mucronate, entire, and perfectly smooth. Flowers very small, in axillary panicles, similar to those of the other species; fruits very small, pea-shaped, reddish when ripe. The sweet fragrant stimulant resin called *Mastic* is obtained from the trunk by incisions made in the month of August. It is used to strengthen and preserve the teeth and in diarrhoea. [MASTICH, in ARTS AND SC. DIV.]

PISTIACEÆ, *Lemnææ*, or Duck Weeds, a natural order of Endogenous Plants. The species are floating or land plants with very cellular, lenticular, or lobed fronds or leaves, some of them wholly destitute of spiral vessels, except perhaps in the pistil. The flowers appearing from the margin of the fronds 2 or 3, naked, inclosed in a spathe, but without a spadix. In the male flowers the stamens are definite, often monadelphous: in the female flowers the ovary is 1-celled, with one or more erect ovules; style short, stigma simple, ovules anatropal, hemianatropal, or atropal. Fruit membranous or capsular, not opening, one or more seeded; seeds with a fungous testa and a thickened indurated foramen; embryo either in the axis of fleshy albumen and having a lateral cleft for the emission of the plumule, or at the apex of the nucleus, covered in by a hardened endostome.

The common Duck-Weed *Lemna* may be regarded as the most simple of all Phænogamous Plants. It inhabits the ditches of the cooler parts of the world. [LEMNA.] *Pistia* is found in the tropics; *Ambrosinia* in the basin of the Mediterranean.

P. stralioites grows in water-tanks in Jamaica, where, according to Brown, it is acrid, and in hot dry weather impregnates the water with its particles so as to become injurious. There are 6 genera and 20 species in this order.

(Lindley, *Vegetable Kingdom*.)

PISTIL, the name applied to the chauged leaves called Carpels, which are found in the centre of the flower. This part ultimately becomes the Fruit. [FRUIT.] The term pistil is applied to these organs, whether there is but one or many of them, or whether they are united or separate. The carpel consists of three parts: the Ovary or germeu, generally of a spherical form, and hollow, containing the ovules; the Style, an elongated organ, formed of a continuation of the tissue of the ovary, possessing a canal in communication with the interior of the ovary; and the Stigma, which is the point or summit of the style. The carpels, like all other parts of the flower, are modifications of the leaf, and examples of their reversion to their normal form are not unrequent. This is well seen in the double cherry, in which the pistil often appears as a little leaf in the centre of the flower. The blade of the leaf corresponds to the ovary of the carpel; the midrib, which is elongated, to the style; and the stigma is nothing more than a secreting surface at the point of the style, communicating with the interior of the ovarial leaf. The carpel presents two sutures, called dorsal and ventral. The first of these corresponds with the midrib of the leaf, and the latter with the folded margins. The ventral suture is always opposite the axis of the plant, and is the point from which the Placenta is developed, to which the young ovules are attached.

When there is only one carpel in the flower, it is called a simple pistil; but when there are several carpels, they are called a compound pistil. The carpels of a compound pistil may be either united or separate. When they are united, they are called by Lindley Syncarpous. This union may occur between the ovaries only, leaving the styles distinct, as in *Nigella damascena*; or the ovaries, styles, stigmas, and all may be united, forming one body, as in the tulip. When the carpels are all separate, as is seen in *Caltha*, *Ranunculus*, &c., the pistil is said to be apocarpous.

The Pistil is either superior or inferior. When it is placed on the receptacle on the same plane or above the other organs of the flower it is called superior. It frequently however contracts a union with the parts of the calyx, or it sinks into the receptacle, and the calyx and corolla are placed above it; it is then called inferior.

The structure of the pistil differs according to the modes of its origin. Like every newly forming part of a plant, it consists originally of uniform delicate parenchyma, in which an epithelium on both the outer and inner surfaces is distinguishable. Gradually, but sometimes not till a late period, or in certain cases not at all, the vascular bundles are organised from the parenchyma; in the single carpel there is usually one main bundle, corresponding with the central rib of the leaf, and two others at the edges of the leaf; in many-membered 1-celled germens, the latter are frequently wanting. In rare cases the vascular bundles are ramified in the same way as in the leaf, which indeed is the natural consequence of their morphological import, since germen and style correspond to the sheath and petioles which are supplied with only a few vascular bundles. The stamen on the other hand corresponds to the lamina, and is so imperfectly developed that in most instances it contains no vascular bundles. In a few cases, interesting modifications of cellular tissue are presented in the interior of the germen; yet oil-passages or vittæ [UMBELLIFERÆ], milk-vessels, and cells containing crystal, &c., occur here and there. The external epithelium of the outer surface is commonly soon changed into epidermis, which often exhibits stomates, and under this the parenchyma is somewhat lax and almost spongy. The surface of the germen exhibits all the various appendages of young epidermis, hairs, prickles, glands, &c. The formation of the epithelium of the inner surface is more important; it is sometimes developed with the next subsequent layers into a true epidermis, but only in the cavity of the germen, as in *Passiflora* and some *Crucifera*. On the stigma it is converted, either partially or entirely, into papillæ, as it also is sometimes in the canal of the style, if this is distinctly hollow; and in the cavity of the germen along the placenta, as far as the ovules, where the papillæ frequently become long hairs. All these papillæ commonly secrete at the time of the perfecting of the pistil an adhesive substance, containing gum or sugar, the stigmatic fluid. A similar substance is frequently secreted in the intercellular spaces of the cellular layers lying immediately beneath the epithelium of the stigma and the styles, and often so copiously that the cells are loosened from their union with one another, and lie loosely imbedded in this mucilaginous semi-fluid matter. The process may be easily followed in the *Orchidaceæ* and the *Onagraceæ*.

The Style is not at all essential to the existence of the carpel, and is frequently absent. When present, it is composed of just the same tissues as the ovary, which in most cases consist of vascular surrounded by cellular tissue. The style varies in form and size; sometimes it is flat, as in the *Iris* and *Canna*, but is mostly cylindrical and filiform. It generally proceeds from the apex of the ovary, but in some cases, from an alteration in the position of the ovary, it proceeds from other parts besides the apparent apex, as from the side in *Alchemilla*, and from the base in *Lamiaceæ* and *Boraginaceæ*. The length of the

style varies very much; in some plants, as in *Colchicum*, it is 7 or 8 inches long, whilst in the *Nymphæaceæ* and *Papaveraceæ* it can hardly be said to exist at all. The canal of the style was first discovered by Malpighi. It is a continuation of the cavity of the ovary, and terminates in the surface of the stigma. This canal varies in extent in different places, in some being very narrow, and in others very wide. It is lined with a peculiar kind of cellular tissue, having a papillary character, and is covered with a viscous secretion. It is called by Brongniart 'tissu conducteur,' or conducting tissue, on account of its supposed office in conducting the pollen tubes from the stigma to the ovule.

The style is often covered with hairs, which, on account of their supposed office of clearing the pollen from the cells of the anthers, have been called collectors. Sometimes these hairs are united together into a kind of cup around the stigma, as in *Goodeniaceæ*, when they form what is called an Indusium.

The Stigma is composed of the same kind of tissue as the interior of the canal of the style, but has a more spongy appearance. Its papillary character also is more evident, and the little swellings on its surface are often called papillæ. These papillæ become less evident as the canal of the style approaches the ovary. The stigma assumes a variety of forms, the distinction of which is often of importance in systematic botany. These forms depend principally upon the tissue of which its surface is composed. Sometimes the papillæ are developed into little hairs, as is seen in the stigma of *Urtica urens*. In other cases it is perfectly smooth, as in *Nymphæaceæ*. In rhubarb it is composed of three flat orbicular discs. In grasses it is in the form of a tufted hairy body like a little brush. In *Mimulus* it has two lips which have the power of contracting, and in *Clarkia* it consists of four broad lobes. In *Orchidaceæ* it has a structure in accordance with the anomalous character of all the parts of the flower in these plants; it consists of an oval humid space which occupies the middle of the central column, and is covered with a thick viscous secretion. In some cases however the stigma is not distinguishable from the style, as in *Asclepias* and *Tupistra*.

The position of the stigma is sometimes anomalous. As it forms the apex or point of the carpellary leaf, it ought always to be alternate with the placenta, which are formed at the margins of the leaf, but in *Cruciferae* the stigmata are opposite the placenta. This may be explained in two ways. Dr. Lindley supposes that in this order there are originally four carpels, two of which being abortive, the stigmata are left opposite the placenta. Brown on the contrary supposes that the stigmata are originally 2-lobed, and that the lobes have united on each side, and thus obtained their abnormal position. [SEED; REPRODUCTION IN PLANTS.]

PISTACITE. [EPIDOTE.]

PISUM, a genus of Plants belonging to the natural order *Leguminosæ*, and the tribe *Viciæ*. It has a calyx with foliaceous segments, the two upper ones being shortest; the vexillum ample, reflexed; the style compressed, carinated, villous above; the legume oblong, rather compressed, but not winged; the seeds globose, numerous, with a roundish hilum.

P. sativum has two or many-flowered peduncles, with red or white flowers, and is the common pea of our fields and gardens.

P. arvense has 1-flowered peduncles and always red flowers, and yields the gray peas of the fields. [PEAS, in ARTS AND SC. DIV.]

P. maritimum, the Sea-Pea, has an angled stem, the petiole flattened on the upper side; the stipules broad, sub-sagittate; the peduncles many-flowered, shorter than the leaves. This plant is a native of France, Denmark, and other parts of Europe, and also of Kamchatka. In Great Britain it is found on the pebbly beach of Lincolnshire, Sussex, Kent, and Suffolk. It is said to have been first observed in Great Britain, at Orford in Suffolk, in the year 1555, when during a great scarcity of food the poor people of that district were almost entirely supported for some time by its seeds. There is a tradition that it sprung up after the wreck of a vessel loaded with peas on the coast, but this could not be the case, as the Sea-Pea is a very different species from any other. The seeds are bitter, and cattle are fond of the herb. There are three or four other species of pea, affording edible seeds, but not so valuable as the first.

PISUM (Zoology), Megerle's name for a genus of Conchiferous *Mollusca* (*Pisidium*, Leach), separated from *Cyclas*.

PITCHBLEND. [URANIUM.]

PITCH-PLANTS. [LEAF; NEPENTHACEÆ.]

PITCHSTONE, a Mineral occurring massive. Structure compact, sometimes slaty, occasionally curved. Fracture imperfectly conchoidal. Hardness 5.0 to 6.0. Colour brown, black, gray, red, &c., and variously mixed. It is generally dull, but has sometimes a resinous vitreous lustre. Translucent. Opaque. Specific gravity 2.3 to 2.7. It occurs at Meissen in Saxony, at Newry in Ireland, and in the island of Arran, and other places.

Analysis of Irish Pitchstone by Knox:—

Silica	72.80
Alumina	11.50
Soda	2.85
Lime	1.20
Protoxide of Iron	3.03
Water	8.50

Pitchstone is also applied to a Siliceous Rock of igneous origin, generally occurring in dykes which traverse the strata, or in overlying columnar masses. Among recent volcanic rocks its analogue is Obsidian. M'Culloch gives the characters of Pitchstone in the following leading divisions:—

1. Simple: a, amorphous, massive; b, concretionary.

2. Porphyritic: Pitchstone-Porphry of mineralogists.

3. Concretionary spheroidal: Pearlstone of mineralogists.

4. Amygdaloidal: containing imbedded zeolites, &c.

The colours are extremely various; the texture varies from almost glassy to granular, and thus allows of passage into Hornstone.

PITH is a cellular substance found in the centre of the branches, but not the roots, of Exogenous Plants. [EXOGENS.]

PITHE'CIA. [SAKIS.]

PITHE'CUS. [APE; CHIMPANZEE; ORANG-UTAN.]

PITHYS. [MERULIDÆ.]

PITONNELLUS, De Montfort's name for a genus of Turbinate Testaceous Gastropods, *Rotella* of authors. [TURBINIDÆ.]

PITPIT. [DACSIS.]

PITTA, M. Vieillot's name for a genus of remarkable birds, placed by Mr. Swainson among the *Myiotherine*, or Ant-Thrushes. [MERULIDÆ.]

Pitta (Vieill., Temm.).—M. Lesson remarks that, under the name of *Myiothera*, Illiger and Cuvier united the Brèves of Buffon and the Ant-Thrushes properly so called. These Brèves are remarkable, he observes, for the vivid colours of their plumage, their long legs, and their very short tail. They are only found, he adds, in the Malasian Islands, whilst the Ant-Thrushes belong to the New Continent as well as to the Old World.

Mr. Swainson notices the genus *Pitta* as one of remarkable beauty, and observes that they have the gradually-curved bill of the true Thrushes, but much stronger.

P. gigas, Brève Geant, or Giant Pitta. Size equal to that of a magpie, but the tail is short and squared, and the wings cover it entirely. A very brilliant azure-blue covers the back, the scapulars, the rump, and tail; a less vivid tint is spread over the wings, the quills of which are black, covered with azure towards the tips; summit of the head, nape, and demi-collar of the lower part of the neck black; feathers of the front and eye-brows ashy-brown; throat whitish; an ashy-brown tint is spread over all the lower parts; the feet are very long and of a horny-ash colour. Total length 9 inches.

It is found in Sumatra. (Temminck.)

Giant Pitta (*Pitta gigas*).

Sub-Genus *Chlorisoma*. (Sw.)

C. thalassinum (*Kitta thalassina*, *Piroll Thalassina*, Temm.). Greater part of the plumage very brilliant celadon-green; a velvety black band springs at the angle of the bill, passes backwards so as to include the eye, and surrounds the occiput; tail deep tarnished green; wings reddish, but the three or four secondary feathers nearest the body are

opaline bluish-ash; iris, bill, and feet, very bright vermillion-red. Total length 11 inches 2 or 3 lines.

The male and female have nearly the same livery.

The Young of the Year differ in the colour of their bill and feet, which are black; in that of the wings, which is a tarnished rusty-red, and in the very clear blue, which is nearly whitish, of all the rest of the plumage. This blue tint is more vivid in middle age, and passes by degrees from bright azure-blue to celadon-green. Individuals during moult have the plumage varied with these two tints very vivid and pure.

It is a native of Java and Sumatra. (Temminck.)

Chlorisoma thalassinum.

Sub-genus *Grallaria*. (Vieill.)

G. Rex (Roi des Fourmilliers, Buff.; King-Thrush, Lath.; *Turdus Rex*, Gmel.). Brown, inclining to red, lighter beneath; occiput plumbeous; forehead varied with black and white.

It is a native of South America, Guyana, and Brazil especially.

King-Thrush (*Grallaria Rex*).

PITTOSPORACEÆ are Polypetalous Exogenous Plants with a definite number of hypogynous stamens, a superior 1- or 2-celled ovary, which in the former case has parietal placentas, numerous ovules, a single style, and hard seeds containing a very small embryo in the region

of the hilum. Their position in a natural arrangement is unsettled, but appears to be near the Vitaceous Order, rather than the Rhamna- ceous or Polygalaceous. All the species contain in greater or less abundance a resinous substance, the use of which is unknown. Many of the species are pretty shrubs or bushes, sometimes extremely graceful, but they are of no known use. Most of them are natives of Australia. The names of *Sollya* and *Billardiera* recall to the mind some of the prettiest twiners of the greenhouse. [SOLLYA; BILLARDIERA.]

Pittosporum tomentosum.

1, the stamens and pistil; 2, a ripe fruit; 3, the same divided transversely; 4, a section of a seed with the minute embryo near the base.

PITZITE. [IRON.]

PITUS, a genus of Fossil Plants.

PITYLUS. [TANAGRINÆ.]

PLACENTA (Botany). [SEED.]

PLACENTA (Schumacher), a genus of *Mollusca*.

PLACENTA. [REPRODUCTION IN ANIMALS.]

PLACENTULA, a genus of *Foraminifera*.

PLACOBANCHIATA, or PLACOBANCHIDÆ, M. Rang's name for a family of *Mollusca*, forming his fifth family of *Gasteropoda* (Cuvier), but placed by Cuvier among his *Nudibranchiata*. [NUDIBRANCHIATA.]

PLACOBANCHUS. [NUDIBRANCHIATA.]

PLACODINE (*Arseniuret* of Nickel), a Mineral which occurs in crystalline masses and crystallised. Primary form an oblique rhombic prism. Colour bronze-yellow; streak black. Fracture conchoidal, uneven. Hardness 5.0. Lustre metallic. Specific gravity 7.988 to 8.062. It is found at the Jungfer mine, Milsen. The analysis by Plattner gives—

Arsenic	39.707
Nickel	57.044
Cobalt	0.900
Copper	0.862
Sulphur	0.617
	—99.130

PLACUNA. [PECTINIDÆ.]

PLACUNANO'MIA. [PECTINIDÆ.]

PLAGIODONTIA. [HYSTRICIDÆ.]

PLAGIONITE, a Mineral which occurs massive and crystallised. Primary form an oblique rhombic prism. Cleavage lateral, perfect, but seldom affording smooth surfaces. Colour blackish lead-gray. Fracture imperfectly conchoidal. Hardness 2.5. Brittle. Lustre metallic. Opaque. Specific gravity 5.4. It is found at Wolfsberg in the Harz. The analysis by Rose and Kudernatsch gives—

Sulphur	21.53
Lead	40.52
Antimony	37.94
	—99.99

PLAGIOSTOMA. [SPONDYLIDÆ.]

PLAGUSIA. [GRAPHIDÆ.]

PLAICE. [PLEURONECTIDÆ.]

PLANARIA (Brown), a genus of Fossil Shells which are discoid, and much resemble *Planorbis*; but the outer lip is reflected, and the form is considered to have been marine. Dr. Lea notes a species, *P. nitens*, from the Claiborne Beds, Alabama. *Planaria* had been used by Müller, Lamarck, and others, to designate a genus of animals placed by Cuvier among his *Intestinaux Parenchymateux*, but they do not live in other animals, and are only found in fresh or salt waters.

PLANAXIS. [ENTOMOSTOMATA.]

PLANE. [PLATANUS.]

PLANIPENNES. [NEUROPTERA.]

PLANORBIS. [LIMNÆADÆ.]

PLANORBULINA, a genus of *Foraminifera*.

PLANTA GENISTA. [GENISTA.]

PLANTAGINACEÆ, a small natural order of Plants belonging to the Monopetalous Exogenous series, principally characterised by having a superior 1-celled simple ovary, terminated by a simple linear stigma, many seeds, with a minute embryo in the midst of much albumen, and stamens with extremely weak filaments. They consist of herbaceous or suffrutescent plants, of which the Common Ribgrass, or *Plantago lanceolata*, may be taken as the type, and are of no material importance to man. The mucilage surrounding the seeds of some is occasionally used in the stiffening of muslins by the manufacturers, and the *P. lanceolata* is sown on sandy bad lands as a material for sheep food. In structure, *Plantago* possesses the rare peculiarity of having the cavity of its simple carpel divided into two by a vertical additional plate. [PLANTAGO.]

Great Plantain (*Plantago major*).

1, a flower; 2, a corolla cut open; 3, a seed-vessel, with the upper half of the style removed.

PLANTAGO, a genus of Plants, the type of the natural order *Plantaginaceæ*. It has a 4-cleft calyx, a corolla with an ovate tube, and a 4-parted reflexed limb. The capsules burst transversely; they are 2-4 celled, and have from 2 to 4 seeds.

P. Coronopus, Buck's-Horn Plantain, has linear pinnatifid leaves, with a slender spike; the bracts are subulate from an ovate base, erect; the midrib of the lateral sepals with a ciliated membranous wing; the placenta 4-winged, with one seed in each cell. This species is found in gravelly and sandy places, both near the sea and inland. It is a native of Great Britain. It has been eaten as a salad, but it is too bitter and astringent to be palatable, and these qualities have given it some reputation as an expectorant and vulnerary. Strange accounts are given of its efficacy in medicine, and some very improbable cures attributed to its use.

P. maritima has linear grooved fleshy leaves, convex on the back; the sepals not winged; the capsules 2-seeded; the tube of the corolla pubescent; the spike cylindrical; the bracts ovate acuminate. It is found on the sea-coast and on high mountains in Great Britain.

P. lanceolata is distinguished by its leaves being lanceolate, attenuated at both ends, and 5-nerved; the scape furrowed, the spike ovate or oblong; cylindrical bracts, ovate-acute or cuspidate; the capsules 2-celled, the cells 1-seeded; the tube of the corolla glabrous. The root produces long fibres; the neck is clothed with dense wool, and the scape and leaves with silky hairs. This species was once cultivated as an agricultural plant, but was found to be unprofitable, and has long ceased to be sown.

P. media is known by its ovate leaves, with short broad pubescent stalks; the sepals are not keeled; the capsules 2-celled, and each cell contains one seed. It is found in meadows and pastures in England. The leaves and root have been used in decoction as an astringent lotion.

P. major, Great Plantain, has broadly ovate leaves on a long channelled stalk; terete scapes; an elongated spike; ovate-obtusely keeled bracts; the sepals with a prominent dorsal nerve; the capsules

2-celled, each cell containing many seeds. It is found in Great Britain, and has been called Way-Bred, from its prevalence on the way-side. This plant has a peculiar tendency to grow in the neighbourhood of the abodes of men, and seems as though it followed the migrations of the human species. Thus, although not intentionally conveyed, it has accompanied our colonists to every part of the world, and is known in some of our settlements to the natives under the name of 'The Englishman's Foot'; for, with a strange certainty, wherever our countrymen have trod there it is to be found. Small birds are almost universally fond of the seeds of these plants, which are covered with mucus. According to De Candolle, the seeds of *P. arenaria* are exported in considerable quantities from Nismes and Montpellier to the north of Europe, and are supposed to be consumed in the completion of the manufacture of muslins. The seeds of *P. Ispaghula* are of a very cooling nature, and with boiling water form a rich mucilage, which is much used in India in catarrh, gonorrhœa, and nephritic affections. Soda is obtained in Egypt from the ashes of *P. squarrosa*.

(Babington, *Manual of British Botany*; Lindley, *Vegetable Kingdom*; Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

PLANTAIN. [PLANTAGINACEÆ; PLANTAGO; MUSA.]

PLANTAIN-EATER. [MUSOPHAGIDÆ.]

PLANTAIN, WATER. [ALISMACEÆ.]

PLANTIGRADA. [CARNIVORA.]

PLANTS, FOSSIL. Those plants which are found embedded in the various strata of the earth are called Fossil. The nature and general character of such remains are referred to in the article ORGANIC REMAINS. The greatest development of vegetable life occurred during the deposit of the Coal Measures. The characters of that vegetation, with a list of the species, will be found in the article COAL-PLANTS. Lists of the genera of plants found in formations above and below the Coal will be found in the accounts of those formations. [GEOLOGY.]

PLANTS, REPRODUCTION IN. [REPRODUCTION IN PLANTS.]

PLANULATI. [AMMONITES.]

PLASMA. [AGATE.]

PLASTER OF PARIS. [GYPSUM.]

PLASTIC CLAY. The lower part of the Tertiary Series of England and France yields, with greensands and pebbles, beds of red, white, or mottled clay, often of excellent quality for the potter. [TERTIARY SYSTEM.]

PLATALEA, a genus of Birds belonging to the family *Ardeidæ*. The peculiar form of the bill in this genus has gained for these birds the common name of Spoonbill. It has the following generic characters:—Bill very long, strong, very much flattened, point dilated and rounded into the form of a spoon or spatula; upper mandible channelled, transversely furrowed at its base; nostrils at the surface of the bill, approximated, oblong, open, bordered by a membrane; face and head partially or entirely naked. Feet long, strong; three toes anteriorly united up to the second joint by membranes or webs; posterior toe touching the ground. Wings moderate, ample; the first quill nearly as long as the second, which is the longest.

Bill of Spoonbill.

The Spoonbills live in society in wooded marshes, generally not far from the mouths of rivers, and are rarely seen on the sea-shore. Their food consists of small fishes, spawn, and small fluviatile testaceous molluscs, as well as small reptiles and aquatic insects. According to circumstances they build their nests either in high trees, in bushes, or among rushes. Their moult is simple and ordinary, but the young bird does not take the confirmed livery of the adult till the third year; the bill is gradually developed, and appears covered with a membrane. The crest makes its appearance at the second year. The sexes have external distinctions, but the characters are but slightly marked. (Temminck.)

P. leucorodia, Linn., the Common White Spoonbill. This species is, there can be little doubt, the *Λευκερῶδις* of Aristotle ('Hist. Anim.' book viii. c. 3), of which he says that it haunts *περὶ τὰς λίμνας καὶ τοὺς ποταμούς* ("about the lakes and rivers"); and which he thus describes:—"In size it is less than the other," the *Ἐρῶδις* (one of the Herons, perhaps *Ardea cinerea*), "and has a broad and long bill;" a description which, when coupled with the white colour indicated by the name, can hardly be deemed inapplicable; nor can the term 'broad' be with any propriety referred to the bill of any of the true Herons. It is the *Becquaroueglia* (Belon) and *Cucubiarone* (Bonaparte) of the modern

Italians; Pale, Poche, Cuesler, Truble (Belon), and Spatule of the French; Weisser Löffler and Löffel Gans of the Germans; Lepelaar of the Netherlands; Y Llyden Big of the Welsh; and Spoonbill and White Spoonbill of the English.

This bird has a very full long occipital crest, formed of loose and subulate feathers.

Very old males have all the plumage pure white, with the exception of that of the breast, where there is a large patch of reddish yellow; the extremities of this patch lessen into bands which unite on the upper part of the back. Naked skin about the eyes and throat pale yellow, but slightly tinged with red on the lower part of the throat. Bill black, but bluish in the hollow of the furrows, apex ochreous yellow; iris red; feet black. Total length 2 feet 6 inches; length of bill 8 inches 6 lines.

Old females are rather less than those of the male; the crest is less full and shorter, and the sternal patch is only very feebly indicated.

Young of the Year.—White on leaving the nest, with the exception of the external quills, which are black along the shafts and at their ends; all the shafts are also of a deep black. Head covered with short rounded feathers; the bill, 4 inches 6 lines long at most, is of a deep ash-colour, soft, very flexible, and covered by a smooth skin; iris ash-coloured; naked parts tarnished white. The yellow sternal patch does not begin to appear till the second or third year. (Temminck.)

Mr. Selby observes that in its anatomy it shows an affinity to the Cranes in the form of the windpipe, which, previous to entering the thorax, undergoes a double flexure to the extent of about two inches, and forms a convolution similar to the figure 8. The flexures touch, but do not cross each other, the points of contact being united by fine membranes. This double flexure, according to Willughby and Temminck, was supposed peculiar to the males, but Mr. Selby remarks that Montagu disproves that idea, as the specimen he dissected was a female, and yet possessed the flexure to the extent above described; and this indiscriminate characteristic was corroborated by the dissection of the specimens which Mr. Selby obtained.

It feeds on very small fish, spawn, testaceous molluscs, insects and aquatic worms, small reptiles, and the roots of some weeds and grasses.

The Common Spoonbill haunts the mouths of rivers. Its nest is built sometimes on lofty trees, sometimes in rushes and reeds, according to circumstances, and the eggs are from two to four in number, generally three, sometimes entirely white, but most frequently white marked with obscure red spots. They breed annually in the time of May in a wood at Sevenhuys, not far from Leyden, but the wood has been long destroyed.

Common White Spoonbill (*Platalea leucorodia*).

They are generally distributed throughout Europe. Holland appears to be a principal place for their summer meetings; and Temminck states that it has two periods of passage along the maritime coasts, and that it journeys with the storks. As winter approaches it migrates to more southern regions till the milder weather recalls it. Mr. Bennett states that in winter it takes up its quarters in various parts of Africa, extending southwards even to the Cape of Good Hope. It is, he observes, rarely met with in inland countries except on the banks of the larger rivers; but it is by no means uncommon during the season on the coasts of the great extent of country which it embraces in its visits. In England it only appears occasionally; Pennant mentions a large flight which arrived in the marshes near Yarmouth in April 1774. Montagu records it as having been sometimes seen during winter on the coast of South Devon, and mentions the receipt of two specimens from that part of the country, one in November 1804, and a second in 1807. Mr. Yarrell records two specimens which were shot in Lincolnshire in 1826, and Mr. Selby, when in London in 1830, obtained a male and female, in fine adult plumage, from Norfolk.

Dr. Latham states an instance of its occurrence on the Kentish coast. The old quatrain in the 'Portraits d'Oyseaux,' speaks of the Spoonbill under the name of Pale, as living "es marches de Bretagne."

The flesh of the Spoonbill, when well fed and fat, is said nearly to resemble that of the goose in flavour.

PLATANACEÆ, *Platan*, a natural order of Exogenous Plants. The species are amentiferous trees or shrubs, with alternate deciduous palmate or toothed stipulate leaves, and unisexual naked flowers in globose catkins. The barren flowers with stamens single, mixed with scales. Fertile flowers with ovary 1-celled, style thick and subulate. Ovules 1-2, orthotropical; suspended. Nuts clavate, with a persistent style. Seeds usually solitary and albuminous; radicle inferior. They are natives of the Levant and North America chiefly. They are fine trees, but their timber is not durable.

Platanus orientalis, Oriental Plane, has palmate leaves resembling those of the common Sycamore. It grows in the western parts of Asia, and extends as far east as Cashmere. Its wood is fine-grained and hard, and when old it acquires dark veins so as to resemble walnut-wood. The tree was valued for its shade by the Greeks and Romans, and it was held sacred in the East. *P. occidentalis* is found in most parts of North America, from Mexico as far as Canada. The timber is of a reddish colour, and will not bear exposure to the weather. There is but this one genus in the order and six species. The family resembles *Artocarpaceæ* and *Altingiaceæ*.

(Lindley, *Vegetable Kingdom*; Balfour, *Class-Book of Botany*.)

PLATANISTA, [CETACEÆ.]

PLATANTHE'RA, a genus of Orchidaceous Plants, struck off *Habenaria* on account of the stigmatic processes of the column being small and inconspicuous, or altogether obsolete, instead of being lengthened into horn-like projections below the arms of the anther. The species are numerous, and inhabit the temperate parts of the Old World, but are rarely ornamental, and never of any known use. The British Flora comprehends two species, *P. bifolia* and *P. chlorantha*, both white-flowered, and called Butterfly-Orchis. [**HABENARIA.**]

PLATANUS, [PLATANACEÆ.]

PLATAX, [CHÆTODON.]

PLATEMYS, [CHELONIA.]

PLATESSA, [PLEURONECTIDÆ.]

PLATIN-IRIDIUM, [PLATINUM.]

PLATINA, [PLATINUM.]

PLA'TINUM, or PLA'TINA, an important metal, although it was not known earlier than about the middle of the last century. It was first made known in Europe by Mr. Wood, assayer-master in Jamaica, who met with its ore in 1741. In 1750 he published a paper upon it in the 'Philosophical Transactions.'

The name of this metal is the diminutive of 'plata,' silver, given to it on account of its colour, and it was originally called Platina del Pinto, because it was found in the auriferous sand of the river Pinto. It has since been found in Brazil, Colombia, St. Domingo, and in the Ural Mountains.

Platinum is separated from the sand and other matters with which it is mixed, by washing with a great quantity of water, from which the heavier parts of course subside, and these contain the ore in question.

The ore of platinum is composed of irregular rounded grains, which are sometimes flattened; they are of various sizes, often very small, and occasionally they exhibit traces of crystallisation; but these are probably derived from the presence of some other metal. These grains possess no cleavage. Fracture hackly. Hardness 4.0 to 4.5. Specific gravity 17.332. Opaque. Lustre metallic. Colour steel-gray.

Berzelius has analysed many varieties of this ore, from which we select two examples: (1) the ore of Barbacoas, in the province of Antioquia, Colombia, and (2) that of Goroobodat in Siberia:—

	(1.)	(2.)
Platinum	84.30	86.50
Palladium	1.06	1.00
Rhodium	3.46	1.15
Iridium	1.46	
Osmium	1.03	
Iron	5.31	8.32
Copper	.74	.45
Gangue	.60	1.40
	97.06	98.82

The following are the properties of pure Platinum:—Its colour is grayish-white, intermediate between silver and tin. When it is free from iridium, it is so very ductile, that it may be drawn into very fine wire, not exceeding the 2000th part of an inch in diameter; it is also very malleable, and may be beaten into thin leaves. According to Berzelius, when perfectly pure, it is softer than silver, and it is susceptible of receiving a fine polish. Of all metals it is the least expansible. Its density varies: when fused, it is 19.50; when forged, it is as high as 21.4 to 21.5.

Platinum suffers no change by exposure to the air, nor is it oxidised when heated in it. It does not under any circumstances decompose water. It is infusible in the strongest heat of a smith's forge, but it may be melted by voltaic electricity or by the oxyhydrogen blow-pipe. Of all metals, except iron and copper, it is the most tenacious; a wire of the diameter of 0.787th of a line is capable of sustaining a weight

of about 274 lbs. Like iron, Platinum possesses the very valuable property of welding at a high temperature, and this enables us to form it into chemical vessels of great and daily use.

The metals iridium, osmium, and palladium, occur in conjunction with Platinum.

Platin-Iridium consists of 76·8 Iridium and 19·64 Platinum, with some palladium and copper. It is obtained at Nischnei Tagilsk, and also at Ava in the East Indies. Another variety is found in Brazil.

Iridosmine is a compound of Iridium and Osmium from the platinum mines of Russia, South America, and the East Indies. Its composition varies. One variety contains—

Iridium	46·8
Osmium	49·3
Rhodium	3·2
Iron	0·7
	—100

Iridium and Rhodium are very hard, and are used as nibs for gold pens.

Native Palladium.—Its form is supposed to be the regular octahedron. It occurs mostly in grains, apparently composed of divergent fibers. Colour steel-gray, inclining to silver-white. Ductile and malleable. Hardness above 4·5. Specific gravity 11·8—12·2. This ore consists of palladium, with some platinum and iridium. It fuses with sulphur, but not alone. It is found in Brazil with gold, and is distinguished from platinum, with which it is associated, by the divergent structure of its grains. *Selenpalladite* is nothing but the native palladium; and *Eugenesite* is a similar compound.

This metal is malleable, and when polished has a splendid steel-like lustre which does not tarnish. A cup weighing 3½ lbs. was made by M. Breat in the mint at Paris, and is now in the Garde-Meuble of the French crown. In hardness it is equal to fine steel. One part fused with six of gold forms a white alloy; and this compound was employed, at the suggestion of Dr. Wollaston, for the graduated part of the mural circle, constructed by Troughton for the Royal Observatory at Greenwich. Palladium has been employed also for certain surgical instruments. Large masses of the metal Palladium are brought from Brazil.

PLATYCARCINUS (Latreille), a genus of *Crustacea*. [CANCER.]
PLATYCERCUS. [PSITTACIDÆ.]
PLATYCRINITES. [ENCHIRITES.]
PLATYDACTYLUS. [GECKOTIDÆ.]
PLATYLEPAS. [CIRRIPEDIA.]
PLATYLOPHUS (Swainson), a sub-genus of *Barita*. [BARITA.]
PLATYMERIA. [OXYSTOMA.]
PLATYONYX, a genus of extinct *Mammalia* belonging to the family *Megatheriidae*.

PLATYPEZIDÆ, a family of Insects belonging to the order *Diptera*, the sub-order *Proboscidea*, and the tribe *Nemoceræ*.

PLATYPUS. [ORNITHORHYNCHUS.]
PLATYRHOPALUS. [PAUSSIDÆ.]
PLATYRHYNCHUS. [PHOCIDÆ.]
PLATYRHYNCHUS. [MUSCICAPIDÆ.]
PLATYSTERA. [MUSCICAPIDÆ.]
PLATYSTERNON. [CHELONIA.]
PLATYSTOMA and **PLATYSTOMUS**. [MUSCICAPIDÆ.]
PLATYURUS. [SYLVIADÆ.]
PLECOTUS. [CHEIROPTERA.]
PLECTEROPUS. [DUCKS.]
PLECTOGNATHI. [FISH.]

PLECTRANTHUS (from *πλήκτρον*, a cock's spur, and *άνθος*, a flower, in reference to the corolla being spurred or gibbous above the base), a genus of Plants belonging to the natural order *Labiata*. It has a campanulate 5-toothed calyx in the floriferous state; the teeth equal or the upper one largest. The corolla with an exerted tube; the upper lip from 3-4-cleft, the lower one entire, usually longer and concave. There are 4 stamens, declinate, didynamous, the lower ones longest; free toothless filaments; ovate uniform anthers. The species are herbs, sub-shrubs, and shrubs. There are 45 species of this genus described, which are of easy culture and propagation.

P. crassifolius is esteemed in India both as a perfume and a spice, being equally valued in the toilet and the kitchen. The Patchouly, so inimical to vermin and so efficacious in preserving cloths from moths, is said to be the leaves of *P. graveolens*, which have a very powerful odour, but the comminuted state in which it is imported renders this uncertain.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*.)

PLECTRIS. [MELOLONTIIDÆ.]
PLECTROPHANES. [EMBERIZIDÆ.]
PLEIOCENE, or **PLIOCENE**. By this title (derived from *πλεῖον*, more, and *καιός*, new) Sir Charles Lyell characterises the upper part of the Tertiary Strata. There are in his view Older and Newer Pleiocene Formations, and some have used for the latter class the expression Pleistocene, or 'most new'. [TERTIARY SYSTEM.]
PLEIODON. [NAIADACEÆ.]
PLEIONE (Savigny), a genus of Dorsibranchiate (*Amphinome*, Blainv.) *Annelidæ*, which, with the same tentacles as *Chloëia*, Sav., have branchia in the form of tufts. The species are natives of the Indian seas, where some of them grow to a large size.

PLEKOCHEILUS, the Rev. Lansdown Guilding's name for a genus of *Pupadæ* (Guild.), *Bulinus* of authors.

Animal hermaphrodite. Body corrugate, beliciform; head bilobate; tentacles four, the two longer ones with oculiferous terminations; mandible very lunate, the ossicula transverse, the triangular appendage cutaneous. Intromittent organ retractile, at the root of the right greater tentacle. Mantle perforated by a common foramen. Ova few, large, with a calcareous shell or crust.

Shell barely umbilicate, dextral, oval, spiral; the spire elevated, but obtuse, the two last whorls largest, ventricose. Aperture entire, elongated. Columella with a single plait, which is cavernoso-inflex. Lip thickened, marginate. (Guild.)

P. undulatus has the body olivaceous-black, foot pallid beneath; tentacles white at the apex; eyes black. The shell is stout, turgid, plaited longitudinally, indistinctly striated transversely, ferruginous chestnut, with oblique brown undulated bands; whorls five.

Plekocheilus undulatus, animal and shell. (Swainson, from Guilding's drawing.)

Shell of *Plekocheilus undulatus*.

a, young shell of same; b, egg magnified; c, natural size; d, apex of nucleus, enlarged.

Mr. Guilding states that this fine species occurs in immense numbers in the forests of the island of St. Vincent, generally withdrawn in the daytime. The ova are agglutinated to the vaginating leaves of the *Tillandsia*, which, from holding water, secure a damp atmosphere at all times.

PLEODONTS, the name assigned by Messrs. Duméril and Bibron to their first sub-family of *Lézards Lacertiens* (*Lacertian Lizards*), or *Sauriens Autosaures* (*Autosaurian Saurians*).

The Pleodonts are divided into two great groups: the first with a

compressed tail, surmounted with ereata, as in the Crocodiles; the other with the tail perfectly conical, or very slightly flattened on its four surfaces, so that it still appears rounded.

PLEONASTE. (SPINEL.)

PLESIOSAURUS (Conybeare), a genus of the extinct family of Enaliosaurians. This genus was first described by Mr. Conybeare, with the assistance of Sir Henry de la Beche, in the 'Transactions of the Geological Society of London,' in 1821. A restoration of the skeleton, together with that of *Ichthyosaurus*, was given by Mr. Conybeare in a subsequent volume of the same 'Transactions' (1824), from an almost perfect specimen of *Plesiosaurus dolichodeirus*, and the accuracy of this restoration is still universally acknowledged. This genus is the *Halidracon* of Wagler.

The distinguishing features of the Enaliosaurians consist in the absence of the ball and socket articulations of the bodies of the vertebrae, the position of the nostrils at or near the summit of the head; their separated hæmapophyses; the numerous short and flat digital bones, which must have been enveloped in a simple undivided tegumentary sheath, forming in both the fore and hind extremities a fin resembling in external appearance the paddles of the *Cetacea*.

The characters of the genera *Plesiosaurus* and *Ichthyosaurus*, the types of the two principal modifications of anatomical structure offered by the Enaliosaurians, are mainly derived from modifications of the vertebral column, as well with regard to the form and configuration of the individual bones, as to the relative groups of the cervical, dorsal, and caudal vertebrae. [*ICHTHYOSAURUS*.] Professor Owen has also found that the vertebrae afford the best characters for the distinction of species as well as of genera.

The most conspicuous and remarkable character of the vertebrae in *Plesiosaurus* is the extraordinary length of the cervical portion, including from twenty to forty vertebrae. The articular surfaces of their bodies are either flat or slightly convex in the centre, and most frequently concave at the periphery. Two pits are generally presented at the under part of the bodies, but this character is not constant. The cervical vertebrae of the *Plesiosaurs* generally present the centrum, the neurapophyses, and the ribs in a separate or unanchylosed state, and although in general no transverse processes are developed in this region, an analogy with the structure characteristic of this part of the spine in the Crocodile is maintained in the division of the articular surface for the cervical rib into an upper and lower portion by a horizontal fissure—a structure which, Professor Owen observes, is well described and figured by Conybeare in the *Plesiosaurus dolichodeirus*: as these vertebrae of the neck approach the dorsal, the inferior part of the costal articulation becomes smaller, and a corresponding increase of surface is afforded by the superior facet, which also gradually rises from the centrum to the neurapophyses, and in the dorsal vertebrae stands boldly out as a true transverse process from the upper side of the base of each neurapophysis. The transverse processes of the sacral vertebrae subside to the level of the neurapophyses; and as the caudal vertebrae recede from the trunk, the articular surface, which, as in the neck, represents or takes the place of the transverse process, gradually descends, and passes from the neurapophyses to the side of the centrum, but is not divided by the longitudinal groove which characterises the costal surface in the neck; but it must be borne in mind that this groove is more marked in some species of *Plesiosaurus* than others; and indeed Professor Owen has seen *Plesiosaurian* cervical vertebrae in which no trace of it was visible. "The neurapophyses," he says, "are commonly unanchylosed with the vertebral centres in any part of the spine, and in some instances throughout the cervical and at the anterior part of the dorsal region the neurapophyses have appeared to be joined each by an articular surface to the spine above, as they are to the centrum below—the spines here remaining apparently throughout life unanchylosed to the neurapophyses. This condition of the upper vertebral elements is rarely seen in any cold-blooded vertebrate animals, and never in the warm-blooded classes. In those parts of the spine where the vertebrae enjoyed less mobility upon each other than in the neck, the spines become anchylosed to the neurapophyses at an earlier period. The hæmapophyses co-exist with the ribs or paravertebral elements in the caudal region of the spine, but they continue throughout life to be unattached by bone either to the centrum above or to each other below; and here also their spine is not developed, and consequently no true chevron bone is formed in the *Plesiosaurs*. The hæmapophyses are also continued along the inferior surface of a great part of the abdomen, forming there the sternal or abdominal ribs; and just as the neurapophyses are developed in the transverse direction to protect the expanded cerebral masses in the cranial region, so here the hæmapophyses are in like manner elongated transversely, and their spine is introduced and modified to form a third mesial rib-like bar, connecting however, as usual, the lower or distal extremities of the hæmapophyses, and completing the osseous cincture of the abdominal viscera. The tail in the *Plesiosaurs* is relatively much shorter than in the *Ichthyosaurs*, and there is an obvious reason for the curtailment of this part of the animal; for in the *Plesiosaurs*, the length and mobility of the neck renders a special development of the tail for producing the lateral movements of the head unnecessary. The bodies of the vertebrae, in most species of *Plesiosaurs*, are traversed vertically by two vascular canals, which lead from the medullary or spinal canal

to the inferior surface of the centrum, where they terminate each by an orifice, and sometimes by two orifices on each side of the middle line. These orifices are not however a constant character of the genus *Plesiosaurus*, neither are they peculiar to this genus, being present in the vertebrae of the *Cetacea*, as well as in those of other *Sauria*. In a section of the vertebral centrum of a *Plesiosaurus*, the osseous texture for some lines near the anterior and posterior articular surfaces is denser than in the rest of the vertebrae, and the direction of the laminae and fibres is vertical; in the intermediate portion the laminae are horizontal."

Though the head of the *Plesiosaurs* resembles that of the crocodiles in its general form, it is, relatively much smaller in proportion to the body. The elongated form of the strong and prominent cranial bones, most of which extend from point to point, with wide interspaces like the timbers of a scaffolding, forms one of the first indications of a deviation from the Crocodilian type, and of the affinity of the *Plesiosaurus* to the Lacertian *Sauria*; and this affinity is further exemplified in the condition of many of the individual bones.

The parietal bone is strong and triradiate, consisting of a median piece corresponding with the normal parietal in the Crocodiles, and of two transverse elongated processes, formed, as it were, by a bifurcation of the posterior part of the median piece; and in a young specimen of *Plesiosaurus macrocephalus*, in the museum of the Earl of Enniskillen, Professor Owen found the median or sagittal suture dividing the two parietals still distinct; in older specimens of *P. Hawkinsii* he always found it obliterated; affording evidence to justify the description of the parietal bone as single or triradiate. The other bones of the head present many remarkable distinctions from the ordinary Crocodilian type. The general structure of the head will be seen in the accompanying cuts of the skull of the *Plesiosaurus* restored after Conybeare.

Skull of *Plesiosaurus* restored: a, profile; b, seen from above.

Under jaw of *Plesiosaurus* (anterior part).

a, seen from above; b, profile; c, seen from below. (Conybeare.)

The usual complicated structure observable in the Saurians appears in the Lower Jaw of the *Plesiosaurus*. The dentary piece presents

evidence of its soon becoming ankylosed to its fellow at the symphysis: it is chiefly remarkable for the expansion of its anterior extremity. No intervening vacuity separates the angular and surangular pieces as in the Crocodiles, but those pieces are joined together throughout, as in the Lacertian group. The surangular piece rises higher and forms a sharper edge for the insertion of the temporal muscles than in the Crocodiles, a structure which agrees with the greater development of these muscles, as indicated by the size of the temporal fossae. "The articular piece presents a regular and deep concavity for the reception of the articular end of the tympanic bone; it is, as Mr. Conybeare has well remarked, more developed than in the Crocodile, and thus approximates more nearly to the corresponding part in the Lacertian type. The angular piece is prolonged backwards beyond the joint, but not quite to the same extent as in the Crocodiles." (Owen.)

A tooth slightly magnified. (Conybeare.)

The free extremities of the Ribs are connected together, in the abdominal region, by the series of intermediate slender elongated pieces, to which Conybeare gave the approximate designation of sterno-costal arcs. Each of these sterno-costal arcs includes, in the *Plesiosaurus*, seven pieces.

Sterno-Costal Arcs of *Plesiosaurus*. (Conybeare.)

The broad coracoid bones, remarkably expanded as they are in the antero-posterior direction, are noticed by Professor Owen as the most conspicuous of those composing the Pectoral Arch: he describes their internal and anterior margins as gently convex, and meeting at the mesial plane, where they overlap the anterior thoracic ribs. Into their anterior interspace is wedged the ento-sternal piece, consisting of a short mesial process and two broad lateral expansions. A strong triradiate bone, which, in Professor Owen's opinion, seems to represent, as in the Chelonians, the scapula and clavicle united, is arched from the outer extremity of the coracoid bones, with which it combines to form the shoulder-joint, near which last point it sends upwards and obliquely backwards a branch or process representing the true scapula.

Humero-Sternal part of *Plesiosaurus*. (Conybeare.)

St., sternum; Cl., clavicle; Cor., coracoids.

The Humerus is a stout and moderately long bone, curved slightly backwards, rounded at its proximal extremity, and flattened as it approaches the elbow-joint. The Radius and Ulna are both short and flat bones, but relatively longer and more distinctly marked than in *Ichthyosaurus*. The Carpus consists of a double row of small flat

rounded ossicula, in number from six to eight. The Metacarpal Bones are elongated, slender, flattened, and slightly bent.

The Hinder or Pelvic Extremities are almost always equal, sometimes, as in *P. macrocephalus*, exceeding the anterior ones in size, and the Pelvic Arch consists of a strong and short Ilium, and a broad Pubis and Ischium, both of which are expanded in the antero-posterior direction analogously to the coracoid bones in the pectoral arch.

Pelvis of *Plesiosaurus*. (Conybeare.)

Pub., pubis; Isch., ischium; Il., ilium.

The radiated appenages of the pelvic arch so closely correspond with those of the pectoral arch as to require little notice. The posterior bone, or Fibula, corresponds in its curved form with the Ulna, illustrating an analogy manifested in other animals. The Tarsal Bones are principally remarkable for their small size on the tibial or anterior side of the series, indicating that the hind paddle had a freer inflection forwards, or upon the tibia, than in the opposite direction.

The five Metatarsals and their digits are found to correspond in structure with those of the fore paddle.

Plesiosaurus macrocephalus. (Buckland; Owen.)

For the particular variations in the skeletons of the different species the student should consult Professor Owen's report on the *Enaliosauria*, in the 'Transactions of the British Association,' from which the above general description of the osseous parts is taken.

The following species are recorded by Professor Owen:—*P. Hawkinsii*, Owen; *P. dolichodeirus*, Conybeare; *P. macrocephalus*, Conybeare; *P. brachycephalus*, Owen; *P. macromus*, Owen; *P. pachyomus*, Owen; *P. arcuatus*, Owen; *P. subtrigonus*, Owen; *P. trigonus*, Cuv.;

Skeleton of *Plesiosaurus dolichodeirus* restored. (Conybeare principally.)

P. brachyspondylus, Owen; *P. costatus*, Owen; *P. deditomus*, Owen; *P. rugosus*, Owen; *P. grandis*, Owen; *P. trochanterius*, Owen; and *P. affinis*, Owen.

Dr. Buckland truly observes that the discovery of this genus forms one of the most important additions that geology has made to comparative anatomy. "It is of the *Plesiosaurus*," he says "that Cuvier ascribes the structure to have been the most heteroclit, and its characters altogether the most monstrous that have been yet found amid the ruins of a former world. To the head of a lizard it united the teeth of a crocodile; a neck of enormous length, resembling the body of a serpent; a trunk and tail having the proportions of an ordinary quadruped, the ribs of a camelion, and the paddles of a whale. Such are the strange combinations of form and structure in the *Plesiosaurus*—a genus, the remains of which, after interment for thousands of years amidst the wreck of millions of extinct inhabitants of the ancient earth, are at length recalled to light by the researches of the geologist, and submitted to our examination in nearly as perfect a state as the bones of species that are now existing upon the earth." Conybeare thus speaks of its supposed habits:—"That it was aquatic is evident from the form of its paddles; that it was marine is almost equally so, from the remains with which it is universally associated; that it may have occasionally visited the shore, the resemblance of its extremities to those of the turtle may lead us to conjecture; its motion however must have been very awkward on land; its long neck must have impeded its progress through the water, presenting a striking contrast to the organisation which so admirably fits the *Ichthyosaurus* to cut through the waves. May it not therefore be concluded (since, in addition to these circumstances, its respiration must have required frequent access of air) that it swam upon or near the surface, arching back its long neck like the swan, and occasionally darting it down at the fish which happened to float within its reach? It may perhaps have lurked in shoal water along the coast, concealed among the sea-weed, and, raising its nostrils to the surface from a considerable depth, may have found a secure retreat from the assaults of dangerous enemies; while the length and flexibility of its neck may have compensated for the want of strength in its jaws, and its incapacity for swift motion through the water, by the suddenness and agility of the attack which they enabled it to make on every animal fitted for its prey which came within its reach." ('*Geol. Trans.*' vol. i. part 2, p. 388, N. S.)

PLESTIODON. [SCINCIDÆ.]

PLETHODONTIDÆ. [AMPHIBIA.]

PLEURA is the membrane which envelops the lungs and lines the cavities of the chest. On the walls of each cavity of the chest the *Pleura Costalis* (as it is here called) is formed by a sheet of fine and elastic cellular tissue, loosely attached to the ribs, intercostal muscles, and other subjacent parts. On the exterior of the lung the *Pleura Pulmonalis* is composed of a thin superficial layer of fine cellular tissue, and a deeper layer of coarser fibrous tissue, which in most of the large quadrupeds, and in the seal and some other animals, is very elastic, and affords an important assistance in the act of expiration. The surfaces of the two portions of pleura are contiguous with each other at the root of the lung; each is covered with a delicate layer of epithelium; and they inclose within them a space called the sac of the pleura, into which a small quantity of serous fluid is constantly secreted, which moistens the opposite surfaces of the lung and of the wall of the chest, and permits their free motion upon each other. [MEMBRANE.]

PLEURACANTHUS. [FISH.]

PLEUROBRANCHIÆ. [SEMI-PHYLLIDIANS.]

PLEUROBRANCHUS. [SEMI-PHYLLIDIANS.]

PLEURODONTES. Messrs. Duméril and Bibron make their *Iguaniens Pleurodontes* the first sub-family of the Iguanian Lizards, or *Sauriens Eumotes*. [IGUANIDÆ.]

PLEURONECTIDÆ, a family of Fishes of the order *Malacopterygii* and section *Subbranchiales*. This family contains the Soles, Flounders, and Turbots, and some other fishes, all of which are readily distinguished by the flattened form of the body, and in having both the eyes on one side. This want of symmetry in the form of the head, Cuvier states, is unique amongst vertebrate animals. The side of the body which is uppermost is always coloured, and might be mistaken for the back of the fish, whilst the opposite side is white. The two sides of

the mouth are unequal, and it is uncommon to find the two pectoral fins equal; the dorsal and anal fins extend the whole length of the back and abdomen respectively; the ventrals appear like a continuation of the anal; the branchiostegous membrane has six rays.

The *Pleuronectidæ* are divided into the following genera:—

Platessa, in which the jaws are each furnished with a single row of obtuse teeth; on the pharyngeans are generally some teeth like paving-stones; the dorsal fin is only extended in front to a liue with the eye, and leaves, as well as the anal, an interval between it and the caudal. The form of the body is rhomboidal, and the eyes are usually on the right side.

P. vulgaris, Cuv., the Common Plaice, is usually about a foot or rather more in length; of a brown colour above, spotted with red or orange; on the eye-side of the head are some osseous tubercles; the lateral liue is curved above the pectoral fin; the body is smooth, and the teeth are blunt and contiguous.

This fish is very abundant on various parts of the British coast, and is said sometimes to attain the weight of 15 lbs.

P. flesus, the Flounder; *P. limanda*, the Dab; and *P. microcephala*, the Lemon Dah, are also examples of the genus *Platessa*.

Hippoglossus, Cuv.—The species of this genus differ from the *Plaices* proper in having the body usually more elongated, and the jaws and pharyngeans armed with strong and pointed teeth.

H. vulgaris, Flem., the Holibut, is not uncommon on some parts of our coast, and is often exposed for sale in the London market. It is usually of large size. One specimen, taken in the Isle of Man, is said to have measured 7½ feet in length. In the northern parts of Britain it is called the Turbot; the Holibut however is of a much longer form than the Turbot, and hy no means equal to it in flavour.

Rhombus, Cuv.—The species of this genus have the jaws and pharyngeans furnished with thickly-set small pointed teeth; the dorsal fin commences immediately above the upper lip, and this fin, as well as the anal, extends very nearly to the tail; the eyes are generally on the left side.

The Turbot, Brill, Muller's Topknot, Bloch's Topknot, the Whiff, and the Scaldfish, are British examples of the genus *Rhombus*.

P. maximus, Cuv., the Turbot, next to the Holibut, is one of the largest of the *Pleuronectidæ* found on our coast, and is the most highly esteemed for the table. The Turbot is of a short and broad form, and rather deeper than many of the flat fishes. Its prevailing colour is brown, and the whole of the coloured side is studded with hard and roundish tubercles; the lateral line is considerably arched above the pectoral fin, and thence runs straight to the tail. It is called in Scotland the Rawn Fleuk and Bannock Fleuk.

"On the coasts of Durham and Yorkshire," says Mr. Yarrell, "a considerable fishery of Turbot is carried on by the fishermen of Hartlepool and Scarborough with long lines. . . . A large portion of the Turbot produced in the English market is taken on or near the various sand-banks between the long line of our eastern shore and the coast of Holland."

R. vulgaris, Cuv., the Brill, is very similar to the Turbot in appearance, but inferior in flavour; it is common in the markets, and may at once be distinguished by its less broad form, the want of the osseous tubercles on the coloured side of the body, and the colouring, which is reddish or sandy-brown varied with darker brown, and minutely spotted with white. It is moreover a smaller fish.

Solea, Cuv., contains the Soles, which are distinguished generally by their more elongated form and the blunt and rounded shape of the muzzle. The eyes, as well as the colouring, are on the right side; the teeth are small and confined to that side of the mouth which is opposed to the eyes; the dorsal fin commences in front of the line over the eyes, and extends, as well as the anal, to the tail-fin.

Cuvier separates as a sub-genus from the *Soles* proper those species which have the pectoral fin on the side with the eyes very small, and that on the opposite side either rudimentary or altogether wanting. They are termed *Monochirus*.

S. vulgaris, Cuv., the Common Sole, inhabits the sandy shore all round our coast, where it keeps to the bottom, and feeds upon small testaceous animals and the fry of other fishes; as they will not readily take bait, they are almost entirely caught by trawling. "Eighty-six thousand bushels of Soles were received at Billingsgate-market

only within the last twelve months." (Yarrell, 'British Fishes,' vol. ii. p. 25.)

S. pegusa, Yarrell, the Lemon Sole, is occasionally taken with the common species, from which it differs in being rather broader and of a yellowish colour.

Of the sub-genus *Monochirus*, one species is found on the British coast, and is known by the names Variegated Sole, Red-Backed Flounder, &c. (*M. linguatulus*). There are moreover certain Soles in which the pectoral fins are altogether wanting; they constitute the sub-genus *Achirus* according to Lacépède.

PLEUROPTERA, a tribe of *Mammalia* generally known as Flying Lemurs (*Galeopithecus* of Pallas; Flying Cats and Flying Foxes of

Teeth of *Galeopithecus*, one-third larger than nature. (F. Cuvier.)

Lower jaw and teeth of *Galeopithecus Temminckii*.

1, under side of the lower jaw; 2, side view of the same; 3, the three foremost teeth on either side of the upper jaw; 4, 5, outer and inner incisors of the lower jaw. (Waterhouse, 'Zool. Trans.')

voyagers). They are generally arranged under the order Carnassiers, and some authors place them in the division *Cheiroptera*; but they

Skull of *Galeopithecus Temminckii*.

a, seen from above; b, seen from below. (Waterhouse, 'Zool. Trans.')

Galeopithecus Temminckii.

differ from the Bats inasmuch as the toes of their anterior extremities, which are all furnished with sharp claws, are not more elongated than those of the hind feet, so that the membrane which occupies the interval between the extremities to the sides of the tail can hardly operate in executing more than the functions of a parachute.

The dentition, according to Mr. Waterhouse, is as follows:—

Incisors, $\frac{2-2}{4}$; Canines, $\frac{0-0}{1-1}$; False Molars, $\frac{2-2}{2-2}$; True Molars,

$$\frac{4-4}{4-4} = 34.$$

Cuvier states that the *Galeopithecii* live on trees in the islands of the Indian Archipelago, and there pursue insects, and perhaps birds, as their prey: judging from the detrition of the teeth with age, he thinks that they must also feed on fruits. They have a very large cæcum. In their teeth they present many analogies to the *Lemuridae*.

Dr. Gray makes the *Galeopithecidae* the fourth family of the *Primates*, and places it between the *Lemuridae* and *Vespertilionidae*. ('Outline, &c., in Ann. of Philosophy,' 1825.)

Three species have been recorded:—1, *Galeopithecus rufus*, Geoff. Audeb. (*Lemur volans*, Linn.); 2, *G. variegatus*, Cuv., Geoff.; 3, *G. Ternatensis*, Geoff.: but the general opinion seems to have been that one only, the *Lemur volans* of Linnæus, had been satisfactorily made out. Mr. Waterhouse has however described two species, of which the following are the characters:—

G. Temminckii measures about 2 feet in total length, and its skull was 2 inches 11½ lines in length. The anterior incisor of the upper jaw is broad, and divided by two notches into three distinct lobes; the next incisor on each side has its anterior and posterior margins notched; and the first molar (or the tooth which occupies the situation of the canine) has its posterior edge distinctly notched. This tooth is separated by a narrow space, anteriorly and posteriorly, from the second incisor in front and the second molar behind; the temporal ridges converge towards the occiput, near which however, he observed,

Skull of *Galeopithecus philippinensis*.
a, upper side; b, under side.

Lower jaw and teeth of *Galeopithecus philippinensis*.

1, under side of the lower jaw; 2, side view of the same; 3, the three fore-most teeth, upper jaw; 4, 5, outer and inner incisors of lower jaw. (Waterhouse, 'Zool. Trans.')

they are separated usually by a space of about four lines. This is probably the *G. volans* of authors; but the identity cannot be said to be certain.

G. philippinensis is described by Mr. Waterhouse as being usually about 20 inches in length, and its skull as measuring 2 inches 7 lines in length. He observes that this species may be distinguished from *G. Temminckii* by the proportionately larger ears and the greater length of the hands. The skull is narrower in proportion to its length, the muzzle as broader and more obtuse, and the orbit as smaller. The temporal ridges generally meet near the occiput, or are separated by a very narrow space. The anterior incisor of the upper jaw is narrow, and has but one notch; the next incisor on each side is considerably larger, longer, and stronger than in *G. Temminckii*, and differs moreover in having its edges even—the same remark applies to the first false molar. In this species the incisors and molars form a continuous series, each tooth being in contact with that which precedes and that which is behind it. The most important difference perhaps which exists between the two species in question consists in the much larger size of the molar teeth in the smaller skull, the five posterior molars occupying a space of 10 lines in length, whereas in *G. Temminckii*, a much larger animal, the same teeth only occupy 9 lines. ('Zool. Proc.', 1839.)

PLEURORHYNCHUS (Phillips), a genus of fossil *Mollusca*.

PLEUROSIGMA. [DIATOMACEÆ.]

PLEUROTOMA, a genus of *Mollusca*. [SIPHONOSTOMA.]

PLICA. [IGUANIDÆ.]

PLICATULA. [PECTINIDÆ.]

PLICIPENNES. [NEUROPTERA.]

PLINUS. [SERRICORNES.]

PLOCARIA, a genus of Plants belonging to the alliance *Algae*, the order *Ceramiceæ*, and the sub-order *Spharococceæ*. One of the species, *P. Helminthocorton*, is called Corsican Moss, and has a considerable reputation as a vermifuge. It is a native of the Mediterranean.

PLOCEINÆ, a sub-family of *Fringillidæ*. [FRINGILLIDÆ.] The genus *Ploceus* (Weavers, Tisserins of the French) is thus defined by Mr. Swainson:—Size small. Bill couic, but with the culmen slightly bent, and the tip entire. Under mandible less thick than the upper. Claws large, very long. Wings pointed; but the first quill remarkably short and spurious. It inhabits the Old World only.

The following sub-genera are thus defined by the same observing author, and are arranged under the genus by him:—

Vidua.—Bill short. Wings lengthened, the second, third, and two following quills longest, and of equal length. Tail boat-shaped; males with the two middle feathers excessively elongated, generally broad and convex. (Sw.)

The Whidah-Fiuches, Widow-Birds, as they are familiarly termed by the British, Veuves of the French, are among the most remarkable of the section of hard-billed seed-eating birds to which they belong. These African Bunting are favourites for the cage and the aviary, where the long drooping tail-feathers, not inelegant, though out of all ordinary proportion, that adorn the males in the breeding season—for the birds are, generally, not larger in the body than canaries—immediately attract the attention. The Latin generic name and the French and English familiar ones are most probably derived from the sombre hue which prevails in their plumage, suggesting the idea of a widow's weeds.

V. paradisea. This is *Emberiza paradisea*, Linn.; Grande Veuve-d'Angola, of the French; Whidah-Bunting of English ornithologists; Widow-Bird of the English salesmen and fanciers.

The upper part of the plumage is of a faded or deep brownish-black; but this colour becomes of a paler hue on the wings and lateral tail-feathers. The whole of the head, the chin, and throat are of this faded black, which extends downwards, narrowing as it descends, to the middle of the breast. A broad rich orange-rufous collar proceeds from the upper part of the back of the neck, and unites with a tinge of the same colour on the sides of the neck and breast; this last hue passes into the pale buff of the body, abdomen, and thighs, but leaves the under tail-covers black, the colour of the upper ones.

The tail-feathers are black: the four lateral ones on each side are slightly graduated, each being a fraction of an inch, sometimes about a quarter, longer than the one above it. The next two are the long vertical externally convex feathers, so conspicuous in the male. These in fine specimens measure a foot in length from the base, and about three-quarters of an inch in width. The two middle feathers, also placed in a vertical direction, have very broad webs on their basal half (about three inches), but the remainder of the shaft becomes a plumelike hair-like process (somewhere about three inches more). Bill and feet black. Size about that of a canary.

It is a native of Senegal and South Africa.

V. erythrorhynchus, Swainson, the Red-Billed Whidah Fiuch, is of less size than *V. paradisea*, and is altogether an aberrant species of this group. The bill is shorter, thicker, and broader at the top. Of the four middle greatly elongated tail-feathers, two are convex, and two concave, so that when all four are closed, they form a sort of cylinder; and, but for their extremities, appear at first sight as one. It inhabits Senegal.

a, Widow-Bird (*Vidua paradisæa*); b, Red-Billed Whidah Finch (*Vidua erythrorhynchos*).

Next to the sub-genus *Vidua*, in Mr. Swainson's arrangement, come the following:—

Euplectes (Sw.).—Bill shorter than the head. Nostrils round, partly concealed by the frontal feathers. Wings short; the second quill shorter than the third; tertials as long as the primaries. Tail short, even, or very slightly rounded. Feet large, gracile. Toes very long and slender; the lateral of equal length. Claws slender, very slightly curved.

Ploceus (Cuv.).—Bill considerably lengthened, as long as the head. Nostrils almost naked. Wings moderate; the second, third, fourth, and fifth quills nearly equal; tertials shorter than the primaries. Tail short, even. Feet large, thick. Toes robust; the lateral equal. Claws strong, thick, fully curved.

Symplectes (Sw.).—General structure of *Ploceus*; but the bill is more compressed, the commissure curved, but neither sinuated nor toothed. Wings short, rounded; the first quill half as long as the second, which, with the third, is graduated; the next three are nearly equal, and are the longest. Tail moderate, even. Feet strong. The middle toe abbreviated; inner lateral toe shorter than the outer; hinder toe long, equal to the middle toe.

Amadina follows in Mr. Swainson's arrangement, and he speaks of the genus *Ploceus* thus defined as by far the most beautiful of the division of *Coccothraustina*. "It is," says he, "composed of the

Weavers, a name given them on account of that surprising skill with which they fabricate their nests."

Mr. Swainson, when treating of the nests of birds, says—"There is still another sort of suspended nests mentioned by Barrow ('Travels in Africa') as fabricated by a species of *Loxia*, or Grosbeak (probably of the modern genus *Euplectes*). It seems always to build on a branch extending over a river or pool of water. The nest is shaped exactly like a chemist's retort; is suspended from the head; and the shank, of eight or nine inches long, at the bottom of which is the aperture, almost touches the water. It is made of green grass curiously woven." Of this sort of nest (which is very artfully wrought), or rather a collection of them, a plate designed by Daniell is given in Wood's 'Zoography.'

It may be considered certain that the hive-nests noticed by Barrow and Paterson are also the work of Weaver-Birds. This republic of nests, as it has been termed, is attributed by Barrow to a society of the species termed *Loxia socia* by Latham, and this bird is very properly quoted by Mr. G. R. Gray as an example of the genus *Phileterus* of Smith, *Euplectes* of Swainson, and *Ploceus* of Cuvier. The synonyms of *Loxia socia* given by Mr. G. R. Gray are *P. lepidus*, Smith, and *P. Patersonii*, Less.

African Nests.

The birds in question are said to construct their nests in one clump and under one roof or cover, each nest having a separate entrance on the under side, but not communicating with the nest next to it from within. A space of ten feet in diameter is stated to be sometimes reached by these aggregated sylvan dwellings comprising a bird-population of some hundreds.

Paterson thus describes the operations of these social winged citizens:—"The industry of these birds seems almost equal to that of the bee. Throughout the day they appear busily employed in carrying a fine species of grass, which is the principal material they employ for the purpose of erecting this extraordinary work, as well as for additions and repairs. Though my short stay in the country was not sufficient to satisfy me by ocular proof that they added to their nests as they annually increased in their numbers, still, from the many trees which I have seen borne down by the weight, and others that I have seen with their boughs completely covered over, it would appear that this is really the case. When the tree that is the support of this aerial city is obliged to give way to the increase of weight, it is obvious that they are no longer protected, and are under the necessity of building in other trees. One of these deserted nests I had the curiosity to break down, to inform myself of the internal structure of

It, and found it equally ingenious with that of the external. There are many entrances, each of which forms a regular street, with nests on both sides, at about two inches' distance from each other. The grass with which they build is called the Boshman's Grass, and I believe the seed of it to be their principal food, though, on examining their nests, I found the wings and legs of different insects. From every appearance, the nest which I dissected had been inhabited for many years, and some parts were much more complete than others. This therefore I conceive to amount nearly to a proof that the animals added to it at different times, as they found it necessary, from the increase of their family, or rather of the nation and community."

One of these bird-towns is also figured in Mr. Wood's 'Zoography,' and we here present a sketch of part of the plate.

African Nests.

Another Weaver's nest, that of *P. icterocephalus*, Sw., brought together with the male, female, and eggs, from South Africa to Mr. Swainson, has been described by him, a representation of the nest of which we give in the next column.

We subjoin illustrations of some of the more remarkable species of this family.

Plocus spilonotus, Vigors. This is the *P. stictonotus* of Smith ('South African Quarterly Journal'), and *P. flariceps* of Swainson ('Birds of West Africa').

Dr. Smith states that this Weaver inhabits the districts bordering on the south-east coast of Africa, but he had not seen nor heard of its having been found to the westward of Kaffirland. It is rare, and generally is seen on the banks of rivers. From the trees that overhang the waters these birds suspend their nests of a somewhat kidney form, composed of blades of grass so closely interwoven as to form a complete protection against the weather.

P. Capensis, Smith (*P. Abyssiniacus*, Cuvier). Dr. Smith states that it is diffused over the more southerly districts of South Africa, and that flocks of from ten to forty individuals are often to be seen on or near the edges of marshes and rivers. From the trees or shrubs which fringe these rivers they suspend, he says, their nests, five or six of which are sometimes attached to a single branch. These nests are somewhat kidney-shaped, with the entrance towards the upper end, and directed downwards. Dr. Smith adds that trees which overhang pools of water are invariably preferred, and the twigs which approach nearest the water are commonly best supplied with nests.

The head-quarters of *P. subaureus* and *P. ocularius* must be looked for, according to Dr. Smith, to the northward of the Tropic of Capri-

Nests of *Plocus icterocephalus*.

Yellow-Crowned Weaver (*Plocus spilonotus*).

corn; at least the paucity of specimens to the southward of it would, in his opinion, warrant such an inference. During a residence of fourteen years in South Africa, he only met with four specimens of *P. ocularius* and ten of *P. subaureus*. The specimens of *P. subaureus* procured by himself were all killed in the neighbourhood of Algoa Bay, and those contained in the collections submitted to his inspection were either obtained in the same locality or more to the eastward.

Dr. Smith states that there does not appear among the individuals of *P. ocularius* any disposition to congregate; at least he rarely found more than the male and his female associated together; and these were generally discovered in retired situations, well supplied with trees, from a branch of some of which is suspended the nest, formed of delicate fibres of bark closely interwoven, so fashioned as to present when complete the form of a retort. The male and female sit alternately upon the eggs, and while so occupied are so devoted to their duty, that they may with the greatest ease be taken in the nest alive.

Phileterus lepidus, Smith. This is the *Loxia socia* of Latham; *Ploceus socius* of Cuvier; and *Euplectes lepidus* of Swainson.

Sociable Weaver-Bird (*Phileterus lepidus*).

Nests of Sociable Weaver-Bird.

Dr. Smith states that the banks of the Orange River appear to constitute the southern limit of the range of this species, which was only obtained in great abundance in the districts round Latakoo far from

water. "The most striking peculiarity," adds Dr. Smith, "observed in this species is the extraordinary manner in which a number of individuals associate, and build their nests under a common roof. When a nesting place has been selected, and the operation of building the nests is to be commenced ab initio, the community immediately proceed conjointly to construct the general covering which interests them all; that being accomplished, each pair begins to form their own nest, which, like the roof, they construct of coarse grass; these are placed side by side against the under surface of the general covering, and by the time they are all completed, the lower surface of the mass exhibits an appearance of an even horizontal surface, freely perforated by small circular openings. They never use the same nests a second time, though they continue for many years attached to the same roof. With the return of the breeding season, fresh nests are formed upon the lower surface of those of the preceding year, which then form an addition to the general covering. In this manner they proceed year after year, adding to the mass, till at last the weight often becomes such as to cause the destruction of its support: upon which a new building is selected. They appear to prefer constructing these nests upon large and lofty trees, but where such do not occur, they will even condescend to form them upon the leaves of the Arborescent Aloe (*Aloe arborescens*), as occasionally happens towards the Orange River. The commencement of the roof is firmly interwoven with the branches of the trees to which it is intended to be suspended; and often a great part of a principal branch is actually included within its substance. Each female lays from three to four eggs, which are of a bluish-white colour, and freely mottled towards the large end with small brown dots. When once this species has attained maturity, it never afterwards exhibits any change in respect to colours. The male has no summer tints which he throws aside in winter, as is the case in *Euplectes*. Seeds, and occasionally small insects, constitute the food."

Euplectes taha. Dr. Smith states that this species does not appear to extend south of 26°, at least he discovered no individuals before he reached that latitude. They are very destructive to gardens.

Euplectes taha.

Upper figure, male; lower figure, female. (Smith.)

Plocepasser mahali (*Agrophilus*, Sw.). Dr. Smith first saw this bird upon a tree on one of the tributaries of the Orange River. The nests in figure and texture had many of the characters of those of *Ploceus*, but resembled those of some of the South African *Pyrgites* in the manner in which they were armed. The walls of each nest were entirely composed of stalks of grass, the thickest extremities of which were so placed as to protrude externally for several inches beyond the compact structure destined to contain the eggs. Thus each nest appeared armed with numerous projecting spines, and bore considerable resemblance to the body of a porcupine with its spines partially erected.

Plocepasser mahali. (Smith.)

Nests of *Plocepasser mahali*.

Textor erythrorhynchus. This bird is also a native of South Africa, and is found in company with herds of buffaloes, from whose hides it obtains supplies of food.

"This bird, besides being of service to its huge associates by ridding them of many of the insects with which their skins are infested, also performs for them another valuable service. On observing any unusual appearance in the neighbourhood, its attention is immediately directed to it; and, if alarm is eventually excited, the bird flies up, upon which all the buffaloes instantly raise their heads, and endeavour to discover the cause which had led to the sudden departure of this sentinel. If they are successful in the attempt, and see reason to fear for their own safety, they take to flight in a body, and are accompanied by the birds who forewarned them of their danger. On the herd again halting to feed, the birds return to their avocation, and pursue a course similar to that just described, provided the like circumstances recur. We never found this bird attaching itself to any quadruped but the buffalo, nor did we ever find the latter with any other attendants, though we found in the country in which both exist two other birds in the habit of feeding upon parasitical animals, namely *Buphaga africana* and *B. erythrorhynchos*. These restricted their visits exclusively to the Rhinoceros." (*Zoology of South Africa*.)

Textor erythrorhynchus.

PLOCEUS. [PLOCEINÆ.]

PLOMBGOMME, a Mineral consisting of Hydrated Aluminate of Lead. It is found in the French department of Côtes du Nord.

PLOTUS. [PELECANIDÆ.]

PLOUGHMAN'S SPIKENARD. [INULA.]

POLOVER. [CHARADRIADÆ.]

POLOVER-QUAILS. [TETRAONIDÆ.]

PLUCK. [ASPIDOPHORUS.]

PLUM. [PRUNUS.]

PLUMATELLA. [POLYZOA.]

PLUMBAGINACEÆ, a natural order of Monopetalous Exogenous Plants, with a compound superior 1-celled 1-seeded ovary, the ovule in which is supported upon a long curved funiculus, or cord. They are usually plants with a showy flower, herbaceous or under-shrubby, with several styles or stigmata, and a powerful acrid or astringent quality. The principal genus of the order is the *Statice*, whose many species, under the name of Sea-Lavenders, inhabit the salt-marshes or cliffs of all the temperate parts of Europe. [STATICE.] The prevailing colour of the flowers is blue; the instances of yellow, or any other colour, being more rare. Garden Thrift, *Armeria vulgaris*, a plant frequently used for an ornamental bordering in flower-gardens, is said to possess powerful diuretic qualities in its petals.

PLUMBAGO. [GRAPHITE.]

PLUMBO-CALCITE, a Mineral consisting of Calcareous Spar with Lead. [CALCAREOUS SPAR.]

PLUMBO-RESINITE. [LEAD.]

PLUTONIC, a term applied to rocks of igneous origin and ancient geological date. [GEOLOGY.]

PLUVIALIS. [CHARADRIADÆ.]

PLYCTOLOPHINÆ. [PSITTACIDÆ.]

PLYCTOLOPHUS. [PSITTACIDÆ.]

PNEUMOBANCHIATA. [MALACOLOGY.]

PNEUMODERMON. [CLIONIDÆ.]

PNEUSTOIDEA, Fitzinger's name for a family of Saurians, allied to that of the Chameleons. [CHAMELEONS.]

POA (the Greek *ῥοα*, 'grass'), a genus of Grasses belonging to the tribe *Festucineæ*. This tribe is characterised by very short styles, protruded stigmata, and the glumes shorter than the lowest flower. The genus *Poa* has its glumes rather unequal; the outer palea with 3 or 5 nerves, membranous below, scarious at the tip, compressed,

*Plumbago capensis.* [PLUMBAGINACEÆ.]

1, a flower deprived of corolla and stamens; 2, the ovary and stamens surrounding it; 3, a vertical section of the ovary, showing the peculiar position of the ovule.

keeled, unarmed; the styles terminal. The species of this genus are very numerous, constituting the commonest weeds that follow the migrations of man, and generally containing a sufficient quantity of nutritive matter to render them fodder for various animals. Thirteen species of this genus are described by Bahington as natives of the British Islands. Of these the most common are the *P. annua* and *P. pratensis*. The former is perhaps the commonest of British plants, springing up on every neglected spot around the habitations of man. The latter is known by the name of the Smooth-Stalked Meadow-Grass, and is found in most pasture lands. *P. nemoralis*, the Wood Meadow-Grass, is also a common grass in shady places. Many of the recent genera of Grasses were formerly referred to the genus *Poa*.

POCHARD. [DUCKS.]

POCILLO'PORA. [MADREPORÆÆ.]

PODA'RCIS, a genus of Lizards.

PODA'RGUS. [GOAT-SUCKERS.]

PO'DICEPS. [COLYMBIDÆ.]

PODICEPSI'NÆ. [COLYMBIDÆ.]

PODINE'MA, a genus of Lizards. [SAURIA.]

PO'DOA. [PELECANIDÆ.]

PODOCARPUS. [CONIFERÆ.]

PODOCES. [CORVIDÆ.]

PO'DOPHIS. [SCINCOIDÆ.]

PODOPHTHALMATA, or PODOPHTHALMIA. [CRUSTACEÆ.]

PODOPHTHALMUS. [PORTUNIDÆ.]

PODOPHYLLACEÆ, a small group of Polypetalous Exogenous Plants, by some regarded as a distinct natural order, and by others referred to *Ranunculaceæ* as a section. They would be Papaveraceous plants if they had consolidated carpels; but possessing no more than one carpel, they appear more referrible to *Ranunculaceæ*, from which, in fact, they seem to differ in having a solitary carpel, which however also occurs in that order, although not characteristic of it. The only species referred to *Podophyllaceæ* are *Jeffersonia* and *Podophyllum*, two North American plants, with succulent acrid root-stocks, deeply lobed leaves, and white flowers hidden among them. They have 3 or 4 sepals, twice as many petals, indefinite hypogynous stamens with linear or oval anthers, a thick sinuous stigma, and the ovules arranged along the central suture of the solitary carpel. *Podophyllum peltatum*, or May-Apple, is not uncommon in gardens, whither it has been introduced from the United States, where it is employed as a safe and active cathartic.

*Podophyllum peltatum.*

1, a flower; 2, a carpel; 3, a transverse section of the same; 4, a vertical section of a seed.

PODOPSIS. [SPONDYLIDÆ.]

PODOSTEMA'CEÆ, *Podostemata*, an obscure natural order of tropical submersed aquatic Plants, with minute incomplete flowers. They appear to have no very obvious relation to any other natural group, and are little known even to botanists except by name. They however are certainly Exogens, and probably allied to *Urticaceæ* and *Piperaceæ*. Endlicher places them among his aquatic class, consisting of *Ceratophylleæ*, *Callitricheæ*, and *Podostemeæ*, and enumerates seven genera.

PÆCILASMA. [CIRRIPEDIA.]

PÆCILONITTA, a genus of Ducks. [DUCKS.]

PÆCILO'PODA, M. Latreille's name for his sixth order of *Crustacea*, and arranged by him under his second sub-class, *Entomostraca*. The following is M. Desmarest's character of the order:—

Head confounded with the trunk; a shell, or the anterior of the body in the form of a huckler; mouth in the shape of a beak, or composed of appendages which cannot be compared to mandibles; antennæ short and simple or null; eyes often distinct and sessile; anterior feet terminated by one or two hooks, or by claws, fit either for walking or prehension; the posterior feet destined for natation, either composed of or accompanied by branchial laminae, or membranous and digitated.

1st Division.

Mouth in form of a beak; antennæ to the number of four; twelve feet, of which the first two are in the form of acetabula, or suckers (ventouses). Family *Argulidæ*, Leach.

Argulus is the only genus of this division.

2nd Division.

Mouth in form of a beak; antennæ to the number of two only. Family *Caligidæ*, Leach.

These, says M. Desmarest, like the last, are crustaceous aquatic parasites; the greater part of them are marine, adhering to the branchiæ and the axillæ of fishes, having the antennæ inserted at the external angle of two lobes on the anterior surface of their shell, and the eyes most frequently not apparent.

1st Subdivision or Race.

Twelve feet; the six anterior terminated by hooks or unguiculated. Extremity of the abdomen furnished with two bristle-like appendages or oviferous tubes, which are cylindrical and elongated.

The genera arranged by M. Desmarest under this subdivision are *Anthosoma*, Leach (*Caligus*, Latr., Lam., Risso), and *Dichelestium* of Hermann the younger and authors.

2nd Subdivision or Race.

Fourteen feet; the six anterior unguiculated; the fourth or fifth pair bifid; the sixth and seventh having the haunches and the thighs very much dilated and united by pairs.

Cecrops, Leach, is the only genus placed by M. Desmarest under this subdivision.

3rd Subdivision or Race.

Fourteen feet; the six anterior unguiculated; all the others bifid.

The genera arranged under this subdivision are *Pandarus*, Leach (*Caligus*, Latr. and Lam.), and *Nogaus*, Leach.

4th Subdivision or Race.

Fourteen feet; the six anterior unguiculated; the fifth pair bifid, with the last joints ciliated with hairs.

Caligus, Müller [CALIGUS], and *Risculus*, Leach, are the genera arranged under this subdivision.

3rd Division.

Mouth with its aperture in the middle of five pairs of feet or jaw-feet, terminated in pincers, the haunches of which, rough with points, may serve for mastication; no antennae; shell in the form of a buckler, consisting of two pieces, and terminated by a long sword-shaped tail; organs of respiration placed under the second piece of the shell. Family *Limulidae*, Leach.

The genus *Limulus* (*Limulus*, Müll., Fabr., Lat., Leach; *Monoculus*, Linn.; *Xiphosura* and *Xiphotheca*, Gronov.; *Polyphemus*, Lam.; *Cancer*, Clus.) is the only one belonging to this division. [XIPHOSURA; LERNÆADE; ENTOMOSTRACA; LIMULUS.]

POEPHIAGUS. [BOYDÆ.]

POGO'NIAS. [BARBETS.]

POINCIANA, a genus of Plants belonging to the natural order *Leguminosæ*. *P. aculeata*, or the Barbadoes Flower-Fence, is a tropical bush, about ten feet high, with bipinnate leaves, obovate leaflets, prickly branches, large terminal corymbose masses of inflorescence, covered with showy yellow or red flowers, having singularly long stamens. It has acquired its name from having been used, on account of its prickly branches, as a material for bedges in the West Indies, for which however it is ill adapted, because its branches are not much subdivided, and are always naked next the root. It is among the most beautiful of plants, and is chiefly on that account cultivated in the West Indies, to which it was introduced from the East Indies, where it is common in gardens, flowering and seeding all the year round. The leaves when bruised have a smell of sassa, and are said to have the power of bringing on abortion. They are well known to be purgative, and to have been used as a substitute for senna. According to Roxburgh, the trunk of this little tree, or large shrub, when old, is constantly hollow, and occupied by a large red dark-brown ant. From this place, when disturbed, the ants issue in swarms, and inflict a severe and painful bite on their disturbers.

POINTER, a variety of the Dog used in shooting, and trained to stop and point where the game lies. This variety is the Chien d'Arrêt of the French, and the *Canis familiaris avicularis* of Linnaeus.

The old Spanish Pointer was slow but very sure; and after all, where game is plentiful, there is as much or more to be picked up before one of these heavy but staunch dogs, now rarely to be found, as with the modern breed, in which swiftness is carried almost as far as it can be. Not that some of these thorough-bred fine-sterned dogs are not as staunch as any pointer of the old school, and there is something very delightful in their dashing style of ranging. A well-bred modern English Pointer, with a strong cross of the fox-hound, has perhaps as much 'travel' as can well be got out of four canine legs, and on light lands is of great endurance; whilst the true descendant of the perfect Spanish Pointer was rarely good for a second day's work. That the fine-sterned modern pointer is staunch, all who have seen high-bred and well-broken dogs act will allow; and it is recorded of Pluto and Juno, the two beauties which are immortalised in Daniel's 'Rural Sports,' that they kept their point while Gilpin took the sketch from which the picture was painted, upwards of an hour and a quarter. Steady enough this; but on the other hand, though blood will do much, these well-bred fine-sterned dogs have been found when tried on the moors to be, though fast, not stout hunters, and unable to stand work and weather like some of their rougher brethren.

Those who are interested in the subject of dog-breaking will find it well treated in Daniel's 'Rural Sports,' 'The Sportsman's Cabinet,' Colonel Hawker's well-known and excellent work, and more particularly in 'Observations on Dog-Breaking,' by William Floyd, gamekeeper to Sir John Sebright, Bart., every word of which is worthy of the best attention. There are also many valuable hints in the 'Treatise on Shooting,' by the author of the 'Oakleigh Shooting Code,' in 'The Rod and the Gun.'

POISON FANGS. [OPHIDIA.]

POKE. [PHYTOLACCA.]

POLANI'IA (from πολ, many, and ἴσος, unequal; stamens numerous and unequal), a genus of Plants belonging to the natural order *Capparidaceæ*. It has 4 spreading sepals; 4 petals; a small torus; silique sessile within the calyx, or hardly stipitate, terminated by a distinct style.

P. icosandra has a stem covered with viscid glandular hairs, 3-5

foliolate leaves, the leaflets obovate, cuneate, or oblong pubescent, scarcely longer than the petiole; the stamens are about 10 in number; the silique terete striated, rough with glandular horns, sessile and acuminate. It is a native of the East Indies, and is used in Cocbin China as a counter-irritant in the same way as sinapisms in Europe, and as a vesicant. The root is used as a vermifuge in the United States of America.

P. graveolens is a plant beset with glandular hairs; it has trifoliate leaves; elliptical oblong leaflets; from 8 to 12 stamens; oblong siliques narrowed at the base, glandularly mucronated and pubescent. It is a native of North America, and is employed as a vermifuge.

POLAR BEAR. [BEAR.]

POLECAT. [MUSTELIDÆ.]

POLEMONIA'CEÆ, a natural order of Monopetalous Exogenous Plants, with a trifid stigma, 3-celled fruit, and seeds attached to an axile placenta, the embryo lying in the midst of albumen. They are allied to *Convolvulaceæ*, from which their calyx, aestivation, placentation, seeds, and 3-celled fruit distinguish them; and also to the Ecbial alliance, from which their placentation, undivided capsular, not nucamentaceous fruit, and straight inflorescence, equally disjoin them. They consist for the most part of gay-flowered herbaceous plants, natives chiefly of North America. The genera *Collomia*, *Phlox*, *Leptosiphon*, *Gilia*, and *Polemonium*, are common objects of cultivation, on account of their beauty; as also is *Cobaea*, a climbing plant which grows with great rapidity, and is much used during the summer for covering trellis-work and places which require to be decorated with foliage for a few months. None of the order are of either economical or medicinal value.

POLEMO'NIUM (Πολεμώνιον of Dioscorides), a genus of Plants, the type of the natural order *Polemoniaceæ*. It has a campanulate 5-cleft calyx, a rotate corolla, and a short tube with a 5-lobed equal erect limb; 5 equal stamens inserted in the throat of the corolla, with filaments dilated at the base, bearded in a continuous ring, and nearly closing the throat, and incumbent anthers; a roundish capsule with membranous crustaceous valves, covered with the permanent calyx and many-seeded cells; the seeds oblong, trigonal, and filled with albumen; the radicle twice as long as the cotyledons. The species are erect herbaceous plants, with alternate unequally-pinnate leaves; the flowers terminal, bracteated, arranged on panicled corymbs, with blue or white corollas. About 12 species have been described, most of them being cultivated and known in our gardens as Greek Valerian.

P. caruleum, Common Greek Valerian, Jacob's Ladder, or Ladder of Heaven, has a glabrous stem, pinnate leaves, ovate lanceolate acuminate leaflets, the segments of the calyx ovate or elliptic, lanceolate, pointed; the panicle downy, glandular. The stem is one or two feet high; the leaves alternate; the flowers numerous, bright blue or white, somewhat drooping. It is a native of Europe and America, and is found in Great Britain, but is a rare plant. A great number of varieties have been described. It is a favourite plant in our gardens, and will grow in any common garden soil, and may be readily propagated by dividing the root or by seed. Although deriving its generic name from the *Polemonium* of Dioscorides, it does not appear to agree at all with his description of that plant, and Fraas refers it to *Hypericum Olympicum*. Great virtues were attributed to the ancient *Polemonium*, and these were transferred to the modern plant; but neither the ancient nor modern plant possesses any active medical properties. Slight astringency is the only property possessed by any of the species of *Polemonium*.

(Fraas, *Synopsis Plant. Floræ Classicæ*; Babington, *Manual of British Botany*.)

POLIA'NTHE, a genus of Plants belonging to the natural order *Liliaceæ*. *P. tuberosa*, or the Tuberose (a corruption of *Plaute Tubereuse*), is a tuberous-rooted plant, highly prized for the delicious fragrance of its flowers, on which account it is cultivated in the warmer parts of both the Old and New World. Doubts are entertained regarding its native country. It appears to have been first seen in Europe by Clusius, who received it from Simou do Tovar as an Indian plant, but whether from the East or the West is unknown. It is extensively cultivated in the East Indies, whence it has been supposed to be an Asiatic plant; but no traveller has found it wild there, and it has no Sanscrit name. It is therefore more probable that it is of South American origin, for it is equally common there in cultivation; and, as Sir James Smith has rightly observed, its constitution is more like a Peruvian plant than one of Ceylon or Java. Of late years a wild Tuberose (*P. gracilis*) has been found in South Brazil, which is probably the origin of the garden plant.

The Tuberose is too tender a plant to be cultivated in England in the open air; but in the south of Europe it finds a climate suitable to it, and the Genoese supply the principal part of the European market with tubers for forcing. The latter are imported into this country by the Italian oilmen, who sell them, with orange-trees, Narcissus roots, and similar products of the south.

POLISHING SLATE, *Polier Schiefer*, a Mineral, occurring massive, with a slaty texture. Its colour is white, yellowish-white, or yellow. Brittle. Opaque. Specific gravity 0.59. It is found near Jiilin in Bohemia, at Zwickau in Saxony, and Auvergne, and is supposed to be a volcanic product. Its analysis by Bucholz gives—

Silica	83.5
Alumina	4.0
Lime	8.5
Oxide of Iron	1.6
Water	9.0

—106.6

The silica is apparently derived from *Diatomaceæ*. [DIATOMACEÆ.]

POLLACK. [MERLANGUS.]

POLLEN. [STAMEN.]

POLLEN. [BEE.]

PO'LLIA (Gray), a genus of *Mollusca*.

POLLI'CIPIES. [CIRRIPEDIA.]

POLLONTES (De Montfort), a genus of *Foraminifera*.

POLLUX, a Mineral containing Silica, Potash, and Soda.

POLYADE'LPHIA, the name given by Linnæus to the eighteenth class of his Sexual System. It was so named from *πολύς*, many, and *ἀδελφός*, a brother, in allusion to the stamens being collected into several parcels.

POLYANDRIA, the name given by Linnæus to the fourteenth class of his Sexual System. Although the name means literally many stamens or males, yet it is applied, in a restricted sense, to those plants only which have many stamens arising immediately from below the ovary.

POLYANTHUS, a garden variety of the Oxlip Primrose, with brown flowers, is one of those plants which have from time immemorial been favourites in gardens. It was probably obtained by accident, and is now propagated either by seeds or division of its root.

POLYANTHUS NARCISSUS is the *Narcissus Tazetta*. [NARCISSUS.]

POLYBASITE. [SILVER.]

POLYBIUS. [PORTUNIDÆ.]

POLYBORUS. [FALCONIDÆ.]

POLYBRACHIONA. [ACALEPHÆ.]

POLYBRANCHIATA, M. De Blainville's name for his second order of *Paracephalophora Monoica*, consisting of the families *Tetracerata* and *Dicerata*. The first of these families consists of the genera *Glaucus*, *Laniogerus*, *Tergipes*, *Carolina*, and *Eolidia*; the second, of the genera *Seylla*, *Tritonia*, and *Tethys*. [NUDIBRANCHIATA.]

POLYCARPON (from *πολύ*, many, and *καρπός*, a seed or fruit: seeds numerous), a genus of Plants belonging to the natural order *Paronychiaceæ*. The sepals are slightly coherent at the base; the petals 5 and emarginate; the stamens 3-5; styles short and 3 in number. The fruit is a 1-celled, 3-valved, and many-seeded capsule.

P. tetraphyllum has triandrous leaves, emarginate petals, the stem-leaves in fours, and the leaves on the branches opposite. In young plants the leaves are often all opposite. It is a native of the coasts of the south-west of England, of Europe, and the Canary Islands.

There are two other species of *Polycarpon*: *P. plaineifolium*, an inhabitant of Europe, the Cape of Good Hope, and Holland; and *P. peploides*, a native of Sicily and France.

(Babington, *Manual of British Botany*.)

POLY'CERA. [NUDIBRANCHIATA.]

POLYCHRUS. [LOUANIDÆ.]

POLYCOTYLEDONOUS PLANTS are those which have more than two cotyledons. Instances of this occur in the *Crucifera*, in *Lepidium*, and *Schizopetalum*; in the *Boraginaceæ* order, in *Amsinckia*; and especially in Coniferous plants. All such plants are referred to the Dicotyledonous type. [SEED.]

POLYCRASE. [YTTRIUM.]

POLYDECTUS, a genus of *Crustacea*. [CORYSTES.]

POLYDONTES (De Montfort), a genus of *Helicidae*.

POLYERGUS, a genus of *Formicidae*, separated from *Formica* by Latreille. The type of the genus is *P. rufescens*, the Amazon Ant. The species are destitute of stings, and have the antennæ near the mouth and the mandibles narrow, curved, or very much hooked. The habits of the Amazon Ant, *P. rufescens*, are very remarkable, the neuters of this species unite with those of *Formica sanguinea* in making war upon the neuters of other species of *Formicidae*, especially *P. cunicularia* and *P. fusca*. The result of the conquest is the making slaves of the latter, who are always found doing the hard work of the colonies of their enslavers. [ANT.]

POLYGALA, a genus of Plants belonging to the natural order *Polygalaceæ*. It has five persistent sepals, the *alcæ* large and petaloid; petals three, their claws all united with the stamiferous tube, the lower ones carinate (keel-shaped), the two additional ones abortive; stamens united into a tube at the base, which is cleft in front; anthers opening by a pore; ovary 2-celled; ovules solitary, pendulous from the apex of the cell; capsule 2, locular, loculicidal, compressed; seeds pendulous from the apex of the cells, pubescent, with a carunculate arillus at the hilum; albumen abundant, fleshy. The species are shrubs or herbaceous plants. The flowers arranged in terminal or axillary racemes.

P. Sæega, Virginian Snake-Root, a perennial plant, native of several parts of North America, but the best is found in Virginia, having a rootstock, about the thickness of a quill, twisted, and generally branched, the rootlets being esteemed the most powerful part in medicine. The leaves are alternate, sessile, lanceolate, with a sharpish-point, smooth, paler underneath; flowers white, in a close terminal spike; sepals 5; corolla small, closed, having two obtuse lateral segments, and a short crested extremity.

P. vulgaris, Milkwort, a British species. It has a crested keel; flowers in a terminal raceme; wings of calyx obovate, mucronate; lateral bracts longer than pedicels; lower leaves smaller than the upper. It is found in dry pastures. *P. calcarea* is a second British species.

P. rubella is found in dry gravelly soils in many parts of the United States. It is used in medicine as a tonic.

There are 14 species of *Polygala* found on the continent of Europe, mentioned in Wood's 'Tourist's Flora.'

POLYGALACEÆ, *Milkworts*, a natural order of Exogenous Plants. The species are herbs or shrubs with simple exstipulate leaves; the pedicels have three bracts, and the flowers are irregular, unsymmetrical, and falsely papilionaceous; sepals five, irregular, odd one posterior, two inner ones (wings) usually petaloid; petals more or less united, usually three, of which one (the keel) is anterior, larger, and sometimes crested; stamens six or eight, usually combined into a tube, which is split on the upper side; anthers 1-celled, opening by pores; ovary usually 2-celled, with a single pendulous anatropal ovule in each cell; style curved; capsule flattened, with albuminous carunculate seeds, containing a straight embryo. The order is considered by St. Hilaire and others as allied to *Sapindaceæ*, and some authors place it near *Leguminosæ*, from which it differs in its hypogynous stamens, and in the odd sepal being superior, and the odd petal inferior. The plants are scattered all over the globe. There are about 500 known species. The genera are *Salomonina*, *Polygala*, *Mundia*, and *Securidaca*. They are generally bitter and acrid, and the roots yield a milky juice. (Balfour, *Classbook of Botany*.)

POLYGAMIA, a Linnæan class of Plants in which the species have male and hermaphrodite, or female and hermaphrodite, or both female, male, and hermaphrodite flowers on the same or different individuals.

POLYGASTRICA. [INFUSORIA.]

POLYGONA'CEÆ, *Buckwheats*, a natural order of Apetalous Plants with triangular fruit and usually with stipules united into a tube or ocrea, through which the stem passes. Their fruit is composed of three asperous carpellary leaves joined by their edges, and surrounding a single erect ovule deriving its origin from a central placenta; and it proves the truth of the modern theory, that in many cases the ovules derive their origin immediately from the centre of vegetation, or the growing point, and not from the margin of carpellary leaves. The order consists of herbaceous plants more frequently than of shrubs, and a large part of them are mere weeds; as for example our docks, and wild polygonums; some however are handsome flowers, as the *P. orientale*, or Garden Persicaria, and *P. amplexicaule* [POLYGONUM]; others are valuable for cooking, as the rhuhrar, whose roots also furnish the important tonic and purgative drug of that name, and in some a great quantity of astringent matter is found, as in the *Coccoloba uvifera*, or Seaside Grape of Jamaica, from which a kind of Kino has been prepared. [COCOLOBÆ.] A species of Indian *Polygonum*, *P. tinctorium*, has recently been introduced into cultivation in Belgium as a substitute for indigo. The flour of the seeds of *P. tartaricum*, *P. Fagopyrum*, and others, is made into a bad kind of bread in Lombardy and other countries. [POLYGONUM.]

The genus *Rheum* also belongs to this order. [RHEUM.]

POLY'GONUM (the Greek *πολύγωνον*, 'much productive'), a genus of Plants belonging to the natural order *Polygalaceæ*. It has a 5-parted perianth, from five to eight stamens, and from two to three styles; a 1-seeded trigonous or compressed nut, lateral incurved embryo, the cotyledons not contorted. This is a very extensive genus, containing the Knotgrasses, Bistorts, Persicarias, and Buckwheats of our own waysides, fields, and gardens. They grow in almost any soil, some being aquatic, and others flourishing in sandy sterile tracts.

P. Bistorta, Snake-Weed, has a dense spike, ovate-subcordate leaves, the radical leaves with winged foot-stalks, the stem leaves half as long again as the perianth, the nut triquetrous, its faces ovate, smooth. The calyx is rose-coloured and deeply 5-cleft, obtuse, and spreading. The fruit is black and shining. This plant is one of the most powerful vegetable astringents, its root contains tannin and gallic acid in abundance; a decoction of it is employed in gleet and leucorrhœa as an injection, as a gargle in sore throats, and as a lotion to ulcers attended with excessive discharge. Internally it has been used combined with gentian in intermittents. It may also be employed in passive hæmorrhages and diarrhœa. [BISTORT, in ARTS AND SC. DIV.]

P. amphibium has a dense ovate cylindrical spike, stalked ovate-oblong floating leaves, a compressed smooth shining nut, five stamens, and a creeping root. The flowers are of a bright crimson colour. It is a native of England in ponds, ditches, and wet places. It is a fine showy plant, but one of the most difficult to eradicate from lands recovered from rivers or drained lakes and marshes. The subaquatic stems root at every joint, and extend to a surprising length, rising through the soil. They bear some resemblance to sarsaparilla, and according to Coste and Willemet they are substituted for this drug by the herbalists of Nancy; these authors also report that the apothecaries and druggists of Lorraine give it the preference.

P. hydropiper, the Water-Pepper, has drooping filiform interrupted spikes, lanceolate wavy leaves, glandular perianths, a large compressed nut, its faces ovate, acute, and of a purplish-black colour. It is a hot acrid plant, and is reputed to be a powerful diuretic, but it loses its activity by drying, and therefore requires to be used in a fresh state.

It dyes wool of a yellow colour. The seeds, according to Bulliard, are used in some of the French provinces instead of pepper. The leaves are so acrid as to act as vesicants. It is a native of England in ditches and wet places.

P. aviculare has from one to three flowers together, axillary lanceolate leaves, or elliptical plane stalked lanceolate acute ocreæ, with few distant simple nerves at length by growth becoming torn, a triquetrous nut with raised points shorter than the perianth. Its numerous seeds supply abundant food for small birds; they are said to be emetic and cathartic. Thunberg says that in Japan a blue dye is prepared from this plant.

There are many other species of *Polygonum*, natives of Great Britain and other parts of the world, but too numerous for description here. *P. tinctorium* is cultivated in France and Flanders on account of the fine blue dye extracted from it. The seeds of *P. barbatum* are used in medicine by the Hindoo practitioners, and are said to ease the pain of griping in the colic. The leaves of *P. hispidum* are said by Humboldt to be substituted in South America for tobacco; and *P. anti-hemorrhoidale* is esteemed in Brazil on account of its astringency in baths, poultices, &c. The juice, as well as an infusion of the ashes when burned, is employed by the Brazilians in the clarification of syrup and the condensation of sugar.

P. Fagopyrum, the Buck-Wheat, is now referred to *Fagopyrum esculentum*. [FAGOPYRUM.]

(Lindley, *Vegetable Kingdom*; Babington, *Manual of British Botany*; Burnett, *Outlines of Botany*; Lindley, *Flora Medica*.)

POLY'GONUM (Schumacher), a genus of Mollusca.

POLYGY'RA, a genus of Helicida.

POLYHALITE. [MAGNESIA.]

POLYHYDRITE. [IRON.]

POLY'LEPAS. [CIRRIPEDIA.]

POLYLITE, a form of Augite. [AUGITE.]

POLYMIGNITE, a Mineral, consisting of Titanate of Iron, Zircon, &c. It occurs crystallised. Primary form a right rhombic prism. Fracture conchoidal. Hardness, scratches phosphate of lime, and is scratched by felspar. Colour black. Lustre nearly metallic. Opaque. Specific gravity 4.806. Before the blow-pipe infusible; acted upon by sulphuric acid, when reduced to fine powder. It is found in imbedded crystals at Frederiksværn in Norway. The following is the analysis by Berzelius:—

Titanic Acid	49.3
Oxide of Iron	12.2
Oxide of Cerium	5.0
Oxide of Manganese	2.7
Zirconia	14.4
Yttria	11.5
Lime	4.2
Magnesia, Potash, Silica, and Oxide of Ti	traces

—99.3

POLYNEMUS, a genus of Fishes, placed by Cuvier in his third division of the *Percida*, the species of which are distinguished by the ventral fins being inserted farther back than the pectorals. These fishes are further distinguished by having several long filaments beneath the pectoral fin; these are, in fact, free rays of that fin: their teeth are minute and dense as the pile on velvet, or recurved like the teeth in a carding-machine; they are found on both jaws, as well as on the vomer and palate. The general form of the body of the *Polynemi* somewhat resembles that of the perch; the muzzle projects over the mouth; the eyes are rather large and placed very forward; the dorsal fins are short and widely separated, and the caudal fin is large, and more or less forked. The scales extend on the fins, as in many of the *Scianidae*, which these fishes appear to approach in some other characters.

Considerable interest is attached to the *Polynemi* on account of their yielding isinglass. This fact was first made known by Dr. Cantor, who found that several species of *Polynemus* might be used for obtaining isinglass.

"The species best known," says Dr. Cantor, in a communication to the Zoological Society, "is the *Polynemus Rissæ* of Hamilton (*P. longifilis*, Cuvier; the Tupsee, or Mango Fish, of the Anglo-Indians): this inhabits the Bay of Bengal and the estuaries of the Ganges, but enters the mouths of the rivers even higher up than Calcutta during the breeding season (April and May), when the fish is considered in its highest perfection, and is generally sought as a great delicacy. This species is the smallest, for its length seldom exceeds eight or nine inches, and one inch and a half or two inches in depth." It is remarkable for the great length of filaments, or free rays, of the pectoral fins, these being about twice the length of the body, and seven in number on each side. *P. aureus* and *P. Toppei* of Hamilton, Dr. Cantor states, are closely allied to this species. "*Polynemus Sele*, Hamilton (*P. plebeius*, Broussonet; *P. lineatus*, Lacépède), is the Suleah Fish first mentioned in Parbury's 'Oriental Herald,' as yielding isinglass. This species, as well as another closely allied to *P. quadrifilis*, Cuvier, which I have dissected, figured, and described, under the name of *P. Salliah* (Saccobih), appears to be equally plentiful, in shoals, all the year round, in the estuaries of the Ganges, and is appreciated by Europeans for its excellent flavour: both species attain a size from three to four feet in length, and eight to ten inches in depth." (Cantor.)

Besides these species found on the coast of the mainland, two other species of *Polynemus*, *P. hexanemus* and *P. heptadactylus*, have been discovered off the coast of Java. On the coast of Africa and in the West Indies, certain species of the present genus are found. One of the African species is confounded by Cuvier with the Indian *P. longifilis*, and the mistake has been rectified by Mr. Bennett. It appears that this species (which is in all probability the *Pentamenus* of Artedi, on which Linnaeus established his *P. quinquarius*) differs from the Mango Fish of India in the number of free rays to the pectoral fins, the latter having seven rays, and the African species only five. Messrs. Cuvier and Valenciennes, not having found any species of *Polynemus* with so few as five free rays, and those longer than the body, imagined that the *P. quinquarius* was founded on a mutilated specimen. Several individuals however having this character being discovered by Captain Belcher, R.N., during his survey of a part of the Atlantic coast of North Africa, Mr. Bennett proposed to name the species after Artedi.

Polynemus Artedii.

The second African species belongs to that section in which the free rays of the pectoral fins are short, and has received the name of *Polynemus quadrifilis*.

Polynemus quadrifilis. (Cuv. et Val.)

In the American *Polynemus* (*P. Americanus*) there are seven free rays to the pectoral fin, and these scarcely reach the tip of the ventral fin: it is about one foot in length, of a silvery colour; the pectoral fins are almost black, and the other fins are spotted with black.

POLYODONTA ('many-toothed' tribe), a name applied by Lamarck and M. De Blainville to the *Arcacea* [ARCADÆ] of the former, the Ark-Shells, &c., of collectors, comprehends the forms collected by Linnaeus, in his 'Systema Nature', under the genus *Arca*, and those designated by more modern zoologists as the genera *Arca*, *Cucullæa*, *Pectunculus*, and *Nucula*.

Lamarck's *Arcacea* constitute a part of his *Conchiferos Ténui-pèdes*, and are arranged by him between the *Cardiacées* and the *Trigonées*.

De Blainville places his family *Polyodonta* or *Arcadæ* between the *Mytilacea* and *Submytilacea*.

Lamarck thus defines the family:—

"Cardinal teeth small, numerous, entering, and disposed in each valve in either a straight, a curved, or a broken line."

M. Rang makes the *Arcadæ* consist of the genera *Cucullæa*, *Arca*, *Pectunculus*, *Nucula*, and *Trigonia*, and gives the following as the character of the family:—Animal having the mantle entirely open throughout its circumference, excepting towards the back, without tubes or any particular apertures, and partially adherent; sometimes prolonged backwards; the foot always very considerable. Shell

generally thick, regular, equivalve, inequilateral, with a similar hinge in each valve always formed of serial teeth, which are often lamellar, fitting into each other, straight or oblique; muscular impressions nearly always united by a pallial impression, which is very narrow, and parallel to the border of the shell.

Cucullæa (Lam.).—Animal very thick, having the mantle a little prolonged backwards, and bordered by an irregular row of tentacular filaments; labial appendages small and triangular; foot large, pedunculated, compressed, and slit longitudinally. Shell thick, navicular, equivalve, inequilateral, ventricose, with distant umbones; hinge linear, straight, formed of small transverse teeth for the greatest part of its length, and of many other teeth or longitudinal ribs; ligament entirely external; anterior muscular impression forming a projection with an angular or auriculate border. (Rang.)

There is only one recent species of *Cucullæa*.

This species is the *Arca concamerata* of Martini, *A. Cucullus* of Gmelin, *A. cucullata* of Chemnitz, and *Cucullæa auriculifera* of Lamarck, under which last name it is generally known; but, as M. Deshayes well remarks, Martini's name has the priority, and it ought to be that by which the species should be designated.

The shape of the shell, which is of fair size, will be seen better from the subjoined cut than from verbal description. The longitudinal striae are more marked than the transverse striae. The colour is rather a deep cinnamon-brown externally, and internally on the anterior part brown tinged with violet. It is a native of the Indian Ocean; sandy bottoms.

Cucullæa auriculifera.

There are about 100 species of *Cucullæa* fossil, chiefly Silurian.

Arca (Linn.).—Animal more or less thick, generally rather elongated; mantle prolonging itself slightly backwards, and with a row of tentacular filaments on its borders; labial appendages very small and slender; foot pedunculated, compressed, and slit throughout its length.

Shell navicular, rather thick, equivalve, inequilateral, elongated, more or less oblique; umbones distant and often a little recurved forwards; hinge linear, straight, furnished throughout its length with a numerous row of small teeth or transverse laminae, which are equal and intransigent; ligament entirely external.

M. Rang, who gives the above as the characters of *Arca*, remarks that the species sometimes adhere by their foot, and more frequently by means of a byssus.

M. De Blainvill divides the *Arcae* into the following subdivisions:—

A. (Les Navicules).—Navicular species; the hinge completely straight; the foot tendinous and adherent. (*Byssarca*, Sw.) [*BYSSARCA*.] Ex. *Arca Noë*.

B. (Les Bistournées; Genus *Trisid*, Oken.) Ex. *A. tortuosa*.

C. (Genus *Cucullæa*, Lam.).—Navicular species; the hinge completely straight; the terminal teeth much longer and more oblique than the others. Ex. *Cucullæa auriculifera*, Lam.

NAT. HIST. DIV. VOL. IV.

D. Species with a straight hinge not notched or not gaping inferiorly. Ex. *A. barbata*.

E. (Les Rhomboides).—Species well closed, of less elongated form, more pectinoid, and with a straight hinge. Ex. *A. rhombea*.

F. Oval species, elongated or a little arched longitudinally, slightly gaping inferiorly, with the umbones at a little distance from each other, the ligament nearly internal, and the dental line a little bent. Ex. *A. mytiloidea*.

This number of recent species recorded by M. Deshayes, in his Tables, is 43. Woodward gives 130 species.

The following descriptions and cuts will give some idea of the difference of form assumed by the shells of this genus:—

A. Noë. Shell oblong, striated; apex emarginate; umbones very remote, incurved; margin gaping. It inhabits the Atlantic Ocean and seas of Europe.

Arca Noë.

a, valves closed, with the umbones and area of the hinge towards the spectator; *b*, valves closed, with the ventral or inferior aspect, showing the margin, opposite to the spectator; *c*, internal view of one of the valves.

A. tortuosa (Genus *Trisid*, Oken). Shell twisted, parallelopiped, striated; valves obliquely carinate; umbones small, recurved. It inhabits the Indian Ocean.

A. antiquata. Shell transverse, obliquely cordate, ventricose, many-ribbed; the ribs transversely striated and blunt; the posterior ribs bifid. Colour white.

Lamarck gives the Indian Ocean, the coasts of Africa, and the Mediterranean, as the localities of this species, of which M. Deshayes, in the last edition of the 'Animaux sans Vertèbres,' says that he is convinced that since the time of Linnæus two species at least have been confounded under the denomination of *A. antiquata*, although they are easily distinguished; the one, more transverse, has the cardinal surface always furrowed into lozenge shapes when the valves are united; the other having a thicker shell, the ribs flatter, wider, and striated, but never with furrows on the cardinal surface. This last, being the most common and most anciently known, should, in his opinion, retain the name of *A. antiquata*, and he cites the following figures of the shell:—'Gualt. Test., pl. 87, f. C.; Chemn., 'Conch., t. vii. pl. 55, f. 548; 'Encyclop., pl. 306, f. 2; Gronov., 'Zooph., pl. 18, f. 13. M. Deshayes further remarks, that the shell figured by Poli and cited by Lamarck in the synonymy constitutes a species distinct from the two others. He adds that this, which inhabits the Mediterranean, is the living analogue of *A. diluvii*. Neither, in his opinion, is this *A. antiquata* of Brocchi a true *A. antiquata*, but the *A. diluvii*, the fossil analogue of the species figured by Poli.

The *Arcae* have hitherto been found on bottoms of sandy mud and dirt, at depths varying from the surface to seventeen fathoms. Some of the species are moored to stones, corals, &c.

*Arca tortuosa.*

a, internal view of a valve; *b*, valves closed, the ventral or inferior margin towards the spectator; *c*, external view of a valve.

*Arca antiquata.*

a, valves closed, inferior or ventral margin towards the spectator.

Pectunculus, Lam.—Animal rounded, more or less thick, with no tentacular filaments on the border of its mantle; labial appendages very narrow; foot large, compressed, and slit longitudinally.

Shell lenticular, thick, solid, equivalve, subequilateral, entirely

closed; umbones rather small, and more or less distant; hinge formed of a curvilinear row of small narrow, rather numerous, intrans teeth, which are often incomplete under the umbones; ligament external. (Rang.)

The *Pectunculi* live on sandy or muddy bottoms, and have been found at depths ranging from 5 to 17 fathoms. They move by means of the foot, which the animal uses to propel itself.

The number of living species stated in the Tables of M. Deshayes is 19. Woodward gives 50.

P. pilorus. Shell orbiculate; ovate, tumid, marked with decussate striae; umbones oblique; epidermis brown, hairy. It inhabits the Mediterranean and the Atlantic Ocean. (Lam.)

*Pectunculus pilorus.*

There are about 200 fossil species of the genus *Arca*. They are found in the Lower Silurian Rocks.

Nucula (Lam.).—Animal rather thick, subtriangular, having the mantle open only in its inferior moiety, with entire borders, denticulated throughout the length of the back, without posterior prolongations; anterior buccal appendages rather long, pointed, stiff, applied one against the other, like a kind of jaws, the posterior ones equally stiff and vertical; foot very large, delicate at its root, enlarged into a great oval disc, the borders of which are furnished with tentacular digitations.

Shell rather thick, sometimes nacreous, subtriangular, equivalve, inequilateral; umbones contiguous, and curved forwards; hinge formed on each valve of a numerous row of small pointed teeth, disposed in a line broken under the umbo; ligament in great part internal, short, and inserted in a small oblique fosset in each valve. (Rang.)

The species have been found on bottoms of sandy mud and sand, both in estuaries and the open sea, at depths varying from the surface to 60 fathoms. According to Mr. Cuming, the same species vary much as to the depths at which they live; for he found *N. cuneata* from 14 to 45 fathoms; *N. obliqua* from 14 to 60 fathoms; and *N. Pisum* from 17 to 45 fathoms.

Animal of *Nucula australis*.

1. *a a*, mantle; *b*, foot; *c*, branchia; *e e*, adductor muscles. 2, Outline of shell, with the foot of the animal projecting.

M. De Blainville divides the *Nuculae* into two sections:—

A. Species with the border entire. Ex. *N. rostrata*.

B. Species with the border crenulated. Ex. *N. margaritacea*.

The number of recent species is 70. They are found in the seas of the United States, Norway, the Cape of Good Hope, Japan, Sitta, and Chili. The number of fossil species is about 100.

The following descriptions and cuts will give some idea of the forms of this genus.

N. rostrata. Shell transverse, oblong, rather convex, thin, transversely striated; anterior side longest, attenuated and rostrated.

Nucula rostrata.

N. margaritacea. Shell obliquely ovate, trigonal, rather smooth; cardinal teeth straight, acute; margin crenulated.

Nucula margaritacea.

1, Interior of Valve, showing the teeth on each side of the hinge, and the cartilaginous pit in the centre. 2, Exterior of Valve. 3, View of the Teeth, the dorsal margin of the shell being towards the observer, enlarged. 4, Valves closed, showing the umbones.

Trigonia is most frequently referred to the family *Trigonidae*. [TRIGONIDE.]

POLYPPES. [POLYPIFERA.]

POLYPHYLLIA. [MADREPHYLLICEA.]

POLYPHYSA (Lamouroux), a little-known genus of Corallines.

POLYPIARIA. [POLYPIFERA.]

POLYPIFERA, POLYPIARIA, or POLYPI, an order of Radiate Animals, thus characterised by M. Milne-Edwards:—Animals organised for a sedentary mode of life, having no locomotive organs, and being provided with a circle of retractile tentacula around the mouth, and a central gastric cavity, not communicating with an anus, and containing the reproductive organs when these exist, in general fissiparous, or multiplying by buds as well as by ovules.

Our knowledge of the forms and functions of this group of animals is comparatively recent. The discoveries of Trembley regarding the structure and animal functions of the Phytoid *Hydra*, and *Plumatella* of fresh-water, opened a new field of research into the nature and relations of many neglected forms of life, and gave occasion for much correct inference and baseless conjecture. [HYDRA.] Borrowing from Aristotle and Pliny the term 'Polypus,' by them applied to a cephalopod, the systematic naturalists who followed Linnæus collected under this title many really animalised masses in the form of plants, and after abundant examinations by Ellis and others of the membranous, horny, or stony 'fulcra,' bases or axes, which remain after desiccation or decay of the softer parts, generally agreed in opinion that to all these plant-like bodies were associated active living animals like the *Hydra* described by Trembley.

As in a tree the flowering and reproductive organs manifest more active and varied functions than the general mass of bark and wood which serves to unite them in one common life, so in these *Zoophyta* the little *Polypi* expanding from their cells for food, light, or aëration, and shrinking back upon the agitation of the water, or withdrawal of the light, seemed like so many animal flowers, which might be studied apart from the *Polypiaria* which they adorned. They were in fact studied apart, and unfortunately attention was more directed to the wonderful permanent fabric, or Polypidom, as Lamouroux calls it, than to the *Polypi* themselves. Hence the imperfection of all the schemes of classification for this portion of the *Zoophytic* division of the animal kingdom, and many of the erroneous generalisations and hypotheses regarding the lower forms of animal life. There was besides a real impediment in the way of accurate and satisfactory observation of these minute parts of creation in the imperfection of microscopes.

Lamarck was the first who attempted to classify these creatures in the following way:—

Polypi Ciliati, as many of the Rotiferous *Infusoria*.

Polypi Denudati, as the *Hydra*.

Polypi Vaginati, as the compound *Sertularia*, Corals, &c.

Polypi Tubiferi, as the *Lobularia* and its allies.

Polypi Natantes, as the *Pennatulæ*.

The *Actinia*, thus expressly excluded from the class of *Polypi*, are very closely related to them.

Dr. Johnston, in his 'British Zoophytes,' gives the following classification of these animals:—

Sub-Class 1. Radiated *Zoophyta*.—Body contractile in every part, symmetrical; alimentary canal with one opening; gemmiparous and oviparous.

Order 1. *Hydroidea*.—Polypes compound; mouth with filiform simple tentacula; stomach excavated in the cellular substance of the body; no distinct muscular apparatus; the body contractile in all its

parts; gemmiparous externally. Polypidom (if existing) external to the polypes. (*Hydra*, *Sertularia*, &c. *Nudibrachia* of Farre.)

Order 2. *Asteroida*.—Polypes compound; mouth encircled with eight fringed tentacula; gemmiparous internally; stomach membranous. Polypidom an internal axis. (*Gorgonia*, &c.)

Order 3. *Helianthoida*.—Polypes single; mouth encircled by tubulous (aquiferous?) tentacula; stomach membranous, plaited; oviparous by internal ovaria. (*Actinia*, &c.) [ACTINIADE.]

Sub-Class 2. Molluscar *Zoophyta* (*Polyzoa* of Thompson; *Cilio-brachia* of Farre; *Bryozoa* of Ehrenberg).—Body not contractile, symmetrical; mouth and anus separate; gemmiparous and oviparous.

Order 4. *Ascidioda*.—Polypes aggregated; the mouth encircled with filiform ciliated tentacula; stomach distinct, intestine recurved to an anus near the mouth; ova internal. (*Cellaria*, &c.)

In this work the last sub-class of Dr. Johnston is treated of in a separate article, POLYZOA, which has been written by Mr. Busk, who has subjected this order of animals to a thorough examination, the results of which have been given in his beautifully illustrated 'Catalogue of the Polyzoa,' in the collection of the British Museum.

In the present article we propose to give a synopsis of the families and the names of the genera of the *Polypi*, drawn up principally from M. Milne-Edwards's 'Introduction to the British Fossil Corals,' published by the Palæontographical Society.

Sub-Class I. CORALLARIA.

Polypi possessing distinct internal reproductive organs, and having the gastric or visceral cavity surrounded by vertical radiating membranaceous lamellæ.

Order 1. ZOANTHARIA.

Polypi with conical, tubular, simple or arborescent but not bipinnate tentacula, and with numerous perigastric membranaceous laminae, containing the reproductive organs.

Sub-Order 1. *Zoantharia Aporosa*.

Corallum composed essentially of lamellar dermic sclerenchyma, with the septal apparatus highly developed, completely lamellar, and primitively composed of six elements; no tabulae.

Family 1. *Turbinolide*.

Corallum in general simple, never fissiparous, and multiplying by lateral gemmation in compound species. Interseptal loculi extending from the top to the bottom of the visceral chamber, and containing neither dissepiments as in the *Astreidae*, nor synapticulae as in the *Fungidae*. Walls thin, lamellar, and imperforated. Septa highly developed, simple, compact, in general regularly granulated on each side, and never denticulated or lobulated at their apex. Costae in general well marked and straight. No cœnenchyma in the compound polypidoms.

First Tribe. *Cyathinæ*.

Calicule presenting one or more rows of pali, placed between the columella and the septa.

A. A single coronet of pali.

Genera, *Cyathina*, *Cenocyathus*, *Acanthocyathus*, *Bathycyathus*, *Bracyathus*, *Discocyathus*, *Cyclocyathus*.

B. Pali of divers orders, forming two or more coronets.

Gen. *Trochocyathus*, *Leptocyathus*, *Thecocyathus*, *Paracyathus*, *Heterocyathus*, *Deltocyathus*, *Tropidocyathus*, *Placocyathus*.

Second Tribe. *Turbinolæ*.

Corallum destitute of pali; the septa extending to the columella, or meeting in the centre of the visceral chamber.

Gen. *Turbinolia*, *Sphenotrochus*, *Platyatrochus*, *Ceratatrochus*, *Discoatrochus*, *Desmophyllum*, *Flabellum*, *Placatrochus*, *Blastatrochus*, *Rhizotrochus*.

Aberrant Group. *Pseudo-Turbinolide*.

Corallum simple, with the loculi open and devoid of synapticulae, or dissepiments, as in *Turbinolide*, but having the septa represented by groups of three vertical laminae, not adhering together, excepting near their external margin, where they are united by a common costa, a mode of structure which is quite anomalous in the whole order of *Zoantharia*.

The only genus is *Dasmia*.

Family 2. *Oculinide*.

Corallum composite, produced by gemmation, and presenting in general an abundant compact cœnenchyma, or common tissue, the surface of which is smooth, delicately striated near the calices, or slightly granular, but never echinulate; walls of the corallites complete (that is to say, presenting no perforations), not distinct from the cœnenchyma, and increasing by their internal surface so as to invade progressively the inferior part of the visceral cavity, and to fill it up more or less completely in old age. Loculi imperfectly divided by a few dissepiments; no synapticulae. Septa entire, or having their upper edge slightly divided.

1. Septa of various sizes forming distinct cycles.

Gen. *Oculina*, *Trymhelina*, *Cyathelia*, *Astrhelina*, *Synhelina*, *Achelia*, *Lophelia*, *Amphelia*, *Diphelia*, *Enallhelina*, *Axhelina*, *Crypthelina*, *Endhelina*, *Stylaster*.

Transitional Group. *Pseudo-Culinidae*.

Corallum composite, with a highly developed spongy or cellulose, echinulate, dermis coenenchymus; costal apparatus rudimentary; walls imperforate, and never invading the visceral cavity. Septal apparatus well developed; dissepiments few in number.

Gen. *Madracis*, *Stylophora*, *Dendracis*, *Atracis*.

Family 3. *Astreidae*.

Corallum composite, or simple, circumscribed by imperforated walls, and often increasing by fissiparity. Corallites becoming tall by the progress of their growth, each individual, or series of individuals, well defined, and separated from the others by perfect walls; coenenchyma not existing, or being formed either by the development of the costae and their dissepiments, or by the epithelial tissue alone, and not forming a compact mass as in the *Oculinidae*. The visceral chamber never obliterated inferiorly by the growth of the walls, but subdivided and more or less completely closed up by the interseptal dissepiments, which are in general very abundant; never any synapticle like those of the *Fungidae*.

First Tribe. *Eusmilinae*.

Septa completely developed and entire (that is to say, with their apical margin neither lobate nor denticulate); costae always unarmed; columella often compact, or even styliform.

Section 1. *Eusmilinae Proprie*.

Corallum simple or composite, and in that case formed by distinct corallites, affecting an arborescent disposition; fasciculate, or presenting a linear arrangement; free laterally, at least in a great part of their length, and never having their calices blended together. Reproduction usually fissiparous in the compound species.

Gen. *Cylicosmilia*, *Placosmilia*, *Trochosmilia*, *Parasmilia*, *Calosmilia*, *Lophosmilia*, *Diploctenium*, *Montivallia*, *Peplosmilia*, *Azosmilia*, *Eusmilia*, *Aplosmilia*, *Leptosmilia*, *Thecosmilia*, *Barysmilia*, *Dendrosimilia*, *Stylosmilia*, *Placophyllia*.

Section 2. *Eusmilinae Confluentes*.

Corallum composite, and presenting no separation between the corallites; united in rows, so as to assume a meandriform disposition; multiplication essentially fissiparous.

Gen. *Ctenophyllia*, *Dendrogyra*, *Rhipidogyra*, *Pachygyra*, *Pterogyra*.

Section 3. *Eusmilinae Aggregatae*.

Corallum composite and massive, in which the corallites are not arranged in series; and although remaining quite distinct, are united together by their walls, by a costal coenenchyma, or by mural annular expansions.

Gen. *Stylina*, *Stylocania*, *Astrocania*, *Stephanocania*, *Phyllocania*, *Dichocania*, *Heterocania*.

Section 4. *Eusmilinae Immerseae*.

Corallum composite; corallites disposed as in the preceding section, but imbedded in an epithelial cellular tissue, and not united by costal laminae or mural annular expansions; gemmation lateral and basal; reproduction never fissiparous.

Genus *Sarcinula*.

Second Tribe. *Astreinae*.

Septa having their upper edge lobulated, dentate, or armed with spines, and often imperfect near their inner edge. Costae also spinulose, dentate, or crenulate, but never forming simple cristae, as is often the case in *Eusmilinae*. Columella in general spongy, rarely lamellar, and never styliform; corallum in general massive.

Section 1. *Astreinae Hirtae*.

Corallum simple or composite, and then formed by perfectly delineated corallites; produced by fissiparity, or by calicular gemmation. [MADREPHYLLICAE.]

Gen. *Caryophyllia*, *Circophyllia*, *Thecophyllia*, *Lophophyllia*, *Symphyllia*, *Mycetophyllia*, *Eunomia*, *Calamophyllia*, *Dasyphyllia*, *Colophyllia*, *Onlophyllia*, *Latomandra*, *Tridacophyllia*, *Trachyphyllia*, *Aspidiscus*, *Scapophyllia*.

Section 2. *Astreinae Confluentes*.

Corallum massive, increasing by fissiparity, formed by a series of corallites, the individuality of which is not distinct. The calices, thus united in a common trench, have their septa arranged in a parallel manner in two lines, and the columella, when existing, is continuous in the whole length of the series. [MADREPHYLLICAE.]

Gen. *Meandrina*, *Manicina*, *Diploria*, *Leptoria*, *Oculoria*, *Astroria*, *Hydnophora*.

Section 3. *Astreinae Dendroidae*.

Corallum always increasing by lateral gemmation; the corallites segregate, and having an arborescent or fasciculate arrangement; septa regularly and delicately serrated, those of the principal cycles always bearing pali.

Gen. *Cladocora*, *Pleurocora*.

Section 4. *Astreinae Aggregatae*.

Corallum composite, massive, increasing by gemmation or by fissiparity, and in that case not presenting a linear mode of arrangement of the corallites, which are always completely united laterally, but

remain well-defined, and never lose their individuality as in the confinent *Astreina*. [MADREPHYLLICAE.]

Gen. *Astrea*, *Cyphastra*, *Oulastra*, *Plesiastrea*, *Leptastrea*, *Solenastrea*, *Phymastrea*, *Astroidea*, *Perionastrea*, *Siderastrea*, *Baryastrea*, *Acanthastrea*, *Synastrea*, *Thamastrea*, *Goniastrea*, *Aphastrea*, *Parastrea*.

Section 5. *Astreinae Reptantes*.

Corallum increasing by the development of buds on stolons, or on membraniform basal expansions; the corallites not united by their sides, excepting accidentally by means of their walls, and remaining short; septa feebly denticulated; dissepiments almost rudimentary.

Gen. *Angia*, *Cryptangia*, *Rhizangia*, *Astrangia*, *Phyllangia*, *Oulangia*.

Aberrant Group. *Pseudo-Astreidae*.

Corallum composite, thin, and foliaceous, and increasing by extracalicular gemmation; corallites short, well-circumscribed and dispersed on the surface of a common lamellar plate; coenenchyma echinulate; septa well-developed, very echinulate; dissepiments not numerous; no synapticle; common basal wall imperforate, sub-costulate, and naked.

Genus *Echinopora*.

Transitional Group. *Pseudo-Fungidae*.

Corallum composite and foliaceous, having a perforated plate or basal wall (as in *Fungidae*), and interseptal dissepiments (as in *Astreidae*). Calices forming rudimentary series, separated by lobes or ridges. No synapticle.

Genus *Merulina*.

Family 4. *Fungidae*.

Corallum simple or composite, very short and expanding, so as to constitute a disc or foliaceous lamina. Calice very shallow, and open laterally in simple species, confluent, and not circumscribed in the compound species; septa not distinct from the costae, and formed by complete, imperforate laminae, with the edges dectate, and the sides covered with stiliform or echinulate processes, which in general meet so as to constitute numerous synapticle, or transverse props, extending across the loculi like the bars of a grate; no dissepiments or tabulae, so that no part of the visceral chamber is completely closed; walls basal, in general porous. The compound species increase by submarginal gemmation, and not by fissiparity.

First Tribe. *Cyclotitinae*.

Corallum simple; plate or basal wall having a well developed epitheca, presenting concentric folds. [MADREPHYLLICAE.]

Gen. *Cyclotites*, *Palaecocyclus*.

Second Tribe. *Funginae*.

Corallum simple or composite; plate or basal wall without an epitheca, in general strongly echinulate and porous. [MADREPHYLLICAE.]

Gen. *Fungia*, *Micrabacia*, *Anabacia*, *Genabacia*, *Hierpolitha*, *Cryptabacia*, *Halomitra*, *Podobacia*, *Lithactinia*, *Polyphyllia*, *Zoopilus*.

Third Tribe. *Lophoserinae*.

Plate (or basal wall) not perforate or echinulate; no epitheca.

Gen. *Cycloseris*, *Diascria*, *Trochoseria*, *Cyathoseris*, *Lophoseris*, *Agaricia*, *Pachyseris*, *Phyllastrea*, *Haloseris*, *Leptoseria*.

Sub-Order 2. *Zoantharia Perforata*.

Corallum composed essentially of porous sclerenchyma, with the septal apparatus well characterised, and consisting of six primitive elements, but being sometimes represented only by series of tabulae. Dissepiments rudimentary; no tabulae.

The principal character of this section of *Zoantharia* is furnished by the structure of the sclerenchyma, which instead of forming imperforated lamella, as in the preceding groups, is always porous, or even reticulate. In general the mural apparatus constitutes here the greatest part of the corallum, does not consist of costal laminae; the walls are always perforated, and completely, or nearly completely, naked. It is also to be remarked that the visceral chamber is almost completely open from top to bottom, and never filled up with dissepiments or synapticle, as in most of the *Z. Aporosa*, or with tabulae, as will be seen in the next two sections of this order.

The perforated *Zoantharia* form three natural families:—*Eupsammidae*, *Madreporidae*, *Poritidae*.

Family 5. *Eupsammidae*.

Corallum simple or complex, with well developed lamellar septa, a spongy columnella, and perforated granular subcostulated walls.

Gen. *Eupsammia*, *Endopachys*, *Balanophylla*, *Heteropsammia*, *Leptopsammia*, *Endopsammia*, *Stephanophyllia*, *Dendrophyllia*, *Lobopsammia*, *Cenopsammia*, *Stereopsammia*.

Family 6. *Madreporidae*.

Corallum composite, increasing by gemmation, and not by fissiparity; coenenchyma abundant, spongy, and reticulate; walls very porous, and not distinct from the coenenchyma; septa lamellous, and well developed; loculi free. [MADREPORICAE.]

First Tribe. *Madreporinae*.

Visceral chambers divided into two equal parts by two of the principal septa, which are more developed than the others, and meet by their inner edge.

Genus *Madrepora*.

Second Tribe. *Explanarinae*.

Visceral chamber presenting at least six equally developed principal septa.

Gen. *Explanaria*, *Astreopora*.

Family 7. *Poritidae*.

Corallum entirely composed of reticulate sclerenchyma.

First Tribe. *Poritinae*.

Cœnenchyma rudimentary or not existing.

Gen. *Porites*, *Litharæa*, *Coccinæa*, *Microsolena*, *Goniopora*, *Rhodaræa*, *Poraræa*, *Holaræa*.

Second Tribe. *Montiporinae*.

Cœnenchyma abundant, spongy.

Gen. *Alveopora*, *Montipora*, *Psammocora*.

Sub-Order 3. *Zoanthariae Tabulatae*.

Corallum essentially composed of a well developed mural system, and having the visceral chambers divided into a series of stories by complete transverse tabulae or diaphragms; septal apparatus rudimentary.

Family 8. *Milleporidae*.

Corallum principally composed of a very abundant cœnenchyma, distinct from the walls of the corallites, and of a tubular or cellular structure; septa not numerous; tabulae numerous and well formed. [MILLEPORIDÆ.]

Gen. *Millepora*, *Heliopora*, *Heliolites*, *Fistulipora*, *Plasmopora*, *Propora*, *Azopora*, *Lobopora*.

Family 9. *Favositidae*.

Corallum essentially formed by lamellar walls, with little or no cœnenchyma; visceral chambers divided by numerous and well developed complete tabulae.

First Tribe. *Favositidae*.

Corallum massive; walls perforated; septa rudimentary; no cœnenchyma. [MILLEPORIDÆ.]

Gen. *Favosites*, *Michelinia*, *Konincka*, *Alveolites*.

Second Tribe. *Chaetinae*.

Corallum massive; walls not perforated; neither septa nor cœnenchyma.

Gen. *Chaetes*, *Dania*, *Stenopora*, *Constellaria*.

Third Tribe. *Halytitinae*.

Corallum composed of corallites constituting vertical laminae or fasciculi, but more or less free laterally, and united by means of connecting tubes or mural expansions; walls well developed and not porous; septa distinct but small.

Gen. *Halytites*, *Harmodites*, *Thecostegites*.

Fourth Tribe. *Pocilloporinae*.

Corallum massive, gibbous; walls imperforated; cœnenchyma abundant.

Genus *Pocillopora*.

Family 10. *Seriatoporidae*.

Corallum arborescent or bushy, with an abundant compact cœnenchyma; visceral chambers filling up by the growth of the columella and the walls, and showing but few traces of tabulae.

Gen. *Seriatopora*, *Dendropora*, *Rhabdopora*.

Family 11. *Theciidae*.

Corallum massive, with an abundant compact spurious cœnenchyma, produced by the septa becoming cemented together laterally; tabulae numerous.

Genus *Thecia*.

Sub-Order 4. *Zoantharia Rugosa*.

Corallum simple or composite, with a septal apparatus never forming six distinct systems, as in all the preceding *Zoanthariae*, but appearing to be derived from four primary elements. The corallites are always perfectly distinct, and are never united by means of a cœnenchyma, nor do they ever form linear series, which is often the case in the preceding sections. They multiply by gemmation, and the reproductive buds are in general developed on the surface of the calices of the parents; this often arrests the growth of the latter, and gives rise to a superposition of generations.

Family 12. *Stauridae*.

Corallum with well-developed septa, extending without any interruption from the bottom to the top of the visceral chamber, united by lamellar dissepiments, and arranged in four systems, characterised by an equal number of large primary septa.

Gen. *Stauria*, *Holocystia*.

Family 13. *Cyathaxonidae*.

Corallum with well-developed complete septa, which extend without interruption from the bottom to the top of the visceral chamber, and not forming a regular radiate circle; those of the primary cyclum not much larger than the others, and not forming a 4-branched cross as in the *Stauridae*, one well-characterised septal fossula; no dissepiments nor tabulae.

Genus *Cyathaxonia*.

Family 14. *Cyathophyllidae*.

Corallum with incomplete septa that do not extend from the

bottom to the top of the visceral chamber in the form of uninterrupted laminae; those of the primary cyclum similar to the others, and not forming a central 4-branched cross; septal fossulae varying in number and in size; visceral chamber divided by a series of superposed tabulae.

First Tribe. *Zaphrentinae*.

A single septal fossula well-developed, or replaced by a sulcus or a crestiform process, and occasioning more or less irregularity in the radiate arrangement of the septal apparatus. The corallum is simple and free in all the known species.

Gen. *Zaphrentis*, *Amplexus*, *Menophyllum*, *Lophophyllum*, *Anisophyllum*, *Baryphyllum*, *Haltia*, *Aulacophyllum*, *Trochophyllum*, *Hadrophyllum*, *Combophyllum*.

Second Tribe. *Cyathophyllinae*.

Septal apparatus radiate and uninterrupted, or divided into four groups; no true columella.

Gen. *Cyathophyllum*, *Pachyphyllum*, *Campophyllum*, *Streptelasma*, *Omphyma*, *Goniophyllum*, *Chonophyllum*, *Ptychophyllum*, *Heliophyllum*, *Meriophyllum*, *Clisiophyllum*, *Aulophyllum*, *Acervularia*, *Strombodes*, *Phillipsatrea*, *Eridophyllum*.

Third Tribe. *Lithodendroninae*.

Axis of the visceral chamber of the corallite occupied by a styliform or lamellar columella.

Gen. *Lithodendron*, *Nematophyllum*, *Lithostrotion*, *Azophyllum*, *Syringophyllum*.

Family 15. *Cystiphyllidae*.

Corallum essentially composed of a vesicular tissue, and presenting little or no traces of septa or radiate striae.

Genus *Cystiphyllum*.

Sub-Order 5. *Zoantharia Cauliculata*.

Polypi supported on a sclerobasis or epidermic stem-like corallum.

Family 16. *Antipathidae*.

Gen. *Antipathes*, *Cirripathes*, *Leipathes*.

Sub-Order 6. *Zoantharia Incertae Sedis*.

Gen. *Heterophyllia*, *Mortieria*, *Cyclocrinites*.

Order 2. *ALCYONARIA*.

Polypi with bi-pinnate tentacula, and only eight perigastric membranaceous laminae, containing the reproductive organs.

Family 1. *Alcyonidae*.

Polypi adherent, and not provided with an epidermic sclerenchyma.

First Tribe. *Cornularinae*.

Polypi simple or aggregate, and produced by gemmation on creeping stolons or basal membranaceous expansions, and having no lateral buds or connecting appendices.

Gen. *Cornularia*, *Clavularia*, *Rhizoaxenia*, *Sarcodictyon*, *Anthelia*, *Symphodium*, *Aulopora*, *Cladoclonus*.

Second Tribe. *Tubiporinae*.

Polypi fasciculate, and provided with independent tubular polydids, united at various heights by means of horizontal connecting plates, the surface of which produces the reproductive buds.

Genus *Tubipora*.

Third Tribe. *Telestinae*.

Polypi segregate; buds in lateral branched tufts.

Genus *Telestho*.

Fourth Tribe. *Alcyoninae*.

Polypi aggregate and multiplying by lateral gemmation, so as to constitute a ramified, lobate, or simple mass. [ALCYONIDÆ.]

Gen. *Alcyonium*, *Xenia*, *Nephthya*, *Paralcyonium*, *Sarcophyton*, *Cespitularia*, *Distichopora*.

Family 2. *Gorgonidae*.

Polypi provided with a thick tuberous cœnenchyma, surrounding a central stem that is adherent to an extraneous body by its basis, and is formed of epidermic sclerenchyma.

First Tribe. *Gorgoninae*.

Common axis inarticulate, horny, or fasciculate, but not calcareous. [GORGONIA.]

Gen. *Gorgonia*, *Pterogorgia*, *Bebruce*, *Phyllogorgia*, *Phycogorgia*, *Muricea*, *Primnoa*, *Solanderia*, *Briareum*.

Gorgonia lepadifera.

Second Tribe. *Isinæ*.

Common axis articulated or composed of segments, the structure of which differs alternately.

Gen. *Isis*, *Mopsea*, *Melitæa*.

Isis hippuris.

Third Tribe. *Corallinæ*.

Common axis inarticulate, solid, and calcareous.
Genus *Corallium*.

Family 3. *Pennatulidæ*.

Polypi aggregate, and having a common peduncle, the centre of which is occupied by a peculiar cavity, and usually contains a solid axis, this sclerobasis styliform and never expanding at its under

Pennatula grisea.

extremity so as to adhere to extraneous bodies. The polyp-mass is consequently free.

Gen. *Pennatula*, *Virgularia*, *Paronaria*, *Graphularia*, *Umbellularia*, *Veretillum*, *Litularia*, *Cavernularia*, *Renillia*.

Umbellularia encrinurus.

Virgularia mirabilis.

Order 3. *Podactinaria*.

Polypi having the gastric cavity surrounded by four vertical membranaceous septa, at the upper end of which are placed four pairs of intestiniform reproductive organs. The tentacula discoidal, pedunculated, not tubular as in *Zoantharia* and *Alcyonaria*, but organised much in the same way as in *Echinoderma*. The mouth probosciform, and the fauces surrounded by numerous internal filiform contractile appendices.

The genus *Lucernaria* is the only representative of this zoologica type, and comprises no coralligenous *Polypi*. [LUCERNARIADÆ.]

Sub-Class II. *HYDRARIA*.

Polypi with a simple non-lamelliferous digestive cavity. No interna generative organs. Tentacula filiform and subverrucose. [HYDROIDA.]

We subjoin illustrations of three of the genera belonging to this sub-class.

Dynamena operculata.

Sertularia pluma.

Campanularia volubilis.

(Johnston, *A History of the British Zoophytes*; Milne-Edwards, *A Monograph of British Fossil Corals*; Landsborough, *Popular History of British Zoophytes*; Adams, Baikie, and Barron, *Manual of Natural History for Travellers*; articles on Zoophytology in *Quarterly Journal of Microscopical Science*.)

POLYPLECTRON. [PAYONIDE.]

POLYPODIA'CEÆ are one of the chief divisions of the natural order of Ferns. [FILICES.] They constitute the highest form of Aërogenous or Cryptogamic vegetation, and are regarded as approaching more nearly to Cycadaceous Gymnosperms than to any other part of the vegetable kingdom now in existence.

They are usually herbaceous plants, with a permanent stem, which remains buried and rooting beneath the soil, or creeps over the stems of trees, or forms a scarcely moveable point of growth, round which new leaves are annually produced in a circle; or it rises into the air in the form of a simple stem, bearing a tuft of leaves at its apex, and sometimes attaining the height of 50 or 60 feet. [ACROGENS.]

The stems seem always to produce roots in great quantities from their surface, even when elevated in the air; such roots are more especially met with near and under the ground, where they form a stratum of some thickness; acting both as feeding-organs and as an external protection; on all Tree-Ferns they appear upon the stem at least in the form of tubercles; and in *Cibotium Billardieri* they cover over the whole surface from the top to the bottom with a dense layer several inches deep.

The surface of tree-fern stems may be taken to represent that of the order in general. It is always marked with scars of considerable

size, having either a lozenge form or that of an irregular oval, and bearing within their area evident traces of the fracture of woody plates which passed from the stem into the leaves.

These scars lengthen as the stem increases in age, till the lozenge or oval form is entirely destroyed; the scars then become separated to considerable distances, and extended into long and often irregular and indefinite spaces separated by deep furrows. Hence it happens that the appearance of the upper and lower end of the same tree-fern stem is so dissimilar, that they would not be supposed to belong to even the same species. Below the scars, or interposed among them, are found openings down into the interior of the stem, filled with pulverulent matter, and of unknown use. They appear to be of the same nature as the apertures into the superficial cells of *Sphagnum*, or more especially as the perforations in the rhizoma of *Nymphaea*.

Although tree-ferns are unknown in any countries except those having either a damp tropical climate, or at least an equable mild temperature and humid atmosphere, yet the common ferns of this country, whose stems, vulgarly called roots, are formed under ground, exhibit the same kind of organisation as that just described, only in a less conspicuous manner. It does not therefore follow that the remains of tree-ferns found in this country in a fossil state prove Great Britain to have had formerly a tropical climate, especially as the number of such remains hitherto met with has been extremely small; the utmost value that can be assigned to their evidence is that of probability. In those tropical lands where the tree-fern acquires its full size, as for example Brazil, the Philippines, Pitcairn's Island, &c., it becomes one of the most majestic and graceful objects, having an enormous plume of the most delicate and verdant foliage at the extremity of a lofty flexible stem, which sways beneath the gentlest breeze.

POLYPODIUM, a genus of Ferns, the type of the natural order *Polypodiaceæ*. The species of this genus are known by the thecae being in clusters on the back of the frond, and by their opening transversely; the ring is usually vertical and incomplete. This is the case with *Allosorus* and *Woodsia*. *Polypodium* is distinguished by the sori being circular and naked, and the margin of the frond is flat, not reflexed. Several species are found in Great Britain.

P. vulgare, Common Polypody, has the fronds deeply pinnatifid; the lobes linear-oblong, somewhat serrated, all parallel, upper ones gradually smaller. This plant is very common in every part of Great Britain, delighting in shady banks, walls, and old trees. It may be easily cultivated in a Ward's case, amidst the smoke of our most populous cities. It is subject to a great many varieties. These have been beautifully illustrated in Mr. Henry Bradbury's process of 'Nature Printing.' 'The Ferns of Great Britain and Ireland,' executed by this process, and edited by Dr. Lindley and Mr. Moore, is one of the most useful works that the student of ferns can consult.

P. Phlegopteris has pinnate fronds, with the lowest pair of pinnae turned downwards and forwards; the rest are turned upwards. It loves damp places, near the spray of waterfalls.

P. Dryopteris has the fronds ternate and glabrous. It inhabits shady mountainous places.

P. calcareum has triangular subternate fronds, which are glandular-mealy; the lower branches are pinnate. It is found on broken limestone ground.

(Babington, *Manual of British Botany*.)

POLYPO'GON (from πολύ, and γων, a beard), a genus of Grasses belonging to the tribe *Agrostideæ*. It has scarious nearly equal glumes, each furnished with a long seta from just below the emarginate summit. The palæ are shorter than the glumes, the outer ones usually curved from below the summit.

P. Monspelienis has the setæ more than twice as long as the rather obtuse glumes. It has a fibrous root, a stem from a foot to a foot and a half high, a dense-lobed silky panicle often two inches long. The glumes are linear and hairy. It is a very beautiful grass, and is a native of Great Britain in salt marshes. It is the Ἀλωπέκουρος (Fox-Tail) of Theophrastus, 'Hist. Plant.,' 7, 17.

P. littoralis has its setæ equalling the acute glumes. The root is somewhat creeping, the stem about a foot high, the panicle close lobed and purplish. The glumes are linear lanceolate. It is a British species and is found in muddy salt marshes.

(Babington, *Manual of British Botany*.)

POLYPORUS. [DRY-ROT.]

POLYPTERUS, a genus of Fishes belonging to the family *Clupeidae*. The sides of the upper jaw are immovable; the head is covered with sharpened bony plates; the body with strong scales; it has one gill ray; a number of separate fins on the back; the teeth like a rasp, with long ones in front; the stomach large; a double air-bladder, with large lobes, the left one opening freely into the gullet. There are two species, one found in the Nile, the other in the rivers of Senegal. These fish are interesting as forming the only living representatives of a large family now extinct. They belong to the large division of extinct fish called Sauroid, on account of their resemblance to the Lizard tribes. [FISH.]

POLYSTICHUM, a genus of Plants belonging to the natural order of *Filices*, the sub-order *Polypodiaceæ*, and the tribe *Aspideæ*. The indusium is circular, attached by the centre; the veins are distinct after leaving the midrib. There are three British species:—

P. Lonchitis, with rigid simply pinnate fronds. Found in alpine rocks.

P. aculeatum, with linear rigid bipinnate fronds; the pinnules obliquely decurrent. Common in hedge banks.

P. angulare, with the fronds lax, drooping, bipinnate, pinnules truncate below, distinctly stalked. Found in the west of England, on sheltered banks.

(Babington, *Manual of British Botany*; Lindley and Moore, *The Ferns of Great Britain and Ireland*, naturo-printed.)

POLYSTOMELLA. [FORAMINIFERA.]

POLYTHALAMACEA. [ORTHO CERATIDÆ.]

POLYTREMA. [MILLEPORIDÆ.]

POLYZOA, frequently termed *Bryozoa*, are animals belonging to the Molluscons Sub-Kingdom, closely allied in some respects with the *Tunicata*, and especially with the Compound Ascidians, whilst in others they approach the *Brachiopoda*.

The analogies presented in their structure with that in other Molluscons groups having been pointed out in the article MOLLUSCA, it will be needless here further to refer to them. The present article, after giving a brief view of the more important structural peculiarities of the class, will be devoted more especially to their mode of classification; but since the term *Polyzoa*, here employed, has by no means obtained universal adoption, it appears requisite to say a few words explanatory of the reasons which have induced us to prefer that term to the name *Bryozoa*, more usually employed by many British and by most continental naturalists.

Section I. Historical.

Formerly confounded with the Sertularian and other phytoid *Zoophytes*, or *Radiata* [POLYPIFERA], it is only within the last thirty years that the *Polyzoa* have been admitted to their proper place in the animal kingdom, having been advanced in fact from one sub-kingdom to another. Their advance from the *Radiata* to the *Mollusca* may be said to date from the researches of Dr. Grant, contained in his 'Observations on the Structure and Nature of Flustra,' in 1827; and of Milne-Edwards, in conjunction with M. Audouin, given in their 'Résumé des Recherches sur les Animaux sans Vertèbres faites aux Îles Canaries,' in 1828. To the former of these observers we are indebted for the first intimation of several important facts in the anatomy of these creatures—among others, of the existence of cilia on the tentacles, and the curvature of the intestinal canal, with other particulars of less importance. He failed however to notice the existence of a second or anal orifice to the intestinal canal, a fact of the highest importance, as indicating in that respect their close approximation to the *Ascidia*, or tunicate molluscs. This opening was discovered by Milne-Edwards and Audouin, and its importance was by them duly appreciated. In other respects their observations agreed with those of Dr. Grant. The existence of this anal orifice was regarded by its discoverers as sufficient to justify a complete change in the ideas then generally entertained with respect to the natural affinities of these animals with the rest of the *Zoophytes*. They proposed to distribute the animals belonging to the class of *Polypi*, as then received, into four principal groups, which are in fact pretty nearly identical with those in which they are at present most generally placed. The fourth of these families contained the *Flustra* and other *Polypes* whose digestive canal opened on the exterior by two distinct openings, and whose organisation approached that of the Compound Ascidians.

The latter class, though thus distinguished from its apparent allies, received no name from the eminent naturalists to whom its foundation was due; and of the names subsequently applied to it, it remains simply to determine which is entitled to the priority. The appellations proposed for this class that have received any acceptance at all are three—*Polyzoa*, *Bryozoa*, and *Ciliobrachiata*. The first of these terms (as a singular noun) was used by Mr. J. V. Thompson in a Memoir, constituting the fifth part or number of his 'Zoological Researches,' and applied by him "to a distinct class of *Polypes* hitherto in great measure confounded with the *Hydroids*." This paper was published in December, and probably on the 1st of December, 1830. The appellation of *Bryozoa* was given by Professor Ehrenberg to those *Polypes* in which two openings existed to the digestive canal, and which he thus distinguished from a second class, termed by him the *Anthozoa*, in which but one orifice was presented. His paper on the 'Corals of the Red Sea,' in which this subdivision of the *Polypes* was first proposed, was read, or rather was in part read, before the Berlin Academy, on the 3rd of March 1831. It was not completed however till December 1833, nor published until February 1834; and this date, for reasons it is needless here to refer to, should most probably be regarded as the true date of its publication. The part of the same writer's 'Symbolæ Physicæ,' in which the term is used, was not published till June 1831. Consequently, the earliest date which can by any latitude of admission be given to the first publication of the term *Bryozoa*, is March 1831, or at least three months after that of Mr. J. V. Thompson's 'Researches,' in which that of *Polyzoa* is proposed. In a very valuable paper published in the 'Philosophical Transactions' for 1837, Dr. A. Farris proposes to employ the term *Ciliobrachiata* for this class of *Polypes*, from the circumstance that their tentacles are ciliated. But this term, though appropriate and good, has since been but rarely employed, and is obviously without any claim to priority.

Section II. Structure and Functions.

The main points in the anatomy and structural relations of the *Polyzoa* will be found under the article MOLLUSCA; but in order to render the account of their classification (which is properly the subject of the present article) more intelligible, it will be necessary briefly to detail the structural, and with them some of the physiological conditions presented in the soft and hard parts of the animals.

The *Polyzoa* may be defined as Compound Molluscons Animals, in which the nervous system consists of a single ganglion, situated between the mouth and the anus, having a distinct mouth surrounded more or less completely by a row of ciliated tentacles; usually hermaphrodite, and propagated by buds or ova; in the mature state mostly fixed, though some possess the power of locomotion.

Though differing widely in external appearance, the animal itself is constructed upon a very uniform type throughout all the subdivisions of the class, and for this reason, the anatomy of one species or order will, with trifling exceptions, apply to all. The following account of their structure is, in great measure, taken from that given by Professor Allman in his 'Report on the Freshwater Polyzoa,' published in the 'Proceedings of the British Association' for 1850; and, with the exception of the word 'polyzoary,' or 'polyzoarium,' which is here used to express the compound growth formed by the associated animals, instead of 'conacium,' proposed by that naturalist, the terms used by him have been adopted—

1. Polypide, to signify the soft or retractile portion of the *Polyzoan*
2. Ectocyst and Endocyst, to express the two distinct tunics of which the cells of the polyzoary are formed; the former being applied to the external and the latter to the internal tunic. The part surrounding the mouth, upon which the tentacles are placed, is termed, 3, the Lophophore; and 4, the Perigastric Space, is the space included between the walls of the endocyst and the alimentary canal.

But besides these terms, which apply more particularly to the polypide itself, several others are required in the description of the polyzoary. These are—

Cell, the hard portion of the external tunic, into which in most cases the polypide is capable of being retracted by the action of certain muscles. The parts of the cell are—1, the Mouth, or that opening, as it may be termed, through which the polypide makes its exit and its entrance. The borders of this opening are sometimes furnished with Oral Spines, and it is sometimes closed when the creature has retreated into the cell, by a Crescencic Lip, usually having a cartilaginous border, and closed by special muscles. (Figs. 5 and 5a.) In many cases the wall of the cell is of equal thickness and similar structure throughout, but in the Cheilostomatous sub-order the front of the cell, or that side upon which the mouth opens and the animal comes out, very often differs in structure from the rest. That is to say, a greater or less extent of the front may remain wholly or in great measure membranaceous, as in the genus *Membranipora* (fig. 14); or be filled in by a sculptured or perforated calcareous expansion, as in *Catenicella* (figs. 1, 2), *Lepralia* (fig. 15), and many others. The space thus defined when left membranaceous (as it appears in most if not all cases to be at an early period in the formation of the cell), is termed the Aperture. The borders of the aperture are sometimes furnished with Marginal Spines. In some instances, as in *Caberea* and *Scrupocellaria* (sp.), the aperture is protected in front by a curious outgrowth from near the margin, which is termed a Pedunculate Operculum. The back of the cell is that part, of course, which is opposite to the front; the mouth is situated at or near the upper part of the cell, and is either terminal or subterminal. Other parts, which may be regarded as appendages to the cells, but which are not universally present, are certain organs, either of offence, defence, or prehension, termed Avicularia and Vibracula; the former constituting a sort of pincers, and the other consisting of a long, slender, moveable seta. However diverse in appearance, these two kinds of organs are all constructed upon the same general type; that is to say, the organ consists of a hollow cup, or cell, containing two sets of muscles, for the movements of the mobile limb, the nauidible, as it is termed, in the one case, and the seta in the other. The avicularia again are either pedunculate and moveable upon the peduncle, or sessile, which latter may be either simply sessile or deeply immersed. The Ovicell is an organ of an arched or globose or pyriform shape, found on many of the *Cheilostomata* and on some of the *Cyclotomata*, apparently destined for the development of ova. In the former class it is invariably situated above the mouth; and in the latter the analogous organ seems to represent a metamorphosed cell, and in situation corresponds with the other cells of the polyzoary.

The importance of the avicularian and vibracular organs, in a systematic point of view, may be estimated from the circumstance that, out of 36 genera of Cheilostomatous *Polyzoa*, 20 include species armed with one or the other, or with both; and that of 101 species no less than 126 are so furnished. They appear to be confined solely to the *Cheilostomata*.

In many cases the polyzoary is affixed by numerous slender corneous tubes, which seem to be merely subservient to that purpose; these are termed Radical Tubes.

The Polyzoary, or colony itself, is formed of an aggregation of cells, which throughout the two former orders of the class as here arranged

arise one from another, either singly or in pairs, from each cell (*fig. 15a*), which represents the beginning of the polyzoary of *Lepralia ciliata*, and from various parts of the cell, as on the back or sides, near the top or not far from the bottom. And it is to the variety of modes in which the cells arise that the diversity of form of the polyzoary is due. In one division of the third sub-order, the *Ctenostomata*, the cells do not arise one from another, but from a tube common to several cells, and which is either divided or not into distinct internodes. This portion of the polyzoary is termed the Basal Tube.

Having thus defined most of the terms which it is necessary to employ for the purposes of classification, we will briefly describe the anatomy of the various parts of the animal in the order in which it is given by Professor Allman.

Organs for the Preservation of the Individual.

A. Dermal System.

The Polyzoary is formed of a number of little chambers, or cells, organically united, each of which contains a polypide, and consists of two portions—an internal tunic, soft, transparent, and contractile (the Endocyst), and an external investment (the Ectocyst). The endocyst lines the interior of the cells and when it arrives at their orifice would protrude beyond the ectocyst, were it not that here it becomes invaginated, or inverted into itself, and then terminates by becoming attached round the base of the tentacular crown; during the exertion of the polypide it undergoes eversion, sometimes complete, sometimes incomplete. The endocyst consequently constitutes a cell, or sac, in which the polypide is suspended, surrounded by the perigastric space. These sacs are all closed above where they are attached to the polypide, and below, in some cases, their cavities are in communication with those of the neighbouring sacs (or with the basal tube); but more generally no such communication exists. The ectocyst and endocyst represent respectively the external and middle tunics of the *Tunicata*, or the mantle and shell of other Molluscs.

The endocyst is in all cases thin and membranaceous, and often contains transverse muscular fibres. A portion, perhaps the whole, of the inner surface is clothed with vibratile cilia. The ectocyst varies greatly in composition and aspect. Throughout the greater number of the *Polyzoa* it is hardened by the deposition of calcareous matter, whilst in many others it is horny and flexible, and in some even of an almost gelatinous consistence. In the *P. hippocrepeia* it is in most species composed of a tough pergamentaceous brown membrane, strengthened by the deposition of irregularly formed siliceous particles, sometimes rendering it quite opaque. In other cases again, as in the genus *Anguinella* v. Ben., the soft and flexible, and as it were flocculent ectocyst, is pervaded by aluminous and siliceous particles, and the same is the case, to a less marked extent, in some other of the *Ctenostomata*. In *Cristatella* and *Pedicellina* the ectocyst would, at first sight, seem to be entirely absent, and the cell to be composed exclusively of the endocyst. Careful examination however shows that both are present, and that the ectocyst consists of a highly organised and transparent tunic, free from any earthy deposit. In some instances, and very distinctly in the *Selenariadae*, or Lunulites, the surface of the calcareous ectocyst is further covered with a thin horny cuticle, apparently resembling that on the shells of many Molluscs.

B. Organs of Digestion.

These consist of an alimentary canal, commencing at the mouth and terminating at the anus; and subdivided into several portions, which have received the same names as those of the apparently corresponding parts of the alimentary tract in the higher animals. The mouth is edentulous and usually unarmed, though sometimes (as in the proper *P. hippocrepeia*) furnished with a valve-like organ of very peculiar formation, and which is considered by Professor Allman to be analogous with the 'languet' of the Ascidians.

From the mouth an oesophagus, or pharynx, leads downwards to the stomach, or in some cases, as in *Bowerbankia*, into a sort of gizzard, which in that genus is armed on each side with a serrated tooth. The stomach is a thick walled sac, which in most cases dilates inferiorly into a rounded cul-de-sac, or pyloric cavity, from which the intestine springs. The pyloric orifice is distinctly valvular, and is furnished with prominent lips, which project into the intestine. The intestine, wide at the origin, rapidly diminishes in diameter till it terminates at a distinct anus near the mouth. The liver is represented by spherical corpuscles of a brown colour, seated on the wall of the stomach. The mouth and upper part of the oesophagus and the commencement of the intestines, are, in most cases, at any rate, furnished with vibratile cilia.

C. Organs of Respiration and Circulation.

Upon the tentacular crown and the walls of the perigastric space, which corresponds with the 'sinus system' of the *Tunicata*, would seem chiefly to devolve the function of bringing under the influence of the aerating medium the nutritious fluid of the tissues.

The tentacular crown of a Polyzoan consists of two portions: 1, a sort of stage, or disc, which surrounds the mouth—the Lophophore; and 2, of a row of tentacles, which are borne in an uninterrupted series round the margin of the lophophore. The lophophore throughout almost the entire class is orbicular or annular; but in the

Hippocrepeia its posterior margin, or that which corresponds to the rectum, is prolonged into two triangular lobes, or arms, so that in that order it exhibits the form of a deep crescent. This condition of the lophophore is found in no marine species, and in *Fredericella*, a fresh-water form, the arms of the crescent are obsolete, and the lophophore might, on a superficial view, be regarded as orbicular; but a careful examination, Professor Allman goes on to say, will render manifest its departure from the orbicular form, the side corresponding to the arms of the crescent being slightly prolonged obliquely upwards. In all cases the lophophore forms the roof of the perigastric space; in the species with crescentic lophophores the interior of the arms is clothed with vibratile cilia.

The tentacles are tubular, closed at their free extremity and opening at the opposite end through the lophophore into the perigastric space. In all the *Polyzoa* they are armed upon their opposed sides (in *Pedicellina* on one only?) with vibratile cilia, arranged in a single series, and vibrating towards the extremity of the tentacle upon one side and towards the base on the other. A nervous filament and muscular fibres may be traced into the tentacles. In the proper *P. hippocrepeia* the entire plume of tentacles is surrounded at its base by an exceedingly delicate transparent membrane in the form of a cup or calyx, considered by Professor Allman as analogous to the membrane of the respiratory sac in the *Tunicata*; but this calyx has not yet been detected in any marine polyzoan. In the genus *Pedicellina* the tentacles are also surrounded at their base by a kind of membranous calyx, but this is of an entirely different import from the membrane connecting the bases of the tentacles in the *P. hippocrepeia*.

The perigastric space and the interior of the lophophore and tentacles all freely communicate with one another, and are filled with a clear fluid, in which float numerous particles of a very irregular form and size. This fluid obviously represents the blood or common nutrient and respiratory fluid of other Molluscs. It is kept in motion by the cilia with which the endocyst is lined, but there is no special circulatory organ as in the *Ascidia*.

D. Organs of Motion.

The muscular system in the *Polyzoa* is highly developed, and the muscles are especially interesting in a physiological point of view, for they seem to present an example of true muscular tissue reduced to its simplest and essential form. They are composed of bundles of elementary fibres, totally separate from each other, throughout their entire course, and which are distinctly marked with transverse striæ. They resemble in fact very closely the fibres of the thoracic muscles of insects. In the marine *Polyzoa* however another kind of fibres may be noticed, presenting nodular enlargements, which would seem to resemble very closely the isolated, organic muscular fibres of the higher animals. The muscles are disposed in distinct sets, and it is by the agency of these various groups that the different movements of protrusion and retraction of the polypide are effected, together with the actions of the tentacles and of the avicularia and vibracula. For the arrangement of the muscles in the former class of organs see *fig. 2 (5)* in the article MOLLUSCA. The curious analogies in the disposition of these muscles in the *Polyzoa* with that of the muscles which act upon the shells of the *Brachiopoda* are also pointed out in that place.

E. Organs of Life of Relation.

A distinct nervous system was first shown to exist in the *Polyzoa* by M. Dumortier in *Lophopus crystallinus*, and has been demonstrated by Van Beneden in *Laguncula*, and by Allman in all the Hippocrepian genera except *Paludicella*; it may be deemed therefore to exist generally in the class, and will probably be found essentially alike in all. In all the species of the Hippocrepian order there may be seen, attached to the external surface of the oesophagus, on its rectal aspect, just below the mouth, a hollow oval body of a yellowish colour, which is undoubtedly a nervous ganglion, as Professor Allman has succeeded in distinctly observing nervous filaments in connection with it; some of which may be traced going to each tentacle. The ganglion also sends off filaments upwards towards the mouth, and one may be observed passing downwards along the oesophagus; but nothing like a complete collar surrounding the tube has been observed. The *Polyzoa* do not seem to possess any special organs of sense.

F. Organs of Locomotion.

In *Cristatella*, the ectocyst, according to Professor Allman, is highly contractile, and presents, below, a flattened disc destitute of apertures. Upon this disc, which closely resembles the foot of a Gastropod, the singular polyzoary creeps about upon the stems and leaves of aquatic plants. Except in the embryonic condition no other Polyzoan would seem to possess any power of locomotion; or at any rate none has been noticed, but several reasons would seem to render it probable that the species belonging to the *Selenariadae* may be capable of locomotion by means of their curiously-constructed vibracula.

G. Reproduction.

In the *Polyzoa*, observes Professor Allman, three distinct modes of reproduction may be witnessed, namely:—By buds or gemmæ; by true ova; and by free locomotive embryos.

1. Reproduction by Gemmæ.—The gemmæ always originate in the endocyst, first appearing as small tubercles projecting into the

perigastric space, but which may soon be seen to take a development in an outward direction. The bud now presents the appearance of a vesicle projecting from the exterior of the parent-cell, closed at its external or free extremity, but having its cavity in communication with the perigastric space. The polypide is gradually developed in the interior of the gemma by the differentiation of its fine granular contents, and the extremity of the bud ultimately opens so as to admit of the exertion and retraction of the young animal. Thus is produced a fresh cell of the polyzoary, whose ultimate form, as has been before observed, depends upon the point of the cell at which the bud springs. This differs in almost every species, and upon this difference depends the diverse physiognomy of the various species. For instance, if each cell pullulates at a single point at the upper and back part, a polyzoary, consisting of a single series of cells, such as that of *Atea*, or of *Hippothoa* (fig. 6), will be presented; if from each cell two are given off and remain in close apposition, a circularly expanded disc of greater or less regularity will be produced, as seen in *Lepralia* (figs. 15 and 15a), some *Membranipora*, &c., and so on.

2. Reproduction by Ova.—All the fresh-water, and probably, also, all the marine *Polyzoa*, produce true ova, which are formed in a definite organ or ovary; and from the existence of a true ovary and of ova, we are at once led to expect the co-existence of a male organ. That a testis is present in all the species of fresh-water *Polyzoa*, at any rate, no doubt, according to Professor Allman, can be entertained, and in *Laguncula* (Farrella) répens, the existence of this organ is described and figured by Van Beneden. In *Paludicella* Professor Allman says, "that the ovary and testes are both found in the same cell. The former is an irregularly shaped body, adherent to the inner surface of the endocyst, towards the upper part of the cell. The testicle is an irregularly lobed mass attached, like the ovary, to the inner surface of the endocyst. It occupies a position near the bottom of the cell, and is thus separated by a wide interval from the ovary. Both organs are attached to the side of the stomach by a cylindrical cord. The form of the ovary in the proper *Hippocrepia* would appear more to resemble a moniliform cord. In *Laguncula* (Farrella), according to Van Beneden, the ovary and testis, in form and situation would seem very closely to resemble those in *Paludicella*. It would appear also that the impregnation of the ova is effected by their escaping from the ovary into the perigastric cavity, where they are brought into contact with the spermatozoa, which have in like manner escaped from the testis into the same cavity, and are swimming actively about in vast numbers in the fluid with which it is occupied. There does not appear to be any special opening for the escape of the ova after impregnation, which is probably effected by a rupture in some part of the endocyst. The forms of the ova vary a good deal in different genera, and in some cases they are ciliated.

3. Professor Allman also describes a mode of reproduction by free embryos, but does not seem to have noticed their mode or plan of development.

The embryo upon its escape from the ovum appears sometimes to be ciliated, sometimes not. In the case of *Lepralia coccinea*, a cheilostomatous species, the appearance of an embryo of the ciliated kind and its subsequent development are well described by Mr. Gosse. ('Naturalist's Rambles on the Devonshire Coast,' p. 218.)

But although the above brief description of the reproduction of the *Polyzoa* by ova formed and impregnated within the perigastric sac be undoubtedly correct, as applied not only to the species in which it has actually been observed, but from analogy to others as well, it cannot be denied that very considerable obscurity rests upon the mode in which the ova are developed in the ovicells or receptacles, which have received that name, and as to the relation which those organs bear to the rest of the animal. There can be no doubt that these organs do contain an ovum or ova, and that these ova are developed, ab origine, in them, and there undergo segmentation; but how these ova are fertilised, and why a difference so great as this in the position of the ovigerous organ should exist in apparently closely allied genera or even species, is at present inscrutable.

Section III. Classification.

The more general relations of the *Polyzoa* having, as before observed, been described under the head of MOLLUSCA, the remainder of this article will be devoted to the mode in which they may be conveniently arranged among themselves.

With our present defective knowledge of many particulars respecting the conformation of the *Polypides*, the classification of the *Polyzoa* can only be attempted with any prospect of useful results, from the study of the Polyzoary; that is to say, so far as regards the determination of the subordinate groups—the orders themselves, being defined by characters derived from the Polypide, or soft portion of the animal. The following scheme, which in its main features has been long received, appears to offer as convenient, and so far as our present acquaintance with the subject allows, perhaps as natural a classification as can be expected.

Class POLYZOA.

Social molluscanous animals, whose nervous system consists of a single post-oesophageal ganglion, with branches, but without a nervous ring around the oesophagus; and without any special organs of sense

or of circulation. Mouth surrounded more or less completely with a single row of ciliated tentacles.

Polyzoa, J. V. Thompson, 'Zool. Research,' Mem. 5, p. 92 (1830).

Bryozoa, Ehrenb., 'Corallen-Thiere des Roth. Meer,' 1831 (1834).

Molluscan Zoophytes, seu *Zoophyta Ascidioida*, Johnston, 'Mag. Zool. and Bot.,' 1836.

Ciliobrachiata, Farre, 'Phil. Trans.,' 1837.

Order I. *Polyzoa infundibulata*, Gervais.

Tentacles disposed on an uninterrupted annular lophophore, surrounding the unarmed mouth.

Sub-Order I. *Cheilostomata*.

The crescentic subterminal mouth of the cell is furnished with a moveable lip, by which it is closed when the animal retreats.

Escharada, *Flustrada*, *Cellariada* (ex. *Crisia*), Fleming.

Polyparia operculifera et *cellariata* (ex. *Crisia*), Blainville.

Escharina, *Celleporina*, Ehrenberg.

Urceolata (pars), Hagenow.

A. Cells disposed in a single series.

Family 1. *Catenicellidae*, Busk.

Cells connected by short flexible tubes.

Gen. 1. *Catenicella*, Blainv. (Figs. 1, 2.)

Cells connected by short corneous tubes, all facing the same way; polyzoary phytoid, erect, dichotomously-branched; cell at the bifurcation geminate.

a. *Penetrata*. Cells fenestrate in front; ovicells terminal.

B. *Vittata*. Cells with a narrow elongated band or vitta on each side in front; ovicells galleriform, not terminal.

Catenicella, Blainville; 'Brit. Mus. Cat.,' p. 3.

Catenaria, Savigny, 'Egypt,' pl. 13.

About seventeen species known; mostly Australian.

1, *Catenicella taurina*, 2, *Catenicella elegans*; a, geminate cell. 3, *Calpidium ornatum*. 4, *Salicornaria farcinoides*; a, avicularium. 5, *Cellularia Peachii*; a, ovicell.

Gen. 2. *Alysidium*, Busk.

Cells connected by short corneous tubes. Two cells arising from each cell at a bifurcation.

Alysidium, 'Brit. Mus. Cat.,' p. 13.

Three species known.

Gen. 3. *Calpidium*, Busk. (Fig. 3.)

Cells with an avicularium on each side; each cell with three distinct apertures, arising one from the upper part of another in a linear series, connected by short corneous tubes.

Calpidium, Busk; 'Voyage of Rattlesnake,' i. 364 (fig. 3); 'Brit. Mus. Cat.,' p. 14.

One species.

Family 2. *Scrupariade*.

Junctions of the cells rigid.

Crisiade (part), Gray.

Scrupariade, Gray.

Eucratiade (part), Johnston.

Gen. 1. *Scruparia*, Oken.

Cells decumbent; aperture oblique, subterminal; branches given off from the front of a cell below the aperture.

Scruparia (a), Oken.

Scruparia, 'Brit. Mus. Cat.,' p. 23.

Gen. 2. *Hippothoa*, Lamouroux. (Fig. 6.)

Cells decumbent, adherent; branches given off from the sides of the cells.

Hippothoa, Lamx.; Gray; Johnston; 'Brit. Mus. Cat.,' p. 29.

Catenicella (pars), Blainville (non M. Edwards).

Terebripora, D'Orbigny.

Tubulipora (sp.), Jameson.

Three species known.

Gen. 4. *Beania*, Johnston. (Fig. 7.)

Cells arising one from another by a slender filiform prolongation or tube, and open in front; marginal spines hollow, inarching.

Beania, Johnston; Gray; 'Brit. Mus. Cat.,' p. 32.

Two species.

B. Cells disposed in a double or in multiple series.

Family 3. *Salicornariade*.

Cells disposed around an imaginary axis, forming cylindrical branches of a dichotomously-divided erect polyzoary.

Salicornariade, Gray.

Salicornariade, 'Brit. Mus. Cat.,' p. 15.

Gen. 1. *Salicornaria*, Cuvier. (Fig. 4.)

Front of each cell much depressed, surrounded by an elevated ridge, by which the surface of the branch is divided into more or less regular, rhomboidal or hexagonal spaces; avicularia scattered; ovicells immersed, inconspicuous; branches articulated.

Salicornaria, Cuvier; Johnston; 'Brit. Mus. Cat.,' p. 16.

Farcimia, Fleming; Johnston; 'Ed.' i.

Cellaria (a), Lamarck; Lamx.; De Blainville.

Five species.

Gen. 2. *Nellia*, Busk.

Front of cell convex, with a distinct raised border; aperture very large; ovicells (?); no avicularia.

Salicornaria (sp.), Busk., 'Voyage of Rattlesnake,' i. 367.

Nellia, 'Brit. Mus. Cat.,' p. 18.

Two species.

Gen. 3. *Vincularia*, DeFrauce. (Fig. 19.)

Polyzoary rigid, calcareous, inarticulated; surface not arcolated; aperture large; no avicularia; ovicells inconspicuous.

Vincularia, DeFrauce; Blaiuv.; Hagenow; 'Brit. Mus. Cat.,' p. 96.

Glaucanoma, Goldfuss.

Siphonella, Hagenow.

Cellaria (pars), Reuss.

One recent species; numerous fossil.

Gen. 4. *Farciminaria*, Busk. (Fig. 8.)

Polyzoary corneous, flexible; margin of aperture much raised; aperture very large; ovicells cucullate, prominent; no avicularia.

Farciminaria, 'Brit. Mus. Cat.,' p. 32.

One species.

Family 4. *Cellulariade*, Busk.

Cells disposed in the same plane, forming linear branches of a dichotomously divided phytoid, erect, articulated polyzoary.

Bugulide (pars), Gray.

Cellulariade (pars), Johnston.

Escharide (pars), Johnston; Gray.

Cellulariade, 'Brit. Mus. Cat.,' p. 19.

Gen. 1. *Cellularia*, Pallas. (Fig. 5.)

Cells bi-triserial; more than four in each internode; oblong or rhomboidal, contiguous; perforated behind, unarmed, or very rarely with an avicularium on the upper and outer angle of the cells.

Cellularia (pars), Pallas; Fleming; Johnston (pars); 'Brit. Mus. Cat.,' p. 19.

Bugula (pars), Gray; Oken.

Three species.

Gen. 2. *Menipea*, Lamouroux.

Cells oblong, or elongated and attenuated downwards; imperforate behind, with a sessile avicularium (frequently absent) on the upper and outer angle, and one or more sessile avicularia on the front of the cell below the aperture (not always present).

Menipea, Lamx.; 'Brit. Mus. Cat.,' p. 20.

Cellaria (pars), Linn.; Solander.

Crisia (pars), Lamx.

Tricellaria, Fleming; Blainville.

Six species.

Gen. 3. *Scrupocellaria*, Van Beneden.

Cells rhomboidal, with a sinus on the outer and hinder aspect; each furnished with a sessile avicularium at the upper and outer angle, and with a vibraculum behind. Cells biserial and numerous in each internode.

Scrupocellaria, Van Beneden; Gray; 'Brit. Mus. Cat.,' p. 23.

Bicellaria (sp.), Blainville.

Cellularia (sp.), Pallas; Johnston.

Cellaria (sp.), Solander; Lamarck.

Scruparia (sp.), Oken.

Seven species.

Gen. 4. *Canda*, Lamouroux.

Cells rhomboidal, sinuated on the outer side for the lodgment of a vibraculum; no avicularium on the upper and outer angle; sometimes one in front of the cell.

Canda, Lamx.; Blainville; Gray; 'Brit. Mus. Cat.,' p. 26.

Cellaria (sp.), Lamarck.

Cellarina, Van Beneden.

Bicellaria (sp.), Blainville.

6, *Hippothoa catenularia*. 7, *Beania mirabilis*; a, natural size. 8, *Farciminaria aculeata*; a, ovicells. 9, *Dimetopia cornuta*. 10, *Cuberea Boryi*.

Gen. 3. *Atea*, Lamouroux.

Cells tubular, erect, scattered; adnate and decumbent at the base.

Atea, Lamx.; Gray; 'Brit. Mus. Cat.,' p. 30.

Anguinaria, Lamarck; Johnston.

Falcaria (β), Oken.

Four species.

Scrupocellaria, Gray.

Cellularia (sp.), Johnston.

Two species.

Gen. 5. *Emma*, Gray.

Cells in pairs or triplets; a sessile avicularium (sometimes wanting) on the outer side below the level of the aperture.

Emma, Gray; 'Brit. Mus. Cat.', p. 27.

Two species.

Family 5. *Caberrada*, Busk.

Polyzooary dichotomously divided into ligulate bi-multiserial branches; on the backs of which are vibracula, each of which is common to several cells.

Caberrada, Busk.; 'Voyage of Rattlesnake'; 'Brit. Mus. Cat.' p. 37.

Gen. 1. *Caberea*, Lamx. (Fig. 10.)

Cells bi-multiserial, in the latter case quincuncial. Back of branches covered with large vibracula, which are placed obliquely in two rows, diverging in an upward direction from the middle line, at which the vibracula of either side decussate with those of the other.

Caberea, Lamx.; Blainville; Gray; 'Brit. Mus. Cat.', p. 37.

Selbia, Gray.

Crisia (sp.), Audouin.

Cellaria (sp.), Lamarck.

Cellularia (sp.), Fleming; Johnston.

Four species.

Gen. 2. *Amastigia*, Busk.

Cells bi-quadrilateral; vibracula small, resembling avicularia.

One species.

Family 6. *Bicellariada*, Busk.

No vibracula; avicularia, when present, pedunculate.

Bicellariada, Busk.; 'Voyage of Rattlesnake.'

Bugulida, Gray.

Gen. 1. *Bicellaria*, Blainville. (Fig. 11.)

Cells turbinate, distant. Aperture directed more or less upwards. Several spines, marginal or dorsal.

Bicellaria, Blainville; Gray; 'Brit. Mus. Cat.', p. 41.

Cellularia, Fleming; Pallas (sp.).

Cellaria (sp.), Oken; Lamarck.

Bugula (sp.), Oken.

Four species.

11, *Bicellaria ciliata*. 12, *Carlina elegans*; a, front; b, back.

Gen. 2. *Halophila*, Gray.

Cells contiguous, attenuated downwards; much expanded above, with a large plain aperture unarued.

Halophila, Gray; 'Dieff. New Zealand'; 'Brit. Mus. Cat.', p. 43.

Bicellaria, Busk.; 'Voyage of Rattlesnake.'

Gen. 3. *Bugula*, Oken.

Cells elliptical (behind), closely contiguous, bi-multiserial; aperture very large; margin simple, not thickened.

Bugula, Oken; Gray; 'Brit. Mus. Cat.', p. 43.

Acamarchis, Lamx.; Blainville.

Crisia (sp.), Lamx.

Cellularia (sp.), Pallas; Johnston (sp.).

Cellaria (sp.), Solander; Lamarck.

Bugulina (sp.), Gray.

Crisularia (sp.), Gray.

Six species.

Family 7. *Gemellariada*, Busk.

Cells opposite in pairs. Polyzooary continuous.

Gemellariada, Busk; 'Voyage of Rattlesnake'; 'Brit. Mus. Cat.', p. 33.

Gen. 1. *Gemellaria*, Savigny. (Fig. 29.)

Cells joined back to back; all the pairs facing the same way.

Gemellaria, Savigny; Van Beneden; Johnston; Gray; 'Brit. Mus. Cat.', p. 34.

Gemicellaria, Blainville.

Loricaria, Lamx.

Notamia (pars), Fleming.

Loricula, Cuvier.

Crisia (sp.), Lamx.; Lamarck.

Scruparia (B), Oken.

One species.

29, *Gemellaria loricata*.

Gen. 2. *Didymia*, Busk.

Cells joined side to side; no avicularia.

Didymia, Busk.; 'Voyage of Rattlesnake'; 'Brit. Mus. Cat.', p. 35.

One species.

Gen. 3. *Dimetopia*, Busk. (Fig. 9.)

Cells joined back to back; aperture oblique; each alternate pair of cells looking the same way.

Dimetopia, Busk; 'Voyage of Rattlesnake.'

Two species.

Gen. 4. *Notamia*, Fleming.

A pair of tobacco-pipe shaped avicularia, visible above each pair of cells.

Epistomia (sp.), Fleming; Gray.

Dynamena (sp.), Lamx.; Blainville.

Notamia, Fleming; 'Brit. Mus. Cat.', p. 36; Johnston.

Gemicellaria (sp.), Blainville.

Sertularia (sp.), Gmelin.

Cellularia (sp.), Pallas.

One species.

Family 8. *Flustrada*, Gray.

Polyzooary flexible, expanded, foliaceous, erect; sometimes decumbent and loosely attached. Cells multiserial, quincuncial, or irregular.

Flustra, Linn.; Johnston (pars).

Flustrada, Gray (pars); 'Brit. Mus. Cat.', p. 46.

Escharida (part), Johnston; Gray.

Polypters à Réseau (pars), Lamx.

Flustrées (pars), Lamx.

Gen. 1. *Flustra*, Linnæus.

Cells contiguous; on both sides of the frond.
Flustra (sp.), Linn.; Lamarck; Gray; &c.
 Five species.

Gen. 2. *Carbasea*, Gray. (Fig. 12.)

Cells contiguous; on one side only of the frond.
Flustra (sp.), Linn.; Johnston.
Carbasea, Gray; 'Brit. Mus. Cat.' p. 50.
 Ten species.

Gen. 3. *Diachoris*, Busk. (Fig. 13.)

Cells disjunct; each connected with six others by tubular processes.
Diachoris, Busk., 'Voyage of Rattlesnake.'
 Three species.

13, *Diachoris magellanica*; a, avicularia. 14, *Membranipora coriacea*. 15a, Young state of *Lepralia ciliata*.

Family 9. *Membraniporidae*, Busk.

Polyzoary membranaceo-calcareous, or calcareous, expanded, encrusting (sometimes foliaceous, contorted, and suberect). Cells horizontal, quincuncial, or serial.

Flustra, Linn. (pars).

Flustradæ (pars), Gray.

Celleporidae (pars), Johnston.

Membraniporidae, Busk.; 'Brit. Mus. Cat.' p. 55.

* Cells more or less open in front, with raised margins.

Gen. 1. *Membranipora*, Johnston. (Fig. 14.)

Polyzoary encrusting (or suberect, foliaceous, and contorted), spreading irregularly. Cells more or less irregularly disposed or quincuncial, with raised margins; a greater or less extent of the aperture occupied by a thin membrane.

Eschara (pars), Pallas.

Flustra (sp.), Linn.; Esper; Berkeley; Lamarck; Grant; Fleming; Risso; Johnston; Lamouroux.

Membranipora, Johnston; 'Brit. Mus. Cat.' p. 56; W. Thompson; Hassall.

Discopora (pars), Lamarck.

Annulipora, Conopeum, *Callopora*, *Amphiblestrum*, *Micropora*, Gray.

Eighteen species.

** Aperture of cells entirely filled in by a convex calcareous expansion. Cells disposed in more or less regularly radiating lines.

Gen. 2. *Lepralia*, Johnston. (Figs. 15 & 15a.)

15, *Lepralia Peachii*. 16, *Cellepora pumicosa*.

Polyzoarium adnate, crustaceous, spreading from a centre in a more or less circular form; composed of contiguous, or connected, calcareous, decumbent cells, the wall of which is complete in front.

Eschara (sp.), Moll.; Pallas.

Lepralia, Johnston; Gray; 'Brit. Mus. Cat.' p. 63.

Berenicea, Fleming (non Lamouroux nor Peron).

Escharina (sp.), Milne-Edwards; Gray.

Escharoides (sp.), Milne-Edwards.

Cellepora (sp.), Oken; Audouin (pars); Lamouroux (pars); Hagenow (pars).

Flustra (varior).

Discopora, Lamarck (pars); Gray (pars); Lamouroux (pars).

Cribrellina, *Herentia*, *Escharella*, *Porella*, *Celleporella* (all sp.), Gray.

1. *Armatae*. Species provided with either avicularia or vibracula.

A. Species having avicularia.

a. Median and single.

* Superior (above the mouth).

** Inferior (below the mouth).

ß. Avicularia double, or azygous and lateral on each cell, or only on some cells in the polyzoary.

B. Species having vibracula.

2. *Inarmatae*. Species without either avicularia or vibracula.

a. With oral spines.

ß. Mouth unarmed.

About fifty or sixty species.

Family 10. *Celleporidae*, Busk.

Polyzoarium composed of cells, standing more or less vertical to its axis or plane, heaped together, or irregularly overlying each other.

Celleporidae, Johnston (pars); 'Brit. Mus. Cat.' p. 58.

Gen. 1. *Cellepora*, O. Fabricius. (Fig. 16.)

Polyzoarium calcareous, rigid, adnate or erect, composed of urceolate, suberect, contiguous cells, heaped together irregularly, or arranged quincuncially. An ascending rostrum on one or both sides of the mouth usually furnished with an avicularium.

Cellepora (sp.), O. Fabricius; Johnston; Linnæus; Müller; Berkeley; Stewart; Lamarck; Lamouroux; Fleming; Olivi.

Spongites, Oken.

Tubipora (pars), Linn.

Millepora (pars), Pallas; Ellis and Solander (pars).

Eschara (pars), Pallas.

* Adnate, globose, or spreading.

** Erect.

Eight species.

Family 11. *Escharidae*, Busk.

Polyzoary erect, rigid, foliaceous and expanded, lobate or reticulate. Cells disposed quincuncially in the same plane, on one or both surfaces.

Escharidae (pars), Johnston.

Lepratiance (pars), Gray.

Reteporance, Gray.

Gen. 1. *Eschara*, Ray. (Fig. 17.)

Polyzoarium foliaceous and expanded, or contorted, or branched and sublinear. Cells disposed on both surfaces, back to back, immersed, coalescent, horizontal to the plane of the axis.

Eschara, Ray; Fleming; Johnston; Lamarck; Gray; Pallas (pars); Moll (pars); 'Brit. Mus. Cat.' p. 89.

Nullipora (sp.), Solander.

Cellepora (sp.), Esper.

• Polyzoary more or less expanded, foliaceous.

•• Polyzoary subdivided into branching lobes.

Eleven species.

Gen. 2. *Retepora*, Imperato.

(Fig. 28.)

Polyzoarium foliaceous, calcareous, reticulated. Cells immersed, opening at one surface only.

Millepora, Linn. (pars); Ellis and Solander; Esper; Marsigli; Cuvier.

Retepora, Imperato; Lamarck; Risso; Fleming; Stark; De Blainville;

Couch; Johnston; Goldfuss (pars); Hagenow (pars);

'Brit. Mus. Cat.', p. 93.

Frossipora, Oken; De Blainville.

Three species.

28, *Retepora cellulosa*.

Family 12. *Selenariidae*, Busk.

Polyzoary more or less regularly orbicular, convex on one side, plane or concave on the other (probably free). Furnished with large and powerful vibracula, with variously formed setae (probably locomotive).

Selenariidae, Busk; 'Brit. Mus. Cat.', p. 97.

Gen. 1. *Cupularia*, Lamouroux.

(Fig. 18; vide also fig. in CELLARIAE.)

Each cell throughout the polyzoary with a vibraculum at the summit.

Cupularia, Lamouroux (proposed); 'Brit. Mus. Cat.', p. 97.

Lunulites, Lamouroux (pars); DeFrance (pars); Deslongchamps

(pars); Goldfuss (pars); De Blainville (pars); Gray; Cuvier

and Brongniart; Lonsdale (pars); Michelin (pars).

Pencostella (pars), Lonsdale.

Five species (recent); numerous fossil.

Gen. 2. *Lunulites*, Lamouroux.

Cells arranged in series radiating from the centre and bifurcating as they advance; vibracula in linear series alternate with those of the cells.

As in the preceding species.

Four species (recent); numerous fossil.

Gen. 3. *Selenaria*, Busk.

Only a certain number of cells, dispersed at uniform distances apart, furnished with vibracula. The front of each cell furnished, covered by a cribriform calcareous expansion; the others arched above and contracted below.

Lunulites (pars), Busk, 'Voyage of Rattlesnake.'

Selenaria, 'Brit. Mus. Cat.', p. 101.

Sub-Order II. *Cyclostomata*.

Cells tubular, calcareous, immersed or exserted; mouth terminal, without any moveable appendage or lip.

Tubuliporina, Milne-Edwards.

Tubuliporida, Johnston.

Aulopora (pars), Ehrenberg; Johnston.

A. Erectae.

Polyzoary erect, free, simple or branched, linear or expanded above; branches articulated or continuous.

Family 1. *Crisiidae*, Milne-Edwards.

Polyzoarium divided into distinct internodes, connected by a horny substance.

Gen. 1. *Crisidia*, Milne-Edwards.

A single cell in each internode.

Sertularia (pars), Linn.; Berkeley (pars); Esper (pars).

17, *Euchara foliacea*. 18, *Cupularia* Lancel. 19, *Fincularia ornata*.

Cellularia (pars), Pallas; Hogg.

Cellaria, Ellis and Solander (pars); Lamarck (pars).

Eucrateria, Lamouroux (pars); Risso (pars); Fleming (pars);

Templeton.

Unicellularia (pars), Blainville.

Crisidia, Milne-Edwards.

Crisia (pars), Johnston; Hassall (pars), &c.

One or two species.

Gen. 2. *Crisia*, Lamouroux. (Fig. 20.)

Two or more cells in each internode.

Syn. as above.

Three species recent; several fossil.

Family 2. *Idmoneade*.

Polyzoarium continuous throughout, usually polymorphous.

Gen. 1. *Idmonea*, Lamouroux. (Fig. 22.)

Openings of cells disposed in transverse or oblique alternate series on each side of the front of the branches of the polyzoary, on which is a raised line or ridge separating the rows of cells.

Retepora (sp.), Lamarck.

Hornera (sp.), DeFrance.

Idmonea, Lamouroux; Blainville.

Three or four species recent; many fossil.

Gen. 2. *Pustulipora*, De Blainville. (Fig. 26.)

Openings of cells disposed irregularly, on all sides of the cylindrical or compressed branches or lobes of the polyzoary.

Ceripora (pars), Goldfuss.

Idmonea (sp.), De Blainville.

Pustulipora, Blainville; Milne-Edwards; Johnston.

Tubulipora (sp.), Couch.

Five or six species recent; many fossil.

20, *Crisia bicollata*; a, ovicell. 21, *Alecto granulata*. 22, *Idmonea radians*; a, natural size. 23, *Tubulipora serpens*.

Gen. 3. *Hornera*, Lamouroux.

Openings of cells disposed irregularly, or in more or less regular opposite transverse series, on one side only of the branches or lobes of the polyzoary.

Millepora (sp.), Esper.

Retepora (sp.), Lamarck.

Hornera, Lamouroux; De Blainville; Milne-Edwards.

Several species recent; many fossil.

B. Adnatæ, s. decumbentes.

Polyzoarium adnate or suberect above, decumbent and adnate below.

Family 3. *Tubuliporidae*.

Polyzoarium divided into linear or sublinear branches or lobes, sometimes more expanded and lobate upwards, always decumbent, and closely adnate.

Gen. 1. *Alecto*, Lamouroux. (Fig. 21.)

Polyzoarium composed of a single or of multiple series of cells.

Alecto, Lamouroux; Milne-Edwards; Johnston (pars); De Blainville; Fleming.

Millepora (sp.), Linn.

Aulopora (sp.), Goldfuss, &c.

Three or four species recent; several fossil.

Gen. 2. *Tubulipora*. (Fig. 23.)

Polyzoarium arising from a contracted base, and expanding above; either simple or irregularly subdivided; decumbent and adherent below, usually free and suberect above.

Tubulipora, Milne-Edwards (pars); Johnston (pars); Fabricius; Turton; Gmelin; Couch (pars); Fleming (pars); Lamarck (sp.); Risso (sp.).

Tubipora (sp.), Linn.; Jameson; Stewart; Bosc.

Millepora (sp.), Ellis and Soland.

Cellepora (sp.), Esper.

Pherusa (?), Lamouroux, &c.

Five or six species recent; several fossil.

Family 4. *Discoporidae*.

Polyzoarium in the form of a closely adnate, circular, or irregular disc or patch.

Tubuliporidae (pars), Milne-Edwards, &c.

Gen. 1. *Discopora*, Lamarck.

Polyzoarium a circular disc, either flat, concave, or convex in the centre, with the suberect tubes opening irregularly in all parts of the surface, and usually surrounded by a thin calcareous border.

Discopora, Lamarck; Lamouroux; Fleming.

Tubulipora (pars), Johnston.

Melobesia, Audouin.

Obelia, Quoy and Gaimard.

Madrepora, Ellis and Solander; O. Fabricius.

Gen. 2. *Diastopora*, Lamouroux. (Fig. 24.)

Polyzoarium more or less depressed, circular, discoid; the cells subalternating, horizontal, immersed; openings elliptical.

Millepora (sp.), Esper.

Mesenteripora, De Blainville.

Diastopora, Milne-Edwards (pars); Johnston (sp.); Hagenow (pars).

Aulopora (sp.), Goldfuss.

Berenicea (sp.), Lamouroux.

Rosacilla, Römer.

24, *Diastopora* (sp. ?); 25, *Serialaria lendigera*; a, oral setae. 26, *Pustulipora*, (sp. ?). 27, *Farralla prelonga*.

Gen. 3. *Defrancia*, Bronn.

Polyzoary either discoid and adnate throughout, or fungiform and attached by a short stem; openings of tubes disposed in lines or rows radiating from the centre.

Pelagia, Lamouroux.

Lichenopora, Michellin.

Tubulipora, Milne-Edwards (sp.); Johnston (sp.).

Ceripora (aut., pars).

Defrancia, Bronn.; Hagenow; Reuss.

Sub-Order III. *Otenostomata*.

Cells corneous, or fleshy, tubular or depressed, free or coalescent;

mouth terminal or subterminal, contractile, and when the polypide is exerted, surrounded with a fringe or row of setae, connected by a delicate membrane.

Vesicularia, Johnston.

Polysa cornea, Gray, and including—

Halcyonella, Johnston.

Polysa carnea, Gray.

Alcyonidea and *Alcyonidula*, Johnston.

Family 1. *Vesiculariada*, Johnston.

Cells tubular or ovate, separate, arising from a basal tube common to all or to several; mouth terminal.

Vesiculariada, Johnston.

Gen. 1. *Serialaria*, Lamarck. (Fig. 25.)

Cells uniserial or biserial, and unilateral, placed in close sets at stated intervals; basal tube divided into internodes.

Serialaria, Lamarck; Risso; Fleming; Templeton; Couch; De Blainville.

Amathia, Lamouroux, &c.

Three or four species.

Gen. 2. *Vesicularia*, J. V. Thompson.

Cells ovate or subtubular, disjunct, uniserial, and unilateral; polypide with a gizzard.

Valkeria (sp.), Fleming.

Vesicularia, Thompson; Farre; Johnston; Van Beneden; Couch.

One species.

Gen. 3. *Valkeria*, Fleming.

Cells ovate, clustered in whorls at the joints of the basal tube; polypides without a gizzard.

Valkeria, Johnston; Fleming; Farre; Van Beneden.

Vesicularia (sp.), Thompson.

Cuscutaria, De Blainville.

Gen. 4. *Bowerbankia*.

Cells unilateral, irregularly placed, sessile; polypides with a gizzard (armed with two teeth).

Bowerbankia, Farre; Johnston; Van Beneden.

One species.

Gen. 5. *Farrella*. (Fig. 27.)

Cells elliptical, scattered; polypide without a gizzard.

Farrella, Ehrenberg; Johnston.

Lagenella, Farre.

Laguncula, Van Beneden.

Two species.

Gen. 6. *Anguinella*, Van Beneden.

Cells tubular, supported on a common stalk, and branching out in a palmate fashion.

Anguinella, Van Beneden.

Family 2. *Alcyoniada*, Johnston.

Cells fleshy, immersed, angular; mouth terminal, simple, contractile.

Halcyonella, Johnston.

Polysa carnea, Gray.

Alcyoniada, Johnston.

Alcyonidula, Johnston.

Gen. 1. *Alcyonidium*, Lamouroux.

Polypoary variously lobed, massive, fleshy, erect, or adnate.

Alcyonium, Ellis; Baxter; Pallas; Linn.; Oliv.; Esper; Müller;

Lamouroux; De Blainville; &c.

Alcyonidium, Lamouroux; Gray; Hooker; Johnston; W. Thompson; &c.

Halodactylus, Farre; Van Beneden.

Cyclonum (sp.), Hassall.

Sarchochitum (?), Hassall.

Three or four species.

Sub-Order IV. *P. Pedicellinea*, Gervais.

Lophophore produced upwards on the back of the tentacles, uniting them at their base in a sort of muscular calyx.

Family 1. *Pedicellinida*, Johnston.

Gen. 1. *Pedicellina*, Sara.

Polypide not retractile within the delicate closely adnate ectocyst, which is produced downwards into a long tubular pedicle, containing muscular fibres, and rising vertically from a creeping radical tube.

Hydra (sp.), Fleming; Bosc.; Lister; Sharpey.

Pedicellina, Sara; Johnston; Van Beneden.

Lusia, Milne-Edwards; De Blainville; Gervais; Hassall.

Crinomorpha, Van Beneden.

Two or three species.

Sertularia (sp.), Müller; Bosc.; Lamarck.

Three species.

Order II. *Polysa hippocrepia*, Gervais.

Tentacles disposed on a crescentic or horse-shoe shaped lophophore; everton of endocyst only partial.

Polysa hippocrepia, Gervais.

Polysa hippocrepia, Gray.

Lemniades, Johnston; Allman.

Freshwater *Polysa*, Allman.

Freshwater *Bryozoa*, Hancock.

Bryozaires Fluviales, Van Beneden.

Family 1. *Cristatellida*, Allman.

Polypoary free, locomotive.

Gen. 1. *Cristatella*, Cuvier.

Polypoary saciform, hyaline, with a common flattened disc adapted for locomotion; orifices placed on the surface opposite to the disc, and arranged in several concentric marginal series; ova leucular, with annular and marginal spines.

One species.

Family 2. *Plumatellida*, Allman.

Polypoary rooted.

A. Lophophore with two long arms.

Gen. 1. *Lophopus*, Dumortier.

Polypoary saciform, hyaline, with a disc which serves for attachment, but not for locomotion; orifices scattered; ectocyst gelatinous.

Polype à Panche, Trembley.

Bell-Flower-Animal, Baker.

Naisa, Lamouroux; Deslongchamps.

Plumatella (sp.), Schweigger; De Blainville; Gervais; Lamarck.

Alcyonella, Raspail; Johnston; Allman.

Lophopus, Van Beneden; Allman.

One species.

Gen. 2. *Alcyonella*, Lamarck.

Polypoarium tubular; tubes united by their sides; orifices terminal; ectocyst pergamentaceous.

Tubularia, Pallas.

Leucophra, Müller.

Alcyonium, Bruguière.

Spongia, Schmiedel.

Alcyonella, Raspail; Pallas (sp.); Allman, &c.

Plumatella, Gervais.

Three species.

Gen. 3. *Plumatella*, Lamarck. (Fig. 30.)

Polypoary tubular; tubes distinct; ectocyst pergamentaceous.

Tubipora, Linnæus.

Tubularia, Müller; Linnæus; Vaucher; Turton.

Naisa, Lamouroux; Deslongchamps.

Plumatella, De Blainville; Carus; Lamarck; Dumortier; Johnston; Gervais; Allman; Thompson; Van Beneden; Dalzell;

Schweigger; Risso, &c.

Two species.

30. *Plumatella cristata*.

B. Lophophore with the arms obsolete.

Gen. 4. *Fredericella*, Gervais.

Polypoary confervoid, composed of a membrano-corneous branched tube, with the branches distinct and terminated by the orifices; lophophore nearly circular, tentacular crown campanulate; ova bean-shaped, destitute of annulus or spines.

Tubularia, Blumenbach; Gmelin.

Naisa, Lamouroux.

Diffugia, Moen.

Plumatella, Fleming; Dumortier; Johnston.

Fredericella, Gervais; Van Beneden; Thompson; Allinau; Johnston; Hancock.

Family 3. *Paludicellidae*.

Lophophore orbicular, mouth destitute of valve. (Does not perhaps properly belong to the *P. hippocrepia*.)

Gen. 1. *Paludicella*, Gervais.

Polyzoary membrano-corneous, branched; branches composed of a series of claviform cells, placed end to end, and separated from one another by complete septa; orifices tubular, lateral, placed near the wider extremity of each cell; ova leucular, with a narrow annulus.

Alcyonella (sp.), Ehrenberg; Nordmann.

Paludicella, Gervais; Van Beneden; Allman; Thompson; Johnston; Hancock.

POMACANTHUS. [CHETODON.]

POMACEÆ. [ROSACEÆ.]

POMATOMUS. [PERCIDE.]

POME, a form of Fruit. [FRUIT.]

POMEGRANATE. [PUNICA.]

POMPIDIDÆ, a family of Fossorial Hymenopterous Insects. They are sometimes included with the *Sphegidae*. [HYMENOPTERA.] They have the collar either transversely or longitudinally square, with the abdomen more or less oval, and attached to the thorax by a very short peduncle. The legs are very long. The fore wings have two or three perfect submarginal cells, and another commenced at the tip of the wings. The species are called Sand Wasps, and are amongst the most ferocious of the insect tribe. The species of the exotic genus *Pepsis* are amongst the largest of the *Hymenoptera*. The genus *Pompilus* is British. The species are very active, running amongst grass and other plants in hot sandy situations. They are quick in their motions, and their wings are constantly agitated. Their long legs give them the appearance of spiders. (Westwood, *Families of Insects*.)

POMPILIUS. [NAUTILIDÆ.]

POMPILUS, according to Latreille, a genus of Hymenopterous Insects of the section *Fossoria* and family *Sphegidae*. In the systems of Dr. Leach, Mr. Shuckard, and some others, this group of insects is regarded as a family, *Pompilidae*, the principal characters of which are as follows:—Posterior legs at least as long as the head and thorax taken together; antennæ of the female formed of long joints, generally distinct and often curved; prothorax at least as broad again as long; its posterior margin arched; abdomen obovoid, without any long petiole at the base.

The *Pompilidae* are extremely active: they run and fly with great rapidity; are for the most part of moderate size, and often adorned with red and black colours; at least those species which belong to the genus *Pompilus*. These insects burrow in the ground, preferring sandy situations, and store their cells with spiders, which constitute the food of their larvæ.

In the genus *Pompilus* the superior wings have one marginal cell, which is semicircular, and sometimes nearly triangular; and three submarginal cells; the first of these is as long or longer than the two following cells; the second receives the first recurrent nervure about its centre; and the third, which is either triangular or subquadrate, receives the second recurrent nervure. A fourth submarginal cell is sometimes traceable.

This genus contains numerous species. Mr. Shuckard, in his work on the indigenous Fossorial *Hymenoptera*, describes 18 species.

Besides *Pompilus* proper, the genera *Ceropales* and *Aporus* are included in the present family.

PONERA (Latreille), a genus of Insects belonging to the family *Formicidae*. In this genus the neuters and females are armed with a sting. The peduncle of the abdomen is formed of a single knot; antennæ in these individuals thickened at the tip; mandibles triangular; head subtriangular. *P. contracta* is a small species, a native of England.

PONGO. [CHIMPANZEE.]

PONTEDERA'CEÆ, *Pontederads*, a natural order of Plants belonging to the class of Endogens. It has a 6-parted tubular coloured perianth, more or less irregular, with a circinate aestivation. The stamens arising from the calyx 6 or 3 opposite the petals, the anthers turned inwards, opening lengthwise. The ovary is free, more or less completely, 3-celled, many-seeded; one style, the stigma simple. The capsule 3-celled, occasionally acquiring an adhesion to the perianth, 3-valved with loculicidal dehiscence; the seeds are indefinite, attached to a central axis; ascending hilum small; the embryo with its radicle rather enlarged, orthotropical in the axis of somewhat mealy albumen. The species are aquatic or marsh plants. The leaves sheathing at the base, with parallel veins in the larger species, arrow-headed, cordate, or dilated. The flowers are either solitary or in spikes or umbels, spathaceous; frequently blue, sometimes yellow. The aquatic plants comprehended in this order are distinguished by the divisions of their flowers being rolled inwards after flowering, to which may be added mealy albumen and an indefinite number of seeds. They are natives exclusively of North and South America, the East Indies, and tropical Africa. Very little is known of their uses. Some of the species are employed by the native Indian practitioners in liver complaints and diseases of the stomach.

Rubbed down in butter and drank, they are said to remove redness

of the eyes; powdered and mixed with sugar, to relieve asthma; and when chewed, to remove tooth-ache; brayed with milk, some are administered in fever and some eaten as pot-herbs.

(Lindley, *Vegetable Kingdom*.)

PONTO'PHILUS, a genus of Shrimps. (*Egeon*, Risso.)

PONTOPORIA. [CETACEA.]

POONAH-LITE, a Mineral occurring crystallised in long slender crystals. Primary form a right rhombic prism. Fracture uneven. Colourless. Hardness 5.0 to 5.5. Transparent, translucent. Lustre vitreous. Found at Poonah in the East Indies.

The following is an analysis by Gmelin:—

Silica	45.120
Alumina	30.446
Lime	10.197
Soda, with a trace of potash	00.657
Water	13.386

POPINJAY. [PICIDÆ.]

POPLAR. [POPULUS.]

POPPY. [PAPAVER.]

—99.806

POPULUS (from the Latin *Populus*), a genus of Plants belonging to the natural order *Salicaceæ*. It is characterised by possessing dioecious cylindrical many-flowered catkins; wedge-shaped single-flowered jagged bractæ or scales; turbinate calyx, tubular below, and dilated in the border. The barren flowers have eight or more capillary very short filaments, and large drooping quadrangular anthers. The fertile flowers have an ovate pointed ovary, no style, 4-8 awl-shaped stigmas; ovate capsule, with two concave valves and one cell; numerous small ovate seeds, each crowned with a tuft of fine hairs. All the species of this genus are deciduous trees, mostly of a large size, and growing in Europe, North America, Asia, and the north of Africa. The Poplar has long been valued as an ornamental tree, and the various species have been extensively cultivated in Europe. As they are dioecious plants, much difficulty has arisen in determining the number of the introduced species; and it is probable that when the plants with male and female flowers shall have been carefully examined, a considerable reduction in the present number of acknowledged species will take place.

P. alba, the White Poplar, or Abele Tree, has roundish, cordate, lobed, and toothed leaves, glabrous above, downy and very white beneath; fertile catkins, ovate; 4 stigmas; creeping roots; branches very white, downy when young. This tree is a native of Great Britain and most parts of Europe, in woods and thickets in a moist soil.

P. canescens, the Gray Poplar, is by some writers considered only a variety of *P. alba*. It is known by its leaves being roundish, deeply waved, toothed, downy, and hoary beneath; fertile catkins cylindrical; stigmas 8. This tree is of slower growth than *P. alba*, and the wood is finer, and more adapted for the purposes to which timber is applied. The Abele, as well as the Black Poplar, was known to the Romans, and was recommended by Pliny as props for the vine. ('Hist. Nat.' xvi. 23.) It is much planted in some parts of Holland, Flanders, France, and Germany. The principal use to which the Abele is put in England is that of making flooring boards, for which purpose it should be seasoned eighteen or twenty months previous to use. It is also employed by the cooper for making wooden dishes, casks, &c. The Gray Poplar possesses the whitest wood of any of the species, and is used in France and Germany for carving and the lighter kinds of architecture.

P. tremula, the Trembling Poplar, or Aspen. Leaves nearly orbicular, broadly toothed, glabrous on both sides; stalks compressed; stigmas 4, erect, cased at the base. Ten or twelve varieties of this plant are found in the nurseries, and some writers refer several other species to this as varieties. The aspen, like all the genus, is a rapid-growing tree. It has horizontal branches, which become pendulous by age. It is a native of moist woods in Great Britain, and in Scotland is found at an elevation of 1500 feet above the level of the sea. It is also found in the whole of the south of Europe, in the Caucasus, in Lapland, and is very abundant in Russia. The wood of this tree is used for much the same purposes as the last.

The trembling leaves of the Aspen have always excited attention, and have frequently been the subject of superstitious belief and poetical allusion.

P. tremula, the American Aspen, is by some looked upon as a variety of *P. tremula*. The leaf is suborbiculate, with an abruptly acuminate point, toothed, with two glands at the base on its upper surface; silky whilst young, glabrous afterwards. It is found in North America.

P. nigra, the Black Poplar. Leaves twice the length of their foot-stalks, deltoid or unequally quadrangular, serrated with glandular teeth, glabrous; the base more entire, the under side palest; catkins cylindrical, pale, lax. It is a native of Great Britain, and has a geographical range nearly the same as that of *P. alba*. It attains a height of from 70 to 80 feet, and, on account of its rapid growth, has been much cultivated. The wood is used for the same purpose as that of *P. tremula*; it is however softer, and more easy to work, and splits more easily than any other of the species. The cotton from the seeds has been used in France and Germany as wadding, and has been also manufactured into cloth-hats and paper; but the expense

of cultivating the tree for this purpose was too great, and consequently the manufacture has been given up.

P. Canadensis, the Canadian Poplar, is an American species. It has angular branches, a compressed petiole; leaves roundish ovate, deltoid, acuminate, subcordate at the base, where there are glands serrated with unequal teeth, glabrous. It attains a height of 70 or 80 feet, and is found wild in the rocky districts of North America between Canada and Virginia.

P. monilifera, the Black Italian Poplar. Shoots more or less angular; branches round; petiole slender, compressed in the upper part; disc deltoid, glands at the base, subacute, serrate, glabrous; bractes glabrous; stamens 16; stigmas 4. It is doubtful of what country this tree is a native. It appears to have been introduced into England by Messrs. Dickson, from North America. In America however it is called Italian Poplar, and in France Peuplier Suisse. It is probably a variety of an European species that has been introduced into America. It is the most rapid-growing of all the poplars, and in this country the timber is considered equal if not superior to that of any other species.

P. fastigiata, the Lombardy Poplar. Leaf deltoid, wider than long, crenulated, glabrous, in the bud involutely folded, petiole compressed. This tree is readily distinguished among the species by its peculiar conical cypress-like form, and the total absence of horizontal branches. It grows to the height of 100 and 120 feet, and sometimes 150 feet. It is a native of Italy on the banks of the Po, and also of Persia and the Himalaya.

P. balsamifera, Balsam-Bearing Poplar, or Tacamahac-Tree. Leaves ovate-oblong, quite smooth, with fine glandular serratures, deep-green above, almost white but smooth underneath. Sometimes two glands at the apex of the petiole. Buds covered, in the spring, with an abundance of fragrant, viscid, balsamic juice. It is a native of North America, Dattia, and the Altai, and attains a height of 80 feet. It is remarkable for its balsamic secretion, which was formerly collected in Canada in shells, and under the name of Baume Focot, was sent in considerable quantities to various parts of North America.

P. betulifolia, *P. heterophylla*, *P. angulata*, and *P. candicans*, American species, have also been cultivated in this country, and deserve a place in all collections of these plants.

PORCELLANA. [PORCELLANIDÆ.]

PORCELLA'NIDÆ, a tribe of Anomalous Crustacea, placed by M. Milne-Edwards next to the Paguri, and immediately preceding the section of Macrurous Decapoda.

Porcellana (Lam.).—The general form resembling that of the *Brachyura*. Carapace ordinarily as wide as it is long, suborbicular and depressed above. Front advanced above the insertion of the internal antennæ, and even capable of covering them completely when they are bent back, without there being, nevertheless, antennary fossæ. Eyes small and lodged in a sort of orbit, the upper wall of which is well formed, but the limits of which are not determined externally and internally except by the antennæ, and whose inferior border is very short and scarcely projecting; this last border is prolonged externally, and there is between the kind of crest thus formed and the border of the carapace a deep furrow, from which the external antenna springs; these appendages are inserted consequently outside the eyes; their basilar portion is composed of three cylindrical joints, the second of which is the greatest, and their terminal stem is very long.

M. Milne-Edwards divides this genus into the following sections:—

1. Species whose front is entire and does not present lateral teeth.

a. Front triangular.

P. violacea. Length about an inch. It inhabits the coasts of Chili.

aa. Front straight or slightly rounded.

P. sculpta. Colour reddish with great white spots. Length about three lines. It inhabits the coasts of Java.

Two other species are recorded, one of them from the China seas: the other is *P. viridis*, Gray, 'Zool. Misc.' *Pisidia viridis*, Leach.

§ 2. Species whose front is divided into three or five teeth or lobes.

b. Hands very wide and flattened. Pincers triangular.

Porcellana platycheles. a, Tail unfolded.

P. platycheles. Length about seven lines. Colour brownish. It is a native of the coasts of England and France.

bb. Hands long, narrow, and thick; pincers slender.

P. longicornis (*Pisidia longicornis*, Leach; *Cancer longicornis*, Pennant, 'Brit. Zool'). Length about 3 lines. It is found on the coasts of England and France.

M. Milne-Edwards thinks that the division of this genus into two, under the name of *Pisidia*, as well as *Porcellana*, by Dr. Leach, has been effected without sufficient reason. M. Desmarest, though he adopts it, shows that the former genus is established upon insufficient characters; therefore M. Milne-Edwards thinks that it ought to be abandoned.

Eglea, Leach.—Carapace depressed and much longer than it is wide, divided into two portions by a furrow which separates the stomachal from the cardiac and branchial regions; these last are dilated, and terminated externally by a trenchant border. The front is armed with a rostrum, at the base of which is seen on each side a notch which represents the orbit. Ocular peduncles very short and directed forwards. Internal antennæ inserted below the ocular peduncles, and their very short stem bent back between these organs and the base of the rostrum; their basilar joint globular. External antennæ inserted on the same line as the internal ones, in the lateral angle of the carapace; their peduncle composed of four joints, the first three of which are extremely small, and the fourth cylindrical and more elongated.

M. Milne-Edwards remarks that this genus, in his opinion, approaches the *Porcellana* more nearly than the *Galathea*, next to which they had been hitherto placed; but the confirmation of the abdomen of the *Eglea* seems to him to indicate that their natural position is in the section of *Anomura*. [GALATHEIDÆ.]

E. levis. Length about 2 inches. It is a native of the coasts of Chili.

Eglea levis.

Megalops, Leach.—M. Milne-Edwards observes that the small crustaceans designated by this generic name have much analogy with the *Galatheidæ* as well as the *Porcellanidæ*; and if they be really animals arrived at their entire development, they would seem to establish the passage between the Anomalous and Macrurous Decapods; for their abdomen, though it does not present at its extremity five blades united into a fan-shape, as in the last, is very much developed, and serves for natation. But he is led to believe that they are only the young of some anomalous crustacean; and that, when the form has been better studied, it will be erased from the list of genera which compose the order of Decapoda, or at least will be assigned a different place and other characters. [MEGALOPS.]

Monolepis, Say.—M. Milne-Edwards is inclined to believe that this genus ought not to be retained, and that it has only been established on young crustaceans not arrived at their complete development; but not having himself observed them, he cannot form a decisive opinion on this point. They appear, he adds, to have the greatest analogy with *Megalops* and young *Dromia*. The reader is referred to Mr. Say's paper on the subject, in the 'Journal of the Academy of Philadelphia'; to M. Desmarest's work ('Considération sur les Crustacés'); and to the 'Histoire Naturelle des Crustacés' of M. Milne-Edwards. The species recorded are both American.

PORCELLIA, a genus of Fossil Mollusca.

PORCELLIO. [ISOTODA.]

PORCUPINE. [HYSTRICIDÆ.]

PORC. [SKIN.]

PORES OF PLANTS. [STOMATES.]

PORITES. [MADREPOREA; POLYPIFERA.]

PORO'DRAGUS (De Montfort), a genus of *Belemnites*.

PORPESSE. [CETACEA.]

PORPHYRA. [ALGÆ; LAYER.]

PORPHYRIO. [RALLIDÆ.]

PORPHYRY. A large number of rocks of igneous origin, both very ancient and comparatively modern, are thus designated, yet this use of the term is neither accurate nor convenient. Properly speaking, a particular structure is indicated by it, and not a definite rock or family of rocks.

Felspar of a granular texture, without crystals imbedded, is Claystone; with imbedded crystals of felspar it is Porphyry. Hornblende mixed with uncrystallised felspar makes some Greenstones; with imbedded crystals of felspar this becomes Greenstone-Porphyry. Hence, by this mode of designation, we have Pitchstone-Porphyry, Greenstone-Porphyry, Basaltic-Porphyry, Felspar-Porphyry, and even so vague a term as Trap-Porphyry; and, on the other hand, more correctly, Porphyritic Pitchstone, Porphyritic Claystone, Porphyritic Greenstone, Porphyritic Basalt, and Porphyritic Granite.

Among volcanic rocks, Porphyritic Trachytes are common.

Fine examples of porphyry (crystals of felspar in a base of uncrystallised felspar) occur in Scotland, at Inverary and in Ben Nevis; in Cumberland, on Armboth Fell; and in Cornwall, commonly under the title of Eurite.

PORPITA. [ACALEPHÆ.]

PORPOISE. [CETACEÆ.]

PORTLAND OOLITE, a term in Geology, synonymous with Epioolite of Brongniart, and Upper Oolite of some English geologists. [OOLITE.]

PORTULACÆÆ, *Portulacææ*, a small natural order of Polypetalous Exogenous Plants with hypogynous stamens; distinctly characterised by having two sepals, five petals, and a central placenta, whose seeds contain a curved embryo, lying upon mealy albumen. Their fruit is commonly 1-celled, but the edges of the carpels are sometimes so much inflected as to press upon the placenta and divide the interior into cells. They are annual, perennial, half-shrubby or shrubby plants, with entire more or less succulent leaves, rarely furnished with stipules, and with flowers which are often very showy, although more frequently inconspicuous. Their prevailing colour is purple or scarlet. They occur in all the hotter or milder parts of the world, especially in dry exposed situations, for which their succulent leaves render them well suited. About a fourth of the order inhabit the Cape of Good Hope; rather more than another fourth are found in South America; two inhabit Australia; and the remainder are natives of Europe and other parts of the world.

Claytonia Virginica.

1, calyx, stamens, and pistil; 2, capsule, with the two permanent sepals; 3, a transverse section of a capsule; 4, a vertical section of a seed.

Common Purslane (*Portulaca oleracea*), a potherb, now disused, indicates the harmless quality of such plants. The *Talinums* and *Calandrinias*, and a few species of *Portulaca*, are well known as gay garden-flowers.

PORTUNUS (Leach), a genus of Brachyurous Crustacea. It has the following characters:—External antennæ setaceous, very

short, having their first two joints larger than the others, inserted at the internal canthus of the eyes. External jaw-feet having the third joint of their internal branch elongated, nearly conical, and notched internally. First pair of feet large, equal, with the fingers of their pincers rather long; fifth pair of feet terminated by a flattened foliaceous and nearly lanceolate joint. Carapace rather flat above, with the anterior border arched and semicircular, and the posterior border nearly truncated, having its longitudinal diameter equal to the transversal diameter; orbits without fissures; eyes moderate.

P. variegatus may be taken as an example. It is found in the Adriatic Sea, the Mediterranean, and the ocean.

Portunus variegatus, male.

a, External Antenna; b, External Jaw-Foot; c, Tail or Abdomen.

It appears to be identical with *Platyonichus latipes* of Milne-Edwards; nor does there appear to be any sufficient reason for distinguishing the form generically from *Platyonichus*. [PORTUNIDÆ.]

PORTUNIDÆ, a family of Brachyurous Crustacea, nearly allied to the Cancrarians. The species are generally known by the name of Paddling Crabs.

The general form of the *Portunideæ* does not ordinarily differ much from that of the greater part of the Cancrarians; but the carapace is always but little elevated, and sometimes has a lozenge-shape. The orbits are directed upwards and forwards. The internal antennæ are bent back transversely, or at least very obliquely outwards, and the basilar joint of the external antennæ is partially lodged in a gap of the internal orbital angle. The third joint of the external jaw-feet is always wider than it is long, and sharply truncated or notched at its anterior and external angle for the insertion of the fourth joint.

Orbits, Antennæ, Jaw-Foot, &c., of *Portunus*.

The sternal plastron is always very wide, and in general the last thoracic segment is much more developed than all the others, even than that which carries the anterior feet; the suture which separates this segment from the preceding is directed very obliquely forwards and inwards; the vault of the sides is generally nearly horizontal, and the posterior sella turcica very narrow. The anterior feet are in general very elongated, the succeeding feet are somewhat natatory, and the posterior feet always so, their tarsus being lamellar; the second pair of feet are ordinarily more than once and a half as long as the carapace.

The Crustaceans of this group are for the most part essentially swimmers, and live often out at sea. They are vulgarly called Paddlers. The following genera are arranged under the tribe by M. Milne-Edwards:—

Carcinus (Leach).—Carapace approaching in general form that of *Panopeus*, but little convex, although sufficiently elevated, and remarkably wider than it is long. The latero-anterior borders, which are deeply dentated, form with the orbital border a regular curvature, which does not reach beyond the level of the middle of the genital region; latero-posterior borders very long and moderately oblique. The branchial regions very much developed and rounded anteriorly. Front advanced, horizontal, of moderate width. Orbits oval and directed forwards; there is a fissure at their upper border and one at their lower border; the gap at their internal angle lodges the base of the external antenna, the first joint of which is narrow and cylindrical, and reaches to the front; their moveable stem is very long, and inserted in the orbital gap. The internal antennæ are bent back in

their nearly circular fossæ obliquely outwards. The buccal frame is a little wider backwards than it is in front, and the third joint of the jaw-feet is much dilated externally, and notched at its two internal angles. The sternal plastron is similar to that of the *Portuni*, and so would be the feet, if it were not that the tarsus of the posterior feet is not much enlarged, and is of a flattened lanceolate form, though narrow, whilst that of the preceding feet is styliform. The abdomen of the male is only composed of five segments. (Milne-Edwards.)

C. Menas (*Cancer Menas* of authors; Crabe Euragé of the inhabitants of the coast of Normandy), the small Common Crab hawked about London and eaten by the poorer classes. Length rather more than two inches.

Feet of *Carcinus*.

This species is very common on the coasts of England and France, where it is found at low tide between stones and buried in the sand. This species runs on the beach with rapidity, and can sustain a long absence from the water. It is edible, though not much used as an article of food in England; but during the summer a great many are brought to Paris. Colour dirty green; red when boiled.

Platyonchus (Latreille).—Carapace narrower and more regularly convex than that of the other Portunians, often much longer than it is wide, and sometimes circular. Front very narrow and dentated. Latero-anterior borders a little curved and directed backwards, and like those of the *Carcini*, the *Polybii*, and the greater portion of the *Portuni*, divided into five teeth. Orbits not deep, and directed forwards. Internal antennæ bent back obliquely forwards, with their fossæ very imperfectly separated from the orbita. Disposition of the external antennæ different from that in the *Carcini*, the *Portuni*, the *Thalamidæ*, and the *Lupeæ*; their first joint, which is very small, is not soldered to the front, but is moveable, like the succeeding ones, and is inserted between the lower orbital border and the antennary fossæ.

M. Milne-Edwards divides the genus into the following sections and subsections:—

a. Species having the frontal teeth unequal in number, one of them occupying the median line, and a single fissure at the superior orbital border.

aa. Tarsi of the posterior feet of lanceolate form.

P. latipes (*Cancer latipes*, Penn.; *Portunus variegatus*, Leach, 'Malac'; *Platyonchus depurator*, Latreille). Length about an inch. It is a native of the coasts of England and France. [PORTUNUS.]

aa. Tarsi of the posterior feet oval and obtuse at the end.

P. ocellatus (*Cancer ocellatus*, Herbat; *Portunus pictus*, Say; *Platyonchus ocellatus*, Latreille). Length about two inches.

B. Species having the frontal teeth equal, and consequently not one on the median line, and two fissures at the superior orbital border.

P. bipustulatus. Length from two to five inches. It is found in the Indian Ocean.

Platyonchus bipustulatus.

7. Species having the front advanced in form of a triangular muzzle, and simply undulated on its borders.

P. nanus (*Portunus biguttatus*, Risso, 'Cruet. Nice'), very small. It is found on the coasts of the Mediterranean.

Polybius (Leach).—Very nearly allied to *Platyonchus*, from which it hardly differs, except in the form of the feet, which are all natatory; those of the second, third, and fourth pairs are very much flattened, and terminated by a very large and lanceolate joint, which has the same form throughout. The posterior feet have the same form as

those of *Platyonchus bipustulatus*, excepting that their third joint is extremely short and nearly globular. The sternal plastron is wider, especially posteriorly, than in *Platyonchus*, but presents the same disposition as to the median suture. The abdomen of the male has the ordinary number (five) of joints. (Milne-Edwards.)

P. Henslowii. Length about two inches; colour brown. It is found in the British Channel, where it appears to haunt at a distance from the coast.

Polybius Henslowii.

Portunus (Fabr.).—Carapace nearly of the same form as in *Carcinus*, wider than it is long, but with its longitudinal diameter at least equal to two-thirds of its transversal diameter, and the contour of its anterior portion ordinarily more curved than it is in that genus. The fronto-orbital border occupies hardly more than the half of the transversal diameter of the carapace, and the front, which is narrow, advances always much beyond the insertion of the external antennæ, and reaches in a remarkable manner beyond the level of the inferior border of the orbit, and the external angle of this cavity. The latero-anterior border of the carapace is delicate, and armed with four or five large teeth; the orbits are oval. The antennary fossæ are placed on the same level with the eyes, are transversal, and are separated from each other by a partition, the border of which is never prolonged into the form of a spine. The basilar joint of the external antennæ is but little developed, but completely separates the antennary fossæ from the orbit, and is soldered to the front; the moveable stem which succeeds to this joint would seem to spring from the internal angle of the orbit. The structure of the mouth presents nothing remarkable, but it is to be borne in mind that the third joint of the external jaw-feet is at least as wide as it is long, and that its anterior and internal angle is much truncated.

The *Portuni*, though essentially aquatic and swimming with much ease, are not met with far out at sea like the *Lupeæ*. Their haunts are near the shore, and at spring-tides they are often found during the ebb hidden under stones, in the small pools of water left by the sea. Some species inhabit still greater depths, on oyster-beds, &c., and they are never seen to run, like the *Carcini*, on the shore. When withdrawn from the water, they perish in a few hours. They are eminently carnivorous, feeding mostly on the dead bodies of animals which they find in the sea. Many of the species are eatable, and all, with a single exception, inhabit the coasts of England and France. (Milne-Edwards.)

Milne-Edwards divides the species into the following sections and subsections.

a. Species having the front armed with very distinct teeth.

aa. Front armed with at least 10 teeth or spines.

P. puber (*Cancer puber*, Linn.; *Cancer retutus*, Penn.). Length about 2½ inches.

Portunus puber.

It is a native of the coasts of England and France. This is the Crabe à Laine, Crabe Espagnol, &c., of the French.

aa. Front armed with three or five teeth.

aa*. Carapace wrinkled, unequal, rather granulous, and covered with hair.

P. plicatus (*Cancer-Depurator*, var. Penn.; *Portunus Depurator*, Leach; *Portunus lividus* (var. ?), Leach, 'Malac.'). Length about 18 lines. Colour reddish. Found on the coasts of England and France.

aa**. Carapace nearly united, and without hairs.

P. marmoreus (*Cancer Depurator*, Pennant). Found on the coasts of England and France. The last joint of the posterior feet in this species terminates in a point.

B. Species having the front entire or divided only into rounded lobes.

b. Latero-anterior borders of the carapace armed with five teeth.

b*. Front divided into three lobes, of which the median lobe is more advanced than the lateral lobes.

P. corrugatus (*Cancer corrugatus*, Penn.; *Portunus puber*, Blainv.). Length about two inches. Colour reddish. Found on the coasts of England and France; very common in the Mediterranean.

b**. Front entire, or divided only into two symmetrical lobes.

bb. Latero-anterior borders of the carapace armed with four teeth only.

P. integrifrons (*Cancer Navigator* (?), Herbst.). Carapace pubescent. Length about two inches. It is a native of the Indian Ocean.

Lupea (Leach).—The greater part of the *Lupeæ* are remarkable for the flatness and great transversal extent of their carapace, the diameter of which in that direction is more than double its length. Front nearly always narrow, and much less projecting than the lower border or external angle of the orbit; the latero-anterior border of the carapace very long, forming generally, with the anterior border, a very regular and open segment of a circle, and each of them armed with nine teeth, more or less projecting and spiniform; of these spines the last is in general much greater than all the others, and is directed straight outwards, though sometimes it does not differ from that which precedes it. Orbits oval, and directed obliquely forwards and upwards; their lower wall does not reach to the front, and there is, at the internal canthus, a large notch, which the basilar joint of the external antennæ fills; at the upper border of these cavities are two fissures. The fossæ which lodge the internal antennæ are not deep, and hardly covered by the front; the vertical lamina which separates them is armed with a spiniform point, which is often prolonged beyond the anterior border of the carapace. Externally, these cavities are completely separated from the orbits, and the stem of the antennæ, which are there inserted, is sufficiently short to be bent back there entirely. The basilar joint of the external antennæ is soldered to the inferior border of the superior and external angle of the front; it is not wide, and gives insertion, by the extremity of its internal border, to the moveable stem formed by the succeeding joints, so that this stem, the length of which is considerable, would seem to spring from the internal canthus of the eye, and nothing prevents its being bent backward outwards to conceal itself in the orbital cavity. The epistome is extremely narrow, and the buccal frame is very nearly square, but in general wider forwards than it is behind. The third joint of the external jaw-feet is rather abruptly truncated forwards and inwards.

Lupea.

The *Lupeæ* are Pelagic Crustaceans, living in the ocean, where they have been seen by many voyagers, and where they have no other apparent place of repose than the floating *Fuci*. Their swimming

powers are great, and Bosc remarked that they have the faculty of sustaining themselves at the surface of the water, in a state of repose, without the execution of any visible movement.

This genus is divided by M. Milne-Edwards, who gives the above summary of their habits, into the three following groups:—

A.A. Species with the body very thick and convex above; first pair of feet stout, and not much elongated; the hand considerably shorter than the carapace.

Convex *Lupeæ*.

L. Tranquebarica (*Cancer olivaceus*, Herbst; *Cancer serratus* (?) Forsk.; *Portunus serratus*, Rüpp.; *Portunus Tranquebaricus*, Fahr.) This, the largest Portunian known, is six or eight inches in length, of a grayish green, and inhabits the seas of Asia.

A. Species having the body very much compressed; the first pair of feet stout, and but little elongated; the hand remarkably shorter than the carapace. Tarsi of the second, third, and fourth pairs flattened, lamellar, and nearly lanceolate.

Swimming *Lupeæ*. (Second sub-genus.)

* Species having the last lateral spine at least twice as large as the preceding, and the front projecting but little.

a. Median teeth of the front projecting but little, and sometimes hardly visible.

a*. Upper border of the orbit armed with a spine.

L. pelagica (*Cancer pelagicus*, Linn.; *Cancer reticulatus* and *Cancer Cedo Nulli*, Herbst; *Portunus pelagicus*, Fahr.) Length from three to four inches. Colour grayish-green with yellow spots. Found in the Red Sea and the whole Indian Ocean.

Lupea pelagica.

a**. Upper border of the orbit without any spiniform prolongation.

L. sanguinolenta (*Cancer sanguinolentus*, Herbst; *Cancer pelagicus*, var. and *Portunus sanguinolentus*, Fahr.). Length about two inches. Carapace with three large bright red spots on the back part of the carapace. Found in the Indian Ocean.

***. Median teeth of the front small, but projecting.

L. cribraria (*Portunus cribrarius*, Lam.). Length three inches. Colour yellow, with numerous whitish spots. It is a native of the coasts of Brazil.

B. Species having the last spine of the latero-anterior border of the carapace scarcely longer than the others.

b. External border of the arm without spines.

L. spinimana (*Portunus pelagicus* and *Portunus spinimanus*, Latr.). Length from three to four inches. Found on the coasts of Brazil.

bb. External border of the arms spined.

L. lobifrons. Length one inch. It is a native of the East Indies.

C. Tarsi of the second, third, and fourth pair of feet narrow and styliform.

Walking *Lupeæ*. (Third sub-genus)

a. Species having the last tooth of the latero-anterior border of the carapace resembling the others.

a. Teeth of the latero-anterior borders alternately large and small.

L. rubra (*Ciri apoa*, Marc.; *Portunus ruber*, Lam.). Length about two inches. General colour reddish; extremity of the claws black. Found on the coasts of Brazil.

a*. Teeth of the latero-anterior borders of the carapace resembling each other.

L. granulata. Length about an inch. Found in the Mauritius.

a. Species with the last tooth of the latero-anterior border of the carapace at least twice as large as the preceding.

b. Median teeth of the front much more projecting than the lateral teeth.

L. Seba (*Cancer marinus scutiformis*, Seba, 'Mus.' iii., pl. 20, f. 9, copied by Latreille, in 'Encycl.', pl. 272, f. 6, under the name of *Portunus sanguinolentus*). Size about the same as *L. granulata*. A native of the coasts of Brazil. (Milne-Edwards.)

bb. Median teeth of the front less projecting than the others.

bb°. Hands large, of the ordinary form, and shorter than the transversal diameter of the carapace.

L. hastata (*Cancer hastatus*, Linn.; *Portunus hastatus*, Latr.; *Lupa Dufourii*, Desm.). Length about two inches. It is a native of the Mediterranean.

bb°. Hands filiform and of great length, being nearly one and a half the transversal diameter of the carapace.

L. Forceps (*Lupa Forceps*, Leach; *Portunus Forceps*, Latr.). Length about an inch. It is a native of the Antilles.

Lupa Forceps.

Thalamita (Latr.).—Carapace in most of the species characteristic; but in some it gradually approximates to that of the *Lupæ*; in fact, sometimes it has the form of an elongated square; its transversal diameter is nearly double the length, and its fronto-orbital border forms with the latero-anterior borders a nearly right angle; in other cases it is nearly hexagonal, its six borders form nearly equal angles, and its width only exceeds about half of its length. The front is always very wide, projecting, and at least as much advanced as the inferior border and external angle of the orbit, a disposition which is never observable in the *Lupæ*. The latero-anterior borders of the carapace are more or less oblique, but always form with the fronto-orbital border a very strong marked angle, where there are from four to seven teeth, the last of which is never remarkably larger than the others. The eyes are stout and short; the orbits oval, and completely separated from the antennary fossæ; the upper border of the latter presents two small fissures, and their angle is often nearly as distant from the median line as the angle which terminates behind the latero-anterior border. The internal antennæ bend back completely in their fossæ, and the inter-antennary partition projects but little. The basiliary joint of the external antennæ is in general very wide, and always soldered to the front throughout the whole extent of its anterior border, presenting externally a more or less considerable projection which separates the orbit from the point of articulation of the movable stem of those appendages, and which is very long, and inserted sometimes very far from the orbital cavity. The epistome is very distinct and of a lozenge-shape.

M. Milne-Edwards divides the genus into the following sections:—

1. Fronto-orbital border not occupying more than two-thirds of the width of the carapace, and forming a rather open angle with the latero-anterior borders, which are armed with six or seven teeth.

Hexagonal *Thalamita*.

2. Fronto-orbital border occupying nearly the whole width of the carapace, and forming a nearly right angle with the latero-anterior borders, which are armed with four or five teeth.

Quadrilateral *Thalamita*.

The latter form the first sub-genus in M. Milne-Edwards's arrangement.

a. Species having the front entire or divided into lobes, but with no teeth.

T. Chaptalii (*Portunus Chaptalii*, Aud., 'Crust. Sav. Egypte.'). Length about an inch. It is a native of the Red Sea.

Thalamita Chaptalii.

b. Species whose front is armed with deeply cut and flattened teeth. *T. crenata* (*Portunus crenatus*, Latr.; *Thalamita Admete*, Guérin 'Icon. Cr.', pl. 1, f. 4).

2nd Sub-Genus. Hexagonal *Thalamita*.

a. Species having the latero-anterior border of the carapace armed with six teeth.

a. Last lateral tooth nearly the same size as the preceding.

a°. Anterior feet armed with spines, but without elevated granulations.

T. crucifera (*Portunus cruciferus*, Fabr. and Latr.; *Cancer sexdentatus*, Herbst?). Length from three to four inches; colour reddish with yellow spots and bands, the median markings resembling a cross. Found in the Indian Ocean.

Thalamita crucifera.

a°. Anterior feet presenting between the spines with which they are armed, a great number of tubercles or elevated granulations.

T. Natalor (*Cancer Natalor*, Herbst; *Portunus sanguinolentus* Bonc.). Found in the Indian Ocean.

Thalamita Natalor.

aa. Last lateral tooth stouter and much more projecting than the others.

T. Callianassa (*Cancer Callianassa*, Herbst). Length about an inch. Found in the Indian Ocean.

b. Species having the latero-anterior border of the carapace armed with seven teeth, two of which are rudimentary.

T. erythrodactyla (*Portunus erythrodactylus*, Lam.). Length 2½ inches. Found in Australasia.

Podophthalmus (Lam.).—M. Milne-Edwards justly observes, that of all the Portunians the *Podophthalmi* have the most remarkable aspect, and characters the most easy to seize. The enormous length of their ocular peduncles, which are very short in the other Swimming *Brachyura*, is sufficient to distinguish them at first sight.

Eye, Orbit, Jaw-Foot, &c. of *Podophthalmus*.

The eyes are carried on delicate peduncles of extreme length; and these osseous stems are inserted near the median line of the front, and carry at their extremity the second ocular piece, whilst in the Ocypodians, where the eyes are also very much developed, it is on the development of this second piece, and not the first, that the length depends. The ocular bulb is not very large, and reaches the lateral extremity of the carapace. The internal antennæ are situated below the origin of the eyes, a disposition which is met with in no other Portunian, and their stem cannot bend itself back into the cavity where they are lodged. The external antennæ are also below the eyes; they are placed between the antennary fossets and the orbits, at the external side of the first, and their basilar joint is soldered with the borders of these two cavities, so as to complete their walls and to separate them from each other; the moveable stem which terminates these antennæ is formed of two small peduncular joints and of a slender and rather short multiarticulate filament.

P. vigil (*Portunus vigil*, Fahr.; *Podophthalmus spinosus*, Lam.). The only species known. Length from two to four inches. Found in the Indian Ocean.

Podophthalmus vigil.

POSIDONIA. [MALLEACEA.]

POSIDONOMY'A. [MALLEACEA.]

PO'SYDON, a genus of Crustacea.

POTADO'MA (Swainson), a sub-genus of Fluvialile Shells, belonging to the genus *Melania*, and the sub-family *Melaniaceæ*, and the family *Turridæ*.

POTAMIANS. [CHELONIA.]

POTAMIS, a genus of Fresh-Water Shells.

POTAMO'BIA (Leach), a genus of Crustacea.

POTAMO'GETON (from ποταμός, a river, and the termination γετον, which probably means 'produced'), a genus of Plants belonging to the Endogenous class, and the natural order *Potamoceæ*. It has a perfect flower; a 4-parted perianth, 4 sessile anthers opposite to the divisions of the perianth, 4 ovaries, and 4 drupes or nuts. The species are water-plants.

P. natans is a British plant, with floating ovate stalked leaves, the petioles plano-concave above, the nuts large, rounded on the back when fresh, keeled; when dry the peduncles are equal. There is a creeping rhizoma at the bottom of the water. The roots are sometimes eaten in the wilds of Siberia by men, but in more temperate regions are fed on only by swans, who devour them with avidity.

P. crispus has a compressed stem, pellucid ohlong linear leaves, sessile and wavy, the nuts with long beaks, keeled on the back; when dry the peduncles are equal. It is a native of Great Britain.

P. densus has its leaves all opposite, pellucid, clasping, elliptical-lanceolate, or lanceolate; the spikes shortly stalked, ultimately reflexed; the spike is 4-flowered. It is found in ditches and ponds of water in England. Ducks feed on the seeds and leaves of both these species, but they serve a more important purpose in giving out oxygen, and rendering the water respirable for fish and other aquatic animals. There are twenty British species of *Potamogeton*, and Haller says that in the Swiss lakes *P. serratum* grows to the length of from 10 to 20 fathoms, forming extensive sub-aquatic forests.

(Burnett, *Outlines of Botany*; Babington, *Manual of British Botany*.)

POTAMOMY'A, a genus of Fresh-Water Shells.

POTAMOMY'A, a genus of Fossil *Conchifera*.

POTAMON (Savigny), a genus of Crustacea.

POTAMO'PHILA (Sowerby), a genus of *Conchifera*.

POTAMO'PHILUS (Latreille), a genus of Crustacea.

POTASH. [POTASSIUM.]

POTASSIUM, a Metal, the base of the alkali Potash, in which it exists, combined with Oxygen. Potash is in fact an oxide of potassium. On account of its intense affinity for oxygen, potassium is not found pure in nature. In a mineral form it occurs in a great number of minerals. It is present in considerable quantities in Mica [ΜΙΟΛΑ] and Felspar [FELSPAR], which enter, with quartz, into the composition of granite. Its most abundant form in nature is what is called Nitre.

Nitre is a nitrate of potash, and occurs in modified right rhombic prisms; usually in thin white subtransparent crusts, and in needleform crystals on old walls and in caverns. Its taste is saline and cooling. It has the following composition:—

Potassa	46.56
Nitric Acid	53.44

—100

It burns vividly on a live coal. It is distinguished readily by its taste; and from nitrate of soda, which it most resembles, by its not becoming liquid on exposure to the air.

Nitre, called also Saltpetre, is employed in making gunpowder, forming 75 to 78 per cent. in shooting powder, and 65 per cent. in mining powder. The other materials are sulphur (12 to 15 per cent.), and charcoal (9 to 12½ per cent. for shooting, and 20 per cent. for mining powder). It is also extensively used in the manufacture of nitric and sulphuric acids; also for pyrotechnic purposes, fulminating powders, and sparingly in medicine. [NITRE, in ARTS AND SC. DIV.]

It occurs in many of the caverns of Kentucky and other Western States of America, scattered through the earth that forms the floor of the cave. In procuring it the earth is lixiviated, and the lye, when evaporated, yields the saltpetre. India is its most abundant locality, where it is obtained largely for exportation. It readily dissolves in water, lowering its temperature, and is used in India as a frigorifico agent.

Spain and Egypt also afford large quantities of nitre for commerce. This salt forms on the ground in the hot weather succeeding copious rains, and appears in silky tufts or efflorescences; these are crushed up by a kind of hroom, lixiviated, and after settling, evaporated and crystallised. In France, Germany, Sweden, Hungary, and other countries, there are artificial arrangements called 'nitrieries,' or nitre-beds, from which nitre is obtained by the decomposition mostly of the nitrates of lime and magnesia which form in these beds. Refuse animal and vegetable matter putrified in contact with calcareous soils produces nitrate of lime, which affords the nitre by reaction with carbonate of potash. Old plaster lixiviated affords about 5 per cent. This process was employed extensively in France, when the French were prevented from obtaining nitre from foreign sources during the last war with England. Nitre is also employed in the manufacture of glass, and a large consumption of it takes place in this country for this purpose.

Carbonate of Potash is obtained from the ashes of land plants, just as carbonate of soda is obtained from the ashes of sea-shore plants and sea-weeds. When the ashes are purified they form first the potash of commerce, and when further purified, pearlsh.

Sylvine is a chloride of Potassium, which has been found as a mineral. For the further compounds of Potassium, see POTASSIUM, in ARTS AND SC. DIV.

(Dana, *Manual of Mineralogy*.)

POTATO. [SOLANUM.]

POTATO, SWEET. [BATATAS.]

POTENTILLA ('potens,' powerful, from the supposed medicinal qualities of some of the species), a genus of Plants belonging to the natural order *Rosaceæ*. It has a concave calyx, 4-5-parted, with 4-5 bractlets; there are 4-5 petals, numerous stamens, a lateral or nearly terminal style. The fruit consists of numerous small nuts placed on a flattish dry receptacle; the seeds pendulous or ascending, the radicle superior; the flowers white or yellow, rarely red.

P. reptans, Creeping Cinquefoil, is a common British species: it is found likewise in other parts of Europe. The stem is filiform, procumbent, and creeping; the leaves quinate and stalked; the leaflets ohovate, serrated; the peduncles solitary; carpels granulate, scabrous. The flowers are large, bright yellow, and on long hairy axillary stalks.

It appears to have been the official plant of the ancients, and is the *Περδύλλον* of Theophrastus, lx. 19, and of Dioscorides, lv. 42. Pliny mentions it as *Quinquifolium*, 25, 9; 27, 10. It is still used as a febrifuge by some practitioners.

P. Tormentilla has a procumbent or ascending stem, ternate sessile leaves, and longitudinally wrinkled carpels; the leaflets are acute and somewhat hairy. The flowers are bright-yellow, small, with the parts of the calyx and corolla in fours on slender hairy stalks much longer than the leaves. It is the *Tormentilla erecta* of Linnaeus. It abounds in Great Britain. The roots are very astringent, and have been used medicinally. In the Western Isles of Scotland and the Orkneys they are used for tanning leather, and are preferred even to oak-bark. They are also used for dyeing a red colour. We are told that pigs are fed on them in Killarney, and they are also thought to be serviceable in some diseases to which sheep are subject.

P. asserina has a creeping stem, interruptedly pinnate leaves; the leaflets numerous, oblong, acutely serrate, silky beneath; the peduncles solitary. The flowers are large and yellow, and the leaves form a favourite food with geese: they are sometimes used as pot-herbs. Its roots are eaten both by hogs and men; they taste like a parsnep, but are small; the common people roast or boil them for food. In the islands of Tiray and Col they answer in some measure the purposes of bread, and have been known to support the inhabitants for months together during a time of scarcity.

The leaves of *P. fruticosa* and *P. rupestris* are employed in Siberia as a substitute for tea.

P. hirta has a pilose erect few-flowered stem; the leaves with 5-7 leaflets, pilose, and cut at the apex; the stipules lanceolate, entire; the petals obcordate, longer than the calyx. It is native of the Pyrenees, South of France, Silesia, &c., and is the *Περδύλλον* of Hippocrates. ('Ulc.' 880.)

(Lindley, *Vegetable Kingdom*; Lindley, *Flora Medica*; Bahington, *Manual of British Botany*; Burnett, *Outlines of Botany*; Fraas, *Synopsis Floræ Classicæ*.)

POTERIUM (from *porchēos*, a drinking-vessel, or cup, one of the species being infused in drink), a genus of Plants belonging to the natural order *Rosaceæ*. It has monocious or polygamous flowers; a 4-cleft calyx, with three external scales at its base; and a quadrangular tube. The petals are wanting, the style terminal, stamens numerous, and the seed suspended.

P. sanguisorba, Lesser Burnet, is an herbaceous plant, with a slightly angular stem, the calyx of the fruit quadrangular and hardened. The leaves are pinnate, with numerous small ovate coarsely serrate leaflets, glabrous or slightly hairy beneath. It is found on dry calcareous soils in Great Britain. It forms a useful fodder for cattle, and at one time was extensively cultivated for that purpose, but is now generally superseded by Sainfoin and other artificial grasses. On the continent, and occasionally in this country, the young leaves are eaten as salad, and it is said to form one of the ingredients of the favourite cool tankard. It is said to give the name to the species, from the custom of infusing it in liquor. The common people of Siberia eat the roots. There are about nine species of Burnet described, which are distributed over Europe, Africa, and America.

(Lindley, *Vegetable Kingdom*; Bahington, *Manual of British Botany*; Burnett, *Outlines of Botany*.)

POTEROCRINITES. [ENCINITES.]

POTSTONE. [TALC.]

POTTO. [VIVERRIDÆ.]

POULTRY. [PHASIANIDÆ.]

PRÆFEDITUS. [SCINCOIDÆ.]

PRANGOS, a genus of Plants of the natural family of *Umbelliferae*, tribe *Smyrnea*, so named by Dr. Lindley from the name by which the only species is known in its Tartarian habitat, where it was discovered by Mr. Moorcroft, in the neighbourhood of Imbal or Druz, and which he visited for the purpose of examining into the reputed qualities of this plant, of which the accounts seemed to border on exaggeration. Almost all the knowledge which we possess respecting the plant, is derived from the observations of that lamented and enterprising traveller.

The Prangos Hay-Plant is herbaceous and perennial, having a large fleshy root-stalk, usually measuring at the top from 18 to 22 inches in circumference, and formed by the aggregation of an infinite number of crowns or winter-buds, clustered together at or above the surface of the ground. These crowns being closely covered by the fibrous remains of the old leaves, are thus protected from the frosts of winter. The crop consists of the leaves, which rise in abundance from each crown, are finely cut, about two feet in length, and have a highly fragrant smell, extremely similar to that of very good new clover hay.

This Mr. Moorcroft considered as a most important and interesting object of rural economy, and says that the properties of Prangos as a food appear to be heating, producing fatness in a space of time singularly short; it is also destructive to the *Fasciola hepatica*, or Liver-Fluke, which in Britain, after a wet autumn, destroys some thousands of sheep by the rot. The last-mentioned property, of itself, if it be retained by the plant in Britain, would render it especially valuable to our country. But this, taken along with its highly nutritious qualities, its vast yield, its easy culture, its great duration, its capability of flourishing on land of the most inferior quality and

wholly inadapted to tillage, impart to it a general character of probable utility unrivalled in the history of agricultural productions. When once in possession of the ground, for which the preparation is easy, it requires no subsequent ploughing, weeding, manuring, or other operation, save that of cutting and of converting the foliage into hay. Of its duration he relates that its seeds, having been carried westward along with those of yellow lucerne, above 40 years ago, and sown on the eastern frontier of Cashmere, vegetated, and that the plants of the first growth still remain in a flourishing condition. He conceived that by the cultivation of this plant, moors and wastes hitherto uncultivated may be made to produce large quantities of winter fodder, and that the yield of high lands and downs enjoying a considerable depth of soil may be trebled.

Dr. Falconer, in his visit to Cashmere and Tibet, found it in the latter, as well as on a low trap hill in the former, but not so vigorous in the Cashmerian as in its Tibetan habitat. He states that though abundant in various directions, the Cashmerians do not esteem it of any value.

Arrian, in describing Alexander's expedition across the mountains which he calls Caucasus and Paropamisus (iii. 28), says, nothing but *Silphium* and the Turpentine-Tree grow there, notwithstanding which it is very populous, and multitudes of sheep and neat cattle are seen, for they feed upon *Silphium*, of which the sheep especially are very fond. This bears so close a resemblance to the *Prangos*, both in locality and properties, that it is as likely to have been the *Silphium* of the ancients, as the assafoetida plant, which it is supposed to be by others. [SILPHIUM.]

PRANI'ZA. [ISOPODA.]

PRASE. [QUARTZ.]

PRASEOLITE, an imperfectly crystallised Mineral, occurring in prisms of several sides, with the edges rounded. Cleavage in one direction. Colour light or dark green; streak clear green. Fracture splintery and flat conchoidal. Hardness 3.5. Lustre weak. Specific gravity 2.754. It is found near Brevig, Norway. Its analysis by Erdmann gives—

Silica	40.94
Alumina	28.79
Protoxide of Iron	6.96
Protoxide of Manganese	0.82
Magnesia	13.73
Titanic Acid	0.40
Oxide of Lead, Copper, and Cobalt with Lime	0.50
Water	7.38

—99.02

PRASILITE, a Mineral, occurring massive. Composed of loosely adhering fibres. Colour dark leek-green. Hardness not sufficient to scratch selenite, and may be crumbled to powder between the fingers. Specific gravity 2.311. It is found on the Kilpatrick Hills. Its analysis, by Dr. Thomson, gives—

Silica	38.55
Magnesia	15.55
Peroxide of Iron	14.90
Alumina	5.65
Lime	2.55
Oxide of Manganese	1.50
Water	18.00

—96.7

The loss, amounting to 8 per cent., is attributed to an alkali.

PRATICOLA. [SYLVIADÆ.]

PRATINCOLA. [CHARADRIADÆ.]

PRAWN. [PALEMONIDÆ.]

PREHNITE, a Mineral, which occurs crystallised and massive. Primary form a right rhombic prism. Cleavage easy, parallel to the base of the primary form, and less so in the direction of the lateral faces. Fracture uneven. Hardness, scratches glass easily. Becomes electric by heat. Colour white, gray, and various shades of green and greenish-yellow. Lustre vitreous. Transparent, translucent. Specific gravity, 2.926. The variety which occurs in small thin crystals is called *Koupholite*. The crystals of this substance have a remarkable tendency to exhibit rounded faces.

Massive varieties botryoidal, globular, and stalactitic, structure broad fibrous; amorphous, structure granular, compact, with rough surfaces. It occurs also in rolled masses.

Before the blow-pipe it is converted into a white scoria, and fuses into a compact globule; with borax it readily becomes a clear glass.

This mineral was first found at the Cape of Good Hope; it has since been met with in many places in different quarters of the globe, as Scotland, Cornwall, France, &c. Koupholite occurs at Barèges in the department of Hautes-Pyrénées. It is composed of silica, alumina, lime, oxide of iron, potash, soda, and water.

The following forms of *Prehnite* are given by Dana:—

Stellite. In fibrous stellar groups like mesole; lustre silky and shining. It fuses to a white enamel. Gelatinizes with muriatic acid. It comes from Killarney, Scotland.

Antrimolite. A stalactitic zeolite, from Antrim, Ireland.

Diphanite. In six-sided prisms with a distinct basal cleavage; vitreous lustre, transparent. A silicate of alumina and lime, and near prehnite. From the Ural, with emerald.

Hydrous Anthophyllite. In divergent fibres having a silky lustre. Colour white, greenish-yellow, or bluish. Occurs in a talcose rock at Fishkill, New York, and also above New York city.

Zeuxite. A hydrous silicate of alumina and iron, in small brown prismatic crystals, of a vitreous lustre. From Cornwall, in the Huel Unity mine.

Damourite. Occurs in lamellar pearly crystals, a little harder than talc. It is a hydrous silicate of alumina and potash. Reported from Leipsville, Pennsylvania, and Chesterfield, Massachusetts.

Masonite. Near chloritoid; coarsely foliated or tabular; colour dark gray. Lustre nearly pearly; folia brittle and often curved. Fuses with difficulty on the edges. From the vicinity of Natic village, Rhode Island.

Other forms of *Prehnite* will be found mentioned under *EPISTILBITE*; *EDINGTONITE*; *CARPHOLITE*; *FAUJASITE*; *GLOTTALITE*; and *CHLORITOID*.

PREMNA, a genus of Plants of the natural family of *Verbenaceæ*, which is characterised by a cup-shaped calyx, a 5-cleft bilabiate corolla. Stamens 4, didynamous. Drupe pea-shaped, with a 4-celled nut. The species consist of shrubs and small trees, which are indigenous in Asia and Australia, having opposite leaves, inflorescence in terminal cymes, with small flowers.

The majority of the species are remarkable for the fetid odour of their leaves; though those of *P. cordifolia* are somewhat fragrant, and those of *P. esculenta* are employed as diet by the natives of Chittagong, *P. integrifolia* has roots of a burning taste, with leaves of a hircine odour. The leaves, applied to the head, are said to cure headache, and a decoction of the roots is employed as a stimulant in fevers, flatulence, &c. *P. latifolia* has wood of a white colour and firm texture, employed for various economical purposes, in which it agrees in character with the teak tree, *Gmelina arborea*, and others which belong to the same natural family.

PRENANTHES, a genus of Plants belonging to the natural order *Compositæ*. Its only British representative is the *Lactuca muralis*, the *P. muralis* of Smith. [*LACTUCA*.]

PRIMATES, the name given by Linnæus to the first order of *Mammalia*, and thus characterised by him:—*Deutea primores incisores, superiores lv., paralleli. Mammæ pectorales ii.*

The order contains the following genera:—

Homo, of which Linnæus records two species, namely, *H. sapiens* and its varieties (Man), and *H. Troglodytes* (*H. sylvestris*, Orang Outang, Bout.).

Simia, 33 species.

Lemur (including *Lemur volans*). [*PLEUROPTERA*.]

Vespertilio, 6 species. [*CHEIROPTERA*; *MAMMALOGY*.]

PRIMNOA. [*POLYPIFERA*.]

PRIMULA, a genus of Plants belonging to the natural order *Primulaceæ*. It has a tubular 5-cleft calyx, a salver-shaped regular corolla, as long as the calyx, or longer; a spreading limb in five rather deep inversely heart-shaped obtuse segments; a free 1-celled ovary, with a free central placenta. It has a capitate stigma and one style. The fruit is a capsule with numerous roundish seeds.

P. vulgaris, the Primrose, is one of our commonest British plants. It has oblong, ovate, wrinkled crenate leaves; single flowered scapes and a tubular calyx; linear, lanceolate, attenuated teeth, very acute; the limb of the corolla flat. It is found in woods and thickets, and is one of the earliest of our spring flowers.

P. elatior, the Ox-Lip, has ovate leaves contracted below, wrinkled and denticulate, many-flower umbellate scapes, a tubular calyx; lanceolate acute teeth; the limb of the corolla concave, with cordate ovate segments; nodding flowers and erect fruit. It is found in woods and meadows, but rarely in England. The *Polyanthus* is a variety of this species.

P. veris, the Cowslip, has ovate wrinkled crenate leaves, contracted below, many-flowered umbellate scapes; a bell-shaped calyx, rather downy, with short ovate teeth; the limb of the corolla concave, or cup-shaped, of a deeper yellow on the upper side, with five orange spots. It is found plentifully in meadows and pastures in England. The flowers possess a well-marked sedative and diaphoretic qualities, and make a pleasant soporific wine. The fresh root has also a smell resembling anise, and was formerly employed as a tonic medicine and also as a diuretic.

P. farinosa is distinguished by its mealy obovate lanceolate leaves, oblong ovate calyx, linear teeth, and obcordate segments rounded below, distant, and as long as the tube. It is found in the north of England and Scotland, and is called the Bird's-Eye Primrose.

P. Scotica is found only in the north of Scotland. It is known by its swollen calyx, with short ovate obtuse teeth; the limb of the corolla is flat, with broadly obcordate approximate segments half the length of the tube. The flowers are of a bluish purple colour with a yellow centre.

The leaves of *P. auricula* are used in the Alps as a remedy for coughs. Swine are the only animals that feed upon any of these species as their especial sustenance. They are valuable chiefly on account of their beautiful appearance and their early blossoming.

(Lindley, *Vegetable Kingdom*; Lindley, *Flora Medica*; Burnett, *Outlines of Botany*; Babington, *Manual of British Botany*.)

PRIMULACEÆ are Monopetalous Exogenous Plants, peculiarly

distinguished by the etamens being opposite to the lobes of the corolla, and a superior capsule with a free central placenta. In most respects they correspond with *Myrsinaceæ*, but the latter are known by their being trees or shrubs with an indehiscent fleshy fruit. The *Primulaceæ* consist of herbaceous plants inhabiting the temperate parts of the world, in moist situations, such as meadows, morasses, and alpine stations, or in the damp parts of woods, which they adorn with their lively flowers. The *Primula*, *Anagallis*, *Soldanella*, *Cyclamen*, and *Lysimachia*, of various species and under many forms, are the gayest of the genera, some of whose species are found in almost all gardens. The Cowslip is slightly narcotic, but the order is of no known utility. [*PRIMULA*; *ANAGALLIS*; *SOLDANELLA*; *CYCLAMEN*; *LYSIMACHIA*.]

PRINIA (Horsfield), a genus of Birds. It has the following generic character:—Bill rather lengthened, much compressed, entire; riotus smooth, wings rounded, tail broad and cuente; feet large, strong. (Swainson.)

P. familiaris may be taken as an example. It is the Prinia of the Javanese, Familiar Creeper of Latham.

It is abundant in many parts of Java, near villages and gardens, in the confines of which, among trees and shrubs, it builds its nest. It is a sprightly bird, sporting among the branches in short and rapid flights, and has received its native name from its lively and pleasant notes. (Horsfield.)

Familiar Creeper (*Prinia familiaris*).

Mr. Swainson ('Classification of Birds') thinks that *Prinia* may be a subordinate type or sub-genus of *Drymoica*. [*SYLVIADÆ*.] He observes that the *Priniae* have all the activity and familiarity of the true Wrens (*Troglodytes*), and so much resemble them in general appearance, in their short sweet song, and the throwing up of the tail, that it is not very surprising that they should have been classed with the Scansorial Creepers.

PRINOS. [*AQUIFOLIACEÆ*.]

PRINSEPIA, a genus of Plants of the natural family of *Chrysobalanaceæ*, so named by Dr. Royle in honour of James Prinsep, secretary of the Asiatic Society of Calcutta. The genus consists of only a single species, remarkable for its thorny appearance, but it may be considered typical of the labours of the individual whom it is designed to commemorate, as, early in the season, it is conspicuous for the abundance of its inflorescence, and, later, for that of the purple-coloured berries with which it is loaded. The seeds are large, and yield by expression an oil which is highly esteemed by the mountaineers of the Himalayas, where it is indigenous, and which by Europeans is thought a good substitute for salad oil.

PRIONDON. [*ARMADILLO*.]

PRION. [*PROCELLARIIDÆ*.]

PRIONITES. [*MONOTS*.]

PRIONODON, Dr. Horsfield's name for a feline form (*Felis gracilis*, Delundung of the Javanese), and placed by him in a separate section under the name of *Prionodontidae*, between *Felis* and *Viverra*. ('Zoological Researches in Java'.)

Mr. Swainson remarks ('Classification of Quadrupeds'), that of the genus *Prionodon*, at present, but one species has been found, in Java. As a familiar appellation, expressive, in all probability, of its analogy to the *Sorex*, he terms it the Shrew Cat.

Dental Formula:—Incisors, $\frac{6}{6}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{6-6} = 38$.

P. gracilis has the tail elongated, annulated, cylindrical; body pale flavescent, with four very wide dorsal bands and two narrow anal

Head, teeth, and feet of *Prionodon*.

Head two-thirds of natural size.

a, lateral view (external) of the teeth; b, lateral view (internal); c, front view; d, fore foot, covered with fur; e, hind foot, fur removed: these last figures about one-fourth larger than natural size. (Horsfield.)

bands; two broad lateral stric, the narrow cervical stric, the numerous humeral and femoral spots, and the seven caudal rings very deep brown. (Horsfield.)

*Prionodon praecilis*. (Hors., Java.)

Dr. Horsfield discovered this animal in 1806, during the early period of his researches in the district of Blambangan, situated at the extremity of Java; the natives distinguish it by the name above given. Dr. Horsfield was not able to ascertain that it is found in any other part of the island, or that it has another name; but he states that even in Blambangan it is rarely met with. He notices it as inhabiting the extensive forests which, with the exception of the capital of Banyuwangi and a few small villages, cover that district. He obtained but little information as to its habits and manners, and records nothing on the subject beyond what we have mentioned.

PRIONOPS. [LANIADÆ.]

PRISTACANTHUS, a genus of Fossil Placoid Fishes, from the Oolite of Stonesfield. (Agassiz.)

PRISTIDACTYLIS, the name assigned by Messrs. Duméril and Bibron to a group of *Cœlodonta*, being the second of their *Lézards Lacertiens* ou *Autosaures*. The Lacertiens of this group are those which have the toes either dentilated laterally or carinated on their inferior surface, or provided both with carinations below and dentulations along their edges. None of them have the temples covered with plates or large scales. In the greater part of the species the plates which surround the nostrils are more or less convex, the palpebral disc is nearly completely surrounded with a cordon of granules, and the ventral lamellæ, as well as the preanal scales, are smaller and more numerous than in the *Leiodactylous Cœlodonta*.

The following genera are arranged by Messrs. Duméril and Bibron under this group:—

Psammodromus, Fitz. (*Notophis*, *Aspistis*, Wagl., Bonap., Wiegman; *Psammodromus*, Wiegman.); *Ophiops*, Ménestrières (*Amystes*, Wiegman.); *Catosaura*, Dum. and Bibr.; *Acanthodactylus*, Fitz. (*Podarcis*, part, Wagl.); *Scapteira*, Fitz.; *Eremias*, Fitz. (*Podarcis*, part, Wagl.).

PRISTIS. Three species of this genus of Fishes are mentioned as fossil in the tertiary strata of England. (Morris's 'Catalogue.')

PRIVET. [LIGUSTRUM.]

PROBOSCIDIANS. [PACHYDERMATA.]

PROBOSCIS-MONKEY. [NASALIS.]

PROCAPRA. [ANTILOPEÆ.]

PROCELLARIDÆ, a family of Oceanic Birds belonging to the order *Natatores*. They are well known to the seamen when far from land, and with which his superstition was once more husy than it is now; but even at the present day they are not unfrequently regarded as ominous, and many a hard-weather old quarter-master still looks upon 'Mother Carey's Chickens' as the harbingers of a storm.

Though zoologists have differed as to the genera to be included in this extraordinary group, they have been pretty well agreed as to the forms which should be congregated in it.

The genus *Procellaria* of Linnæus was formed by that great zoologist for the Petrels, and it is closely followed by his genus *Diomedea* (Albatrosses), between which and the Petrels there are many points of resemblance both in their structure and their pelagic habits. [DIOMEDEINÆ; LARIDÆ.]

Prince Bonaparte ('Geographical and Comparative List,' 1835) makes the *Procellariidæ* the thirty-fourth family of the birds, and places them between the *Laridæ* and the *Colymbidæ*. It includes the genera *Diomedea*, *Procellaria*, *Puffinus*, and *Thalassidroma*.

Mr. G. R. Gray ('List of the Genera of Birds,' 1840) makes the *Diomedeinæ* the first sub-family of the *Laridæ*. This sub-family comprehends the genera *Pelecanoides*, *Puffinus*, *Daption*, *Thalassidroma*, *Wagellus*, *Procellaria*, *Diomedea*, and *Prion*.

M. Temminck, in his 'Manuel' (2nd part, 1820), arranges all the Petrels under the generic name *Procellaria*, Linn., but divides them into the following sections:—

1. Petrels properly so-called, *P. glacialis*.
2. *P. Puffinus*, *P. Anglorum*, and *P. obscura*.
3. Swallow-like Petrels (*Pétrels Hirondelloes*), *P. Pelagica* and *P. Leachii*.

In the 4th part of his 'Manuel' (1840), Temminck admits the genera *Procellaria*, *Puffinus*, and *Thalassidroma*.

Pelecanoides (Lacépède), *Haladroma* of Illiger, *Puffinaria* of Lesson.—Bill enlarged, composed of many pieces soldered together, the edges smooth and re-entering; the upper demi-bill composed of two pieces, furnished with feathers at the base up to the nostrils, which are very open, forming an oval circle, the aperture of which is above, separated one from the other by a simple internal partition; this partition supports a slight ledge which divides each nasal fossa in half; the enlarged portion of the upper demi-bill goes beyond the lower mandible, and terminates at the contraction of the bill, which is narrow, convex, very much curved, and very robust. The lower mandible is formed equally of two soldered pieces; that of the edge is narrow, inserted in the upper demi-bill; that below is formed by two branches, slightly convex, separated outwards, where the space is filled by a very small and rather indistinct naked skin; the extremity of the mandible is convex on the edges, concave below, and sharp. First and second quills, which are the longest, equal; third and fourth rather shorter. Tail small, nearly equal, pointed, formed of twelve feathers. Tarsi moderate, weak, furnished with small areolated scutella; three anterior toes enveloped in an entire membrane; hind toe wanting. (Lesson.)

P. Urinatrix, the Blue Petrel. Size from the extremity of the bill to the tail, 8½ inches. The plumage has no brilliancy; a blackish-brown on the upper part of the back glazed with a slight tint of blue and a lustrous white on all the foreparts of the body, are the two colours which it presents. Beneath the wings, as well as on the sides, the hue is grayish-white.

The head approaches a little that of the Pelagic Petrel; the bill is articulated and hooked like that of the Puffins, but differs from that genus in the aperture of the nostrils, which is turned upwards in the form of a heart on a playing card; a partition separates the two nasal conduits; the colour is black; the palmated foot, which wants the hind toe, are of the same colour, and are placed very near the tail, which is intermediate between that of the Petrels and the Grebes. The eye,

which is situated a little above the level of the commissure of the mandibles, has the iris of a red-brown. Total length 8 inches 6 lines.

The Blue Petrel (*Pelecanoides Urinatrix*).

This species is found in great flocks along the coast of Peru, flying moderately well in a precipitous manner, and skimming the sea; but it prefers repose on the surface, and dives very frequently, like the Grebes, doubtless for the purpose of capturing the small fish which form its food. M. Garnot thinks that it is intermediate between the Petrels, whose bill and feet it very nearly possesses, and the Grebes, whose port and habit of diving it has; and hence he proposes for it the name of the Grebe-Petrel. The parts between Sangallan and Lima are the localities mentioned by M. Garnot.

Puffinus, Ray (*Thiellus*, Gloger; *Thalassidroma*, Sw.; and *Nectris*, Klug.)—General characters those of the true Petrels, from which *Puffinus* is distinguished by the bill being longer; by the extremity of the lower mandible, which follows the curvature of the upper; and by the tubular nostrils opening not by a common aperture, but by two distinct orifices.

P. Anglorum. This is the *Procellaria Puffinus* of Brunnich and Latham; *Puffinus Arcticus* of Faber; Der Nordische und Englische Sturmtaucher of Brehm; Pétrél Manks of Temminck; Pwffingen Fanaw of the Welsh; and Shearwater-Petrel, Manks-Puffin, and Manks Shearwater, of the English.

Summit of the head, nape, and all the upper parts of the body generally, the wings, the tail, the thighs, and the borders of the lower tail-coverts, of a lustrous black; all the lower parts of a pure white; the black and white of the sides of the neck are in demi-tints which produce a kind of crescents; bill blackish-brown; feet and toes brown, membranes yellowish. Length nearly 13 inches. Male and female. (Temminck.)

Shearwater-Petrel (*Puffinus Anglorum*).

In the fourth part of his 'Manuel,' M. Temminck observes that the natural colour of the feet being badly indicated, he gives it from Graba. The trenchant posterior border of the tarsi and the external toe are deep brown; the other parts of the tarsus are flesh-coloured, and the membranes of a livid tint with brown streaks. Iris deep brown.

Young of the Year.—All the lower parts of a more or less deep ash-colour.

Willughby says:—"At the south end of the Isle of Man lies a little islet, divided from Man by a narrow channel called the Calf of Man, on which are no habitations, but only a cottage or two lately built. This islet is full of conies, which the Puffins, coming yearly, dislodge, and build in their burroughs. They lay each but one egg before they sit, like the Razor-Bill and Guillem, although it be the common persuasion that they lay two at a time, of which the one is always addle. They feed their young ones wondrous fat. The old ones early in the morning, at break of day, leave their nests and young, and the island itself, and spend the whole day in fishing in the sea, never returning or once setting foot on the island before evening twilight; so that all day the island is so quiet and still from all noise as if there were not a bird about it. Whatever fish or other food they have gotten and swallowed in the day-time, by the innate heat or proper ferment of the stomach is (as they say) changed into a certain oily substance (or rather chyle), a good part whereof in the night-time they vomit up into the mouths of their young, which, being therewith nourished, grow extraordinarily fat. When they are come to their full growth, they who are intrusted by the lord of the island (the earl of Darby) draw

them out of the cony-holes; and that they may the more readily know and keep an account of the number they take, they cut off one foot and reserve it, which gave occasion to that fable that the Puffins are single-footed. They usually sell them for about ninepence the dozen, a very cheap rate. They say their flesh is permitted to be eaten in Lent, being for the taste so like to fish. We are told that they breed not only on the Calf of Man, but also on the Scilly Islands. Notwithstanding they are sold so cheap, yet some years there is thirty pounds made of the young Puffins taken in the Calf of Man, whence may be gathered what number of birds breed there." Speaking of the flesh, the same author says, that from its extraordinary fatness, it is esteemed unwholesome meat, unless it be well seasoned with salt. Pennant states that they are salted and barrelled, and when they are boiled, are eaten with potatoes. He further says that they quit the isle the latter end of August or beginning of September; and from accounts then lately received from navigators, he observes that he has reason to imagine that, like the Stormfinch, they are dispersed over the whole Atlantic Ocean. He says it inhabits also the Orkney Isles, where it makes its nest in holes in the earth near the shelves of the rocks and headlands; it is, he says, called there the Lyre, and is much valued, both on account of its serving as food and for its feathers. The inhabitants, he adds, take and salt them in August for winter provisions, when they boil them with cabbage; they also take the old ones in March; but they are then poor, and not so well tasted as the young, and he makes their first appearance to be in February.

Mr. Selby says, on the authority of Sir William Jardine, that they are no longer to be found on the Calf of Man.

Mr. Gould remarks that during the summer months it is nearly as abundant on the coasts of South Wales as it formerly was in the Calf of Man. Four dozens, apparently captured by hand, were sent to Mr. Gould from this locality, with an intimation that he could have as many more. It appeared from the information obtained by him, that the birds visit these localities for the purpose of incubation during the early part of the spring, when they resort to deserted rabbit-burrows, crevices of the rocks, &c., wherein they deposit their single white egg, and the birds then fall an easy prey to the fishermen and others. He further says that they retire southwards, after the breeding season, even beyond the Mediterranean, where, in consequence of the increased temperature, they find a greater supply of food. The coasts of Norway and the shores of the Baltic, he adds, although not without the presence of this species, appear to be much less frequented by it than our own island. Mr. Gould figures three species in his great work ('Birds of Europe'); the bird above described; the Dusky Shearwater (*P. obscurus*); and the Cinereous Shearwater (*P. cinereus*), Stephens.

P. cinereus, according to Mr. Darwin, is common to Cape Horn and the coast of Peru, as well as Europe, and generally frequents the inland sounds. "I do not think," adds Mr. Darwin, "I ever saw so many birds of any other sort together, as I once saw of these behind the island of Chiloe; hundreds of thousands flew in an irregular line for several hours in one direction. When part of the flock settled on the water the surface was blackened, and a noise proceeded from them, as of human beings talking in the distance. At this time the water was in parts coloured by clouds of small *Crustacea*. At Port Famine, every morning and evening, a long band of these birds continued to fly with extreme rapidity up and down the central parts of the channel. I opened the stomach of one (which I shot with some difficulty, for they were very wary), and it contained a small fish and seven good sized prawn-like crabs." ('Journal and Remarks.')

Mr. Gould describes a species, *P. affinis*, from New South Wales. ('Zool. Proc.' 1837.) It is closely allied to *P. obscurus*, but somewhat smaller.

Thalassidroma.—Bill shorter than the head, much compressed in front of the nasal sheath, with the tip of the upper mandible suddenly curving and hooking downwards, and that of the lower one slightly angulated and following the curve of the upper; nostrils contained in one tube or sheath, but showing two distinct orifices in front. Wings long and acuminate, with the first quill shorter than the third, the second being the longest. Tail square or slightly forked. Legs having the tarsi rather long and slender, reticulated. Feet of three toes united by a membrane; hind toe represented by a small straight dependent nail. (Gould.)

The group generically sub-divided as above, or rather the most of them, have been regarded as the indicators of storm and tempest. Rapidly spurning the billows as they skim along the undulating waves, they are ever on the watch for what the troubled water may offer to them, and they congregate in the wake of the sea-going ship not so much perhaps for shelter as for what is turned up from the furrow ploughed by the keel. Mr. G. Bennett, during his voyage, observed that the Cape Petrels, Albatrosses, and other birds followed the ship during the whole of the night, reposing for a short period on the water, but seldom remaining long on the waves. They usually alighted for food, and soon resumed their flight. Marked birds were seen about the ship for days together when the strong gales carried the vessel at a rapid rate through the water. Cape Petrels and Albatrosses were seen flying near the stern as late as midnight, and it was not unusual to hear the twittering note of the Stormy Petrel (*T. pelagica*) under the stern during the night. ('Wanderings in New South

Wales, vol. i.) This genus includes the true Petrels, and is divided into the sub-genera *Daption*, *Thalassidroma*, *Wagellus*, and *Procellaria*, of which we proceed to give examples.

Daption.—*D. Capensis*, Stephens; *Procellaria Capensis*, Linn.; Cape Pigeon of the English; Peintada of the Portuguese, may be taken as an example of this form. Its plumage is variegated with brown and white. The total length of one measured by M. Lesson was 13 inches, that of the tube of the nostrils 6 lines. The testicles were rather deep-gray, the larynx had two muscles proper to it, and the total length of the intestinal tube was 47 inches. M. Garnot communicated to M. Lesson a species which the latter believed to be new, with an elaborate description and anatomical details, which M. Lesson quotes at length.

Cape Pigeon (*Daption Capensis*).

Thalassidroma, Vigors (*Hydrobates* of Boie).—Mr. Selby remarks that the members of this genus, which are all of small size, have been very properly separated by Mr. Vigors from the rest of the Petrel group. They are, he observes, birds of nocturnal or crepuscular habits, and are seldom seen except in lowering weather, or during storms, when they frequently fly in the track of ships. At other times, and in clear weather, they remain concealed during the day in the holes of rocks, rat-hurrows, &c., and only come forth at nightfall in search of food, consisting of marine crustaceans, small molluscs, and other oily animal matter which they find floating on the surface of the ocean. Their flight equals in swiftness that of the Swallow tribe, which they resemble in size, colour, and general appearance. All the known species are of a dark hue, more or less relieved with white, and are widely distributed, some being found in both hemispheres, and in a variety of climate. They breed in the crevices of rocks, caverns, &c., and, like the Fulmars and Shearwaters, lay but one egg, which is white, and comparatively large. ('Illustrations of British Ornithology,' vol. ii.)

T. pelagica. This species is considered to be the smallest of the webfooted birds; it is the *Procellaria pelagica* of Linnæus; Uccello delle Tempeste of the Italians; Oiseau de Tempête, Petrel, and Petrel Tempête, of the French and Temminck; Ungewitter Vogel, Kleinster Sturm-vogel, and Meer Peters Vogel, of the Dutch; Storm Zwalu of the Netherlands; Stromwaders Vogel of the Swedes; Soren Peder, St. Peders Fugl, Vestan-Vinds, or Sonden-Vluds Fugl, and Uveurs Fugl, of the Norwegians; Cas Gan Longwr of the Welsh; Common Storm Petrel, Stormy Petrel, and Storm-Finch, of the English, who call the species also (provincially) Little Petrel, Mitty, Assilag, Spency, Sea-Swallow, Allamouty, Witeli, and (mariners especially) Mother Carey's Chickens, a title which is not confined to *Procellaria pelagica*, but is shared by, and more generally applied to, the more oceanic species, such as *Thalassidroma Wilsonii*, &c.

Head and foot of *Thalassidroma pelagica*.

It has the head, back, wings, and tail dull-black; lower parts sooty black; a large transverse band of pure white on the rump; scapulars and secondary quills terminated with white; tail and quills black, the first quill not the longest, but shorter by four lines than the second and third, which is the longest; bill and feet black; iris brown. The tail is square, and the tips of the wings reach but very little beyond its point. The length of the tarsus is 10 lines. Total length 5 inches 6 lines. (Male and female.)

Young of the Year.—These have the tints less deep, and the edges of the feathers sooty or rusty: in other respects they resemble the adults.

It is more common in North America than in Europe; found on the coasts of England and Scotland; rather common at the Orcaades and Hebrides; more abundant in the island of Saint Kilda; wanders rarely on the coasts of the ocean, and very accidentally on the lakes of the centre of Europe. (Temminck.)

This, or some other species of *Thalassidroma*, is in all probability the *Cypselus* of Pliny, who describes ('Nat. Hist.' x. 39) the swallow-like appearance of his *Cypseli*, their nesting in rocks, their wide spread over the sea, and says that however far ships go from land, these birds fly around them.

The habits of this species very much resemble those of the other Petrels.

T. Wilsonii. This species appears to be the *Procellaria pelagica* of Wilson; *P. oceanica* of Banks; *P. Wilsonii* of Prince Bonaparte; L'Oiseau Tempête of Buffon, 'Enl.' 998; and Pétrel Échasse of Temminck. Head and all the lower parts sooty black; back, scapulars, and wings black; some of the great wing-coverts bordered with whitish; all the upper tail-coverts, and, in some individuals, a part of the feathers of the thighs also, or some of the lower coverts, pure white; tail nearly square, only slightly emarginate, the three lateral feathers white at their base; wings exceeding the tail more than an inch; bill and feet (tarsi 15 lines long) black; on the membranes a long yellow stain and the edges of the toes finely bordered with that colour; iris black; extremity of the nasal tube turned up. Total length of the bird 6 inches 3 or 4 lines. (Both sexes in perfect plumage.)

Thalassidroma Wilsonii.

M. Temminck, who gives the above description, observes that the young birds doubtless differ but little from the adults; but they are not as yet exactly known. ('Manuel,' 4th part, 1840.)

It inhabits the coasts of America to Cape Horn; common on the coasts of Chili, the United States, and Brazil; more rare at the Cape of Good Hope than *P. pelagica*; shows itself accidentally on the coasts of Spain and in the Mediterranean. (Temminck, 'Manuel,' 4th part.)

Nuttall, who enumerates their vulgar names of Stormy Petrels, Devil's Birds, and Mother Carey's Chickens with remonstrance, well describes their habits in his 'Manual of the Ornithology of the United States and of Canada.' Temminck states that their food consists of the seeds of some marine plants, small testaceans, molluscs, &c.; Wilson says that they feed on the gelatinous spores of the Gulf-Weed (*Fucus natans*), as well as small fish, harpaxes, &c. Nuttall informs us that these Petrels breed in great numbers on the rocky shores of the Bahama and the Bermuda islands, and along some parts of the coast of East Florida and Cuba. Mr. Audubon informed him that they also breed in large flocks on the mud and sand islands off Cape Sable in Nova Scotia, burrowing downwards from the surface to the depth of a foot or more. They also commonly employ the holes and cavities of rocks near the sea for this purpose. "The eggs," says Nuttall, in continuation, "according to Mr. Audubon, are three, white and translucent. After the period of incubation they return to feed

their young only during the night, with the oily food which they raise from their stomachs. At these times they are heard through most parts of the night, making a continued clattering sound like frogs. In June and July, or about the time that they breed, they are still seen out at sea for scores of leagues from the land, the swiftness of their flight allowing them daily to make these vast excursions in quest of their ordinary prey; and hence, besides their suspicious appearance in braving storms, as if aided by the dark ruler of the air, they breed, according to the vulgar opinion of sailors, like no other honest bird, for taking no time for the purpose on land, they merely hatch their egg under their wings, as they sit on the water!"

Fulmarus (Leach).—Mr. G. R. Gray gives *Wagellus* (Ray) as the generic name of this form, and Linnaeus quotes *Wagellus Cornubiensium* as a synonym of the species which we are about to illustrate.

Head and foot of Fulmar.

F. glacialis. This is the *Procellaria glacialis* of Linnaeus and authors; Le Pétrel Fulmar and Pétrel de l'île de Saint Kilda of Buffon; Havhest of the Norwegians, by whom it appears to be also called Mallemoko, or Mullemoke; Gwylan y Graig of the Welsh; Fulmar and Fulmar Petrel of the English, by whom it is also named (provincially) Malle-muck, Malmoke, and Mallduck.

This species has been considered the type of the restricted genus *Procellaria*, Linn., by those who confine the subdivision of that genus to the genera *Procellaria*, *Puffinus*, and *Thalassidroma*. The bill of the Fulmar is stout, thick, with the upper mandible considerably hooked at the tip (where it is also dilated) and sulcated. The lower mandible is straight and slightly truncated. The nostrils are united in a single tube. The legs are moderate, and a sharp claw exists in the place of a hind toe.

Fulmar Petrel (*Fulmarus glacialis*).

The head, neck, all the lower parts, rump, and tail pure white; back, capulars, wing-coverts and secondaries, pure bluish-ash; quills bright-

gray brown; tail well rounded, conical; bill bright-yellow tinged with orange on the nasal tube; iris and feet yellow. Length 16 inches. (Both sexes, summer plumage.)

Young of the Year.—The whole body bright-gray clouded with brown; feathers of the wings and tail terminated by a deeper brown; the quills and caudal feathers have only a tinge of gray-brown; in front of the eyes an angular black spot; bill and feet yellowish-ash. (Temminck.)

It inhabits the Polar Regions principally during summer. Mr. Gould ('Birds of Europe') observes, that although the Polar Regions constitute its native locality, it is nevertheless found, but in much less abundance, in more temperate climates, such as the northern seas of Europe and America, extending itself throughout the lengthened coast of Norway, and not unfrequently Holland and France. It frequents also, he adds, the northern isles of Great Britain, resorting to the Orkneys and Hebrides for the purpose of breeding, but particularly to the island of St. Kilda.

Temminck states that the Fulmar never comes to the coast except for the purposes of nesting, or when driven there by gales. Its flight is easy and buoyant. Besides the flesh and blubber of dead whales or seals, for penetrating whose thick skins their trenchant and hooked upper mandible is admirably formed, barnacles and other parasites which attach themselves to the whales, molluscs, &c., form their food. The Fulmar attends the fishing-vessels on the banks of Newfoundland, where it is called John Down, for the offal of the cod-fish, and is often taken with a hook baited with a piece of cod's liver or flesh. At St. Kilda they breed gregariously in the caverns and holes of the rocks; a single white large egg, with a very brittle shell, is deposited by the female, and the young, which are hatched about the middle of June, are fed with oily matter disgorged by the parents. As soon as they are fledged they are eagerly sought by the cragsmen, who scale the precipitous cliffs for them at the risk of their lives for the sake of their down, feathers, and oil.

Procellaria (Linn.).—The type of this genus, as restricted by Mr. G. R. Gray, is *P. æquinoctialis* (Linn.), the Great Black Petrel of Edwards.

Great Black Petrel (*Procellaria æquinoctialis*).

Mr. Darwin, in his valuable 'Journal and Remarks' ('Voyage of Adventure and Beagle'), observes that the southern seas visited by the expedition are frequented by several species of Petrels. The largest kind, *P. gigantea*, or Nelly (Quebrantahuesos, or Break-Bones, of the Spaniards), is, he observes, a common bird, both in the inland channels and on the open sea. "In its habits and manner of flight," continues Mr. Darwin, "there is a very close resemblance with the Albatross, and, as with the latter bird, a person may watch it for hours together without seeing on what it feeds, so it is with this Petrel. The Break-Bones is however a rapacious bird, for it was observed by some of the officers at Port San Antonio chasing a diver. The bird tried to escape, both by diving and flying, but it was continually struck down, and at last killed by a blow on its head. At Port St. Julian also these great petrels were seen killing and devouring young gulls." The same author adds, that the Spaniards were probably aware of the rapacity of this petrel, for Quebrantahuesos means properly an osprey. These large petrels are called Mother Carey's Geese by the sailors.

The species of the genus *Diomedea*, the Albatrosses, will be found under the articles DIOMEDEINE and ALBATROSS. Remains of a fossil bird having the characters of an Albatross have been found in Great Britain. [BIRDS.]

Prion (Lacépède), *Pachyptila* of Illiger.—Bill strong, stout, wide, very much depressed, the upper mandible convex on its sides, terminated by a compressed hook; the edges furnished internally with cartilaginous lamellæ; the lower mandible very much depressed,

formed of two arcs soldered at the point, and forming in their interval a guttural pouch; nostrils opening by two distinct orifices and disposed in the form of a short tube. A very small claw in place of a hind toe. First quill longest.

Blue Petrel (*Prion vittatus*).

The type of this genus is the Blue Petrel (*Procellaria vittata* and *P. carulea*, Gmelin) discovered by Forster. Many individuals were taken during the voyage of the 'Coquille,' in 58° S. lat. The following is from M. Garnot's description of an individual of this species, which, in the form of its bill at least, appears to be leading the way towards the Lamellibranchiate Palmipedes. It is distinguished from the other Petrels by the disposition of its bill. The mandibles are hooked at their extremity; their base is very much widened. The edges of the upper mandible are directed a little outwards; they present within a projecting border striated transversely; the interval which separates them exhibits a small groove. The tongue is very thick and the mouth very dilatible. Total length, from the bill to the extremity of the tail, 11 inches (French). Length of the nasal tube 3 lines. Extent of wings 20 inches. Size a third larger than *Thalassidroma pelagica*; upper part of the body ashy-blue or gray-blue, deepest on the head and on the wings. A blackish band cuts across the wings and the lower part of the back near the origin of the tail. This portion is deepest in colour; the extremity of the tail has the same blackish deep-blue tint; lower part of the body and wings white; above the tail a line of a blue tint; bill and eyes plumbeous blue; middle of the upper mandible and tube of the nostrils blackish. The middle tail-feathers are rather the longest, which gives the tail a rounded appearance. The same author gives an interesting detail of the anatomy of the bird.

PROCERUS. [CARABUS.]

PROCHILUS. [BEAR.]

PROCNIAS, a genus of Birds placed by Mr. Swainson and others under the sub-family *Bombycillina*, Swallow Chatterers. It has the following generic characters:—Bill very broad; the sides inflected; the tip not hooked. Nostrils nearly naked. Wings pointed; the three first quills longest. Inner toe shorter than the outer. Tail slightly forked. (Sw.)

P. ventralis, the Swallow Fruit-Eater. Male.—Blue; front, throat, and temples, black; middle of the body beneath white, the sides with blackish transverse strim. Length about 5½ inches.

Female.—Green; chin and temples gray; body beneath yellowish, transversely striated with dusky-green.

Mr. Swainson ('Zoological Illustrations,' 1st series) remarks that the birds of this genus are remarkable for the enormous width of their mouths, which in some species exceeds that of the Swallow family, thus enabling them with ease to swallow the large *Melastoma* berries and those of other tropical shrubs, on which alone they subsist; not on insects, as Cuvier asserts. Although, he adds, they perfectly resemble the swallows in the construction of their bills; their wings are not formed for rapid flight; and their feet are much stronger, and calculated for searching among branches for their food, in which situations Mr. Swainson frequently saw them. The species noticed is, he observes, a scarce bird; he met with it only three times in Bahia; but he says that it appears more frequent in the southern provinces of Brazil, specimens having been sent to him from Minas Geraes and Rio de Janeiro.

Swallow Fruit-Eater (*Trocnas ventralis*). (Sw., 'Zool. ILL.')

PROCRUSTES. [CARABUS.]

PROCTOTRETUS. [IGUANIDÆ.]

PROCYON. [URSIDÆ.]

PRODUCTA. [PRODUCTIDÆ.]

PRODUCTIDÆ, a family of Brachiopodous *Mollusca*, including the genera *Producta*, *Strophalosia*, and *Chonetes*. The shell is concavo-convex with a straight hinge-line; valves rarely articulated by teeth; closely adpressed, furnished with tubular spines; ventral valves convex; dorsal concave; internal surface dotted with conspicuous funnel-shaped punctures; dorsal valve with a prominent cardinal process; brachial processes (!) subcentral; vascular markings lateral broad and simple; adductor impressions dendritic, separated by a narrow central ridge; ventral valve with a slightly-notched hinge-line; adductor sac central, near the umbo; cardinal impressions lateral, striated.

Producta has the shell free, auriculate, beak large and rounded; spines scattered; hinge area in each valve linear, indistinct; no hinge-teeth; cardinal process lobed, striated; vascular impressions simple, curved; ventral valve deep, with two rounded or subspiral cavities in front.

The species are all fossil. There are about sixty species. They are found ranging from the Devonian to the Peruvian rocks of North and South America, Europe, Spitzbergen, Tibet, and Australia.

Strophalosia has its shell attached by the umbo of the ventral valve. There are 8 species.

Chonetes contains 24 species, which are found fossil from the Silurian to the Carboniferous rocks.

(Woodward, *Treatise of Recent and Fossil Shells*.)

PROITHERA. [GOAT-SUCKERS.]

PROMEROPIDÆ. [UPUPIDÆ.]

PRONG-BUCK. [ANTILOPÆ.]

PROPITHECUS (Bennett), a genus of *Mammalia* allied to the *Lemuridæ*, and thus characterised:—Muzzle moderate. Hinder extremities longer than the anterior ones. Index abbreviated. Tail long, hairy.

Dental Formula:—Incisors, $\frac{4}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, —; (upper)

two first cuspidate, the third elongated, externally bituberculate, the fourth like the preceding; (lower) first unicuspidate, second and third plurituberculate.

P. Diadema. Face nearly naked, with short blackish hairs about the lips, and equally short yellowish-white hairs in front of the eyes. Above the eyes, the long, silky, waved, and thickly-set hairs which cover the body commence by a band of yellowish-white crossing the front and passing beneath the ears to the throat. This is succeeded by black, extending over the back of the head and neck, but becoming freely intermingled with white on the shoulders and sides, the white gradually increasing backwards so as to render the loins only slightly grizzled with black. At the root of the tail fulvous, that colour gradually disappearing until the extreme half of the tail is white, with a tinge of yellow. The under surface white throughout, except the hinder part of the throat, where it is of the same colour with the sides of the body.

Hairs generally long, silky, waved, erect, and glossy; shorter and more dense on the crupper, where they offer a sort of woolly resist-

ance. General character of those on the tail, that of the body hair, but shorter.

Thumb of anterior hands slender, placed far back, and extremely free; length one inch and half, extremity of its penultimate phalanx ranging slightly beyond the end of the metacarpal bone of the index. Index one inch and a half in length, its extremity ranging with the middle of the penultimate phalanx of the second finger. Length of second finger 3 inches; that of third finger $3\frac{1}{4}$ inches. Length of carpus and metacarpus 2 inches.

Thumb of hinder hands very strong, placed forwards and ranging with the fingers, 2 inches long; index $2\frac{1}{2}$ inches, the pointed nail extending half an inch beyond: length of second finger, $3\frac{1}{4}$ inches; of tarsus and metatarsus, 3 inches.

Length of body and head, measured in a straight line, 1 foot 9 inches; of the tail, 1 foot 5 inches. Anterior limbs, exclusive of hands, $7\frac{1}{2}$ inches in length from the body; posterior limbs, $15\frac{1}{2}$ inches.

Muzzle shorter than in the Lemurs generally; the distance from the anterior angle of the orbit to the tip of the nose (one inch and a quarter) being equal to that between the eyes. Ears rounded, concealed in the fur: length one inch; breadth one inch and a half.

Propithecus Diadema.

Mr. Bennett remarks that *Propithecus* is essentially distinguished from *Lemur*, the genus to which it most nearly approaches, by the number and form of its teeth, and especially by the form of the incisors of the upper jaw, which constitute apparently a regular series, a structure unknown in any other Lemuridous animal. It is a native of Madagascar.

PROPOLIS. [BEE.]

PROSIMIA, the name given by Brisson and Storr to some of the Lemurs. [LEMURIDÆ.]

PROTEACEÆ, a natural order of incomplete Exogenous Plants.

It possesses the following characters:—The perianth or calyx is 4-leaved, the sepals distinct, or cohering into a tube with a 4-cleft limb; the sepals subcoriaceous, coloured, pubescent externally, and valvate in æstivation; the stamens definite, opposite the lobes of the calyx, and generally exerted with very short filaments from just below the edges of the sepals; the anthers adnate, 2-celled, linear, and dehiscent longitudinally; the pollen is normally triangular, sometimes elliptic or cuneate, rarely spherical; occasionally there exist four hypogynous scales or glands, or barren stamens, alternating with the lobes of the calyx and prefiguring a corolla; the germen is free, often stipulate, formed of a single carpel, the style simple and terminal, and the ovules 1, 2, or many; the fruit is variable, either dry or succulent, and either dehiscent or indehiscent, 1, 2, or more seeded; the seeds without albumen, often winged, and furnished with a chalaza; the embryo straight and white, with two or more cotyledons, the plumule scarcely visible, and the radicle inferior and short.

The species are shrubs or small trees, with usually umbellate branches, and hard, dry, divided or undivided, opposite or alternate leaves without stipules, and the cuticle often covered on both sides with stomates.

This order is very easily distinguished by the hard, dry, woody texture of the leaves, by the irregular perianths having a valvate æstivation, the stamens placed on the lobes of the perianth, and by its dehiscent fruit. Another character by which it is distinguished

from those which are allied to it is that the radicle points towards the base of the fruit.

Wooden Pear (*Xylometum pyriforme*).

1, Branch with leaves and flowers; 2, flower separated; 3, fruit split open.

The following is an arrangement of the genera of this order, from Brown's 'Memoir.'

* Indehiscent Fruit.

** Distinct Anthers.

*** Anthers free from the Calyx.

**** Dioecious Flowers.—*Aulac*, *Leucodendron*.

**** Hermaphrodite Flowers.—*Pterophila*, *Isopogon*, *Protea*, *Leucospermum*, *Serruria*, *Mimetus*, *Nivenia*, *Sorocephalus*, *Spalalla*, *Adenanthos*, *Guevina*, *Brabejum*, *Cenarrhencs*, *Agastachys*, *Symphionema*, *Bellendena*.

*** Anthers adnate with the Calyx.—*Franklandia*.

*** Coherent Anthera.—*Simia*, *Conospermum*, *Synaphea*.

• Dehiscent Fruit.

• Unilocular.

*** Ovary 2-seeded.—*Anadenta*, *Grevillea*, *Hakea*, *Lambertia*, *Xylomelum*, *Orites*, *Ropala*.

*** Ovary 4-seeded.—*Knightia*.

*** Ovary many-seeded.—*Embothrium*, *Oreocallis*, *Telopoa*, *Lomatia*, *Stenocarpus*.

• Bilocular.—*Banksia*, *Dryandra*.

A great many of these genera are named after botanists and patrons of botany.

Nirenia was named in honour of Mr. James Niven, an intelligent botanist, to whom we are indebted for the discovery of many new species of South African plants. *Simia* was named after Dr. John Sims, for many years editor of the 'Botanical Magazine.' *Franklandia* was named in honour of Sir Thomas Frankland, Bart., who has studied very successfully the submarine flora of this country. *Persoonia* was named by Sir J. S. Smith after C. H. Persoon, who wrote several papers on Cryptogamic Botany, and published a complete edition of the 'Systema Vegetabilium' of Linnæus. *Bellendenia*, named after John Bellenden Ker, who has published many valuable papers on botany in the 'Annals of Botany,' and the 'Botanical Magazine.' *Grevillea* was named by Brown in honour of the right honourable Charles Francis Greville, a lover of natural history, and formerly a vice-president of the Royal Society. This name will also be always associated by every botanist with that of Dr. Greville of Edinburgh, the author of the 'Scottish Cryptogamic Flora.' *Lambertia* was named by Smith in honour of A. B. Lambert, a good botanist and a distinguished patron of the science of botany. *Knightia* is a genus which was discovered by Sir Joseph Banks, and, at his suggestion, named by Brown in honour of Thomas Andrew Knight, author of many valuable papers on various departments of vegetable physiology. *Banksia* was named by the younger Linnæus in honour of Sir Joseph Banks. *Dryandra*, a genus closely allied to *Banksia*, was named in honour of Mr. Dryander, a Swede, librarian to Sir Joseph Banks, and a learned and talented botanist.

The geographical distribution of these plants is interesting. They are almost entirely confined to the southern hemisphere, an observation first made by Mr. Dryander. Their diffusion is very extensive in this hemisphere, not merely in latitude and longitude, but also in elevation. They cover not only the larger southern continents, but are also found in New Zealand and New Caledonia; but they have not hitherto been found in Madagascar or the lesser islands of the South Seas. In America they have been found in Tierra del Fuego, in Chili, in Peru, and even Guyana. The American species have more affinity with those of Australia than of Africa. It may be inferred that this family of plants is diffused over Africa, as they are abundant at the Cape of Good Hope, and Bruce found a genuine species of *Protea* in Abyssinia. Wherever the shores of Australia have been explored, an abundance of Proteaceous Plants have been found, the great mass of the order existing here in about the same latitude as the Cape of Good Hope. On the south-west coast of Australia this order forms a much more decided feature of the vegetation than on the east. From the parallel of the mass the order diminishes in both directions, but the diminution towards the north appears to be more rapid on the east than on the west coast. The most numerous genera are those which are the most widely diffused. *Grevillea*, *Hakea*, *Banksia*, and *Persoonia* contain the largest amount of species, in the order in which they are mentioned, and are found spread nearly in the same proportion. Those genera which consist of one or very few species, and which exhibit the most remarkable deviations from the structure of the order, are the most local, and are found either in the principal parallel or in the highest latitude. The range of the species of the order is very limited, and there has been no instance recorded of a species of this family common to the eastern and western shores of Australia. *Banksia integrifolia* is probably the most widely extended species; but although its range of latitude is very considerable, its extension in longitude is very small.

None of the plants belonging to the natural order *Proteaceæ* are remarkable for their medicinal properties. The fruit of a species of the genus *Guerina* is said to be sold in the markets of Chili under the name of *Avellano*. At the Cape of Good Hope the plants of this order are most frequently made use of as fire-wood. For this purpose the dry woody character of their leaves peculiarly fits them. They are most of them handsome evergreen shrubs, and are much prized by gardeners, and form a part of every good collection of plants. One of the finest collections of these plants in this country is at the Royal Gardens at Kew, where a great variety of this singular and interesting group of plants may be seen. The genera most commonly found in this country are *Grevillea*, *Banksia*, and *Dryandra*. The fruit of the *Xylomelum pyriforme*, which the cut accompanying this article represents, is very hard, and is known in Australia under the name of Wooden Pear.

(Brown, 'On the Proteaceæ of Jussieu,' in vol. x. of Linn. Trans.; Jussieu, art. 'Protées,' in Dictionnaire des Sciences Naturelles; Burnett, Outlines of Botany; Lindley, Natural System.)

PROTEIN (from *πρωτεῖν*, to stand first), a substance first described by Mulder, and obtained from animal and vegetable substances containing nitrogen. Although the existence of Protein as an independent substance has been doubted, the theory of its existence and its relation to animal and vegetable compounds generally has had the most important influence on vegetable and animal physiology. It was through his researches on Protein that Mulder came to the conclusion that certain vegetable and animal compounds, as fibrin, albumen, legumin, gluten, &c., were identical, and that these bodies are first formed in the vegetable before they are appropriated by the animal. Liebig, who was the first to adopt Mulder's views, now denies the independent existence of Protein. Whether however this substance exists as a chemical compound or not, there can be no doubt of the close resemblance in chemical composition and vital properties of albumen, fibrin, and casein, and of their elements being united in the relations in which they are represented in the formula for Protein.

This substance was obtained by Mulder from Albumen, Casein, Horn, and Animal and Vegetable Fibrin. When any one of these is dissolved in a solution of potash, and the filtered solution is mixed with a slight excess of acid, a copious grayish-white flocculent precipitate is formed, and a slight smell of hydrosulphuric acid is perceived. This white substance is Protein, so called from its occupying the first or most important place in relation to the albuminous principles.

Its properties are:—While moist the white flocculi are diaphanous, but by drying they become yellowish, hard, and brittle. It possesses neither smell nor taste, attracts moisture rapidly from the air, and loses water at 212°. It is insoluble in water, alcohol, ether, and essential oils. By long continued boiling in water it undergoes some change of properties, and is rendered soluble.

Acetic and phosphoric acids, whatever may be their state of concentration, dissolve it; hydrochloric acid also dissolves Protein, and acquires an indigo tint. When heated the solution blackens. With concentrated sulphuric acid it produces a jelly which contracts in water, and which, after being washed with water and alcohol, though it does not redden litmus-paper, contains 8.34 per cent. of sulphuric acid. Mulder calls this compound Sulphoproteic Acid. When Protein is boiled in dilute sulphuric acid, it acquires a purple tint.

Protein is precipitated from its acid solutions by the ferro- and ferrid-cyanide of potassium, by tannin, and by neutralisation with an alkali. When strongly heated, Protein is decomposed with the production of ammonia and a charcoal which burns with difficulty, but leaves no residue.

Protein consists entirely of carbon, hydrogen, nitrogen, and oxygen; and it will be observed, that whether obtained from Albumen (1), Casein (2), Horn (3), Animal Fibrin (4), or Vegetable Fibrin (5), the statements of its composition differ so slightly, as to show that it must be the same from whicheversoever of the sources named it is procured.

	(1)	(2)	(3)	(4)	(5)
Carbon . . .	55.30	55.16	55.408	55.44	54.99
Hydrogen . . .	6.94	7.17	7.238	5.95	6.87
Nitrogen . . .	16.02	15.86	15.593	16.65	15.66
Oxygen . . .	21.34	21.81	21.761	21.36	22.48

These analyses may be represented by $C_{40}H_{21}N_5O_{12}$.

When Protein, or the substances which yield it, are boiled in a concentrated solution of potash as long as ammonia is evolved, and the solution is afterwards neutralised by sulphuric acid, evaporated to dryness, and the residue treated with boiling alcohol, three products of the decomposition are dissolved, one of which, Erythroprotide, separates in oily drops as the solution cools; Leucin is deposited in small crystalline scales by spontaneous evaporation; whilst the mother water contains Protide and Formiate of Ammonia in solution.

Dinoxide and Tritoxide of Protein are produced by the long continued action of boiling water upon fibrin in contact with air. They are the chief ingredients of the buffy coat of the blood in a state of inflammation, being produced at the expense of the fibrin.

Protein is undoubtedly the most important of all known substances in the organic kingdom. It is present in all parts of plants, in roots, stems, leaves, fruits, and in their several juices; in the animal body it is the chief constituent of the blood, the muscles, and many other parts, and is the original source of numerous other compounds. In plants it assumes three different forms, being soluble in water, insoluble in water, or soluble in alcohol; in animals it may be either soluble or insoluble in water. It is one of the substances directly prepared for the food of plants, and is found in the youngest roots; whether it is only formed there, and afterwards conveyed to the other parts, or whether it is produced in any other part of the plant, is uncertain. Its property of being readily soluble in water facilitates its transference to the various organs. It may however assume the solid state and become deposited in cells; in this form it occurs in many seeds, occasionally being their principal constituent. This deposition is effected in a very simple manner. Most acids render it insoluble, and therefore the mere presence of an acid is usually sufficient to accomplish the transformation: again, the insoluble Protein may be redissolved by alkalies, and hence, after it has been deposited in the cells in a solid state, it may be removed to another part of the plant through the medium of an alkaline solution.

Whether Protein can be formed within the animal body is uncertain, but it cannot be doubted that the Protein compounds in vegetables are imparted to animals in their food, and as the compounds form the principal component parts of the animal body, this constituent must be supplied either wholly or in part by plants.

The Protein compounds existing in plants were till quite recently known as Soluble Albumen, Coagulated Albumen, Legumin, and Gluten; Liebig has however applied to the three first the names Vegetable Albumen, Vegetable Fibrin, and Vegetable Casein, asserting that they are identical in their physical properties and in their chemical compositions with the corresponding principles in the animal kingdom. Mulder, the discoverer of Protein, denies the accuracy of this statement. "The special character of these animal substances is," he remarks, "determined by the small portions of sulphur and phosphorus they contain, by which they differ from each other and from pure Protein. The proportions of sulphur and phosphorus in the three vegetable substances are still unknown; and therefore the names proposed by Liebig cannot be applied to them. Moreover both vegetable albumen and legumin differ so much from animal fibrin and casein, both in form and appearance, that they ought not to have a similar name."

Soluble Vegetable Albumen is that substance which, being soluble in water, is precipitated from the juices of plants by heat, alcohol, or acids. It is soluble in weak alkaline fluids, from which it is precipitated by acids, and, independently of the sulphur and phosphorus, has the same composition as Protein. Coagulated Vegetable Albumen is the compound of protein, sulphur, and phosphorus, which is insoluble in water; it exists in the seeds of the *Cerealea*, in almonds, &c. Glutin is the substance which can be extracted by alcohol from the ordinary gluten by washing away the starch from flour.

The Protein-compounds contained in the animal body correspond to these in the vegetable. Thus we have Fibrin, Albumen, and Casein.

The bodies of animals contain Fibrin both in a fluid and a solid state; in the former it exists in the blood, and in the latter form in muscular fibre, but that of venous differs from that of arterial blood. To obtain the former, human blood is to be triturated in a mortar with one and a half times its weight of water, and one-third of its weight of nitre; and the mixture is to remain, during at least twenty-four hours, exposed to a temperature of about 100° to 120° Fahr.; by this it is rendered slimy and gelatinous, and at length it becomes liquid, exhibiting the properties of albumen which has been treated with acetic acid. When largely diluted with water, a flocculent substance is thrown down, which closely resembles coagulated albumen. When arterial blood is employed in the same way similar changes are not produced, and the fibrin of venous blood loses the property if it has absorbed oxygen.

Solid Fibrin is procured by washing thin portions of muscular flesh in cold water until they are rendered quite white, or in a purer state by stirring fresh blood with a stick to which the fibrin adheres: it is to be rendered pure by washing first with cold water, and afterwards by treatment with ether. Fibrin, when fresh, exists in the state of long, white, elastic filaments; it is inodorous, tasteless, and insoluble in water whether cold or hot, but by long-continued boiling a portion is dissolved. When dried at a gentle heat it loses about four-fifths of its weight, which loss is water, and it becomes then horny and translucent, and very much resembles albumen which has been coagulated; acetic acid and fresh fibrin when kept for some hours in contact, form a transparent gelatinous mass which is soluble in water; solution of potash dissolves fibrin, and the compound possesses many of the characters which belong to albumen.

According to Mulder dried fibrin consists of

Carbon	54.56
Hydrogen	6.90
Azote	15.72
Oxygen	22.13
Phosphorus33
Sulphur36

—100

If it be admitted that the phosphorus and sulphur are in definite combination, the formula of this substance will be $C_{400}H_{310}N_{50}O_{120}PS$, which certainly includes a very unusual amount of equivalents. Its composition is precisely similar to that of coagulated albumen, and, as already remarked, they have several properties in common. [FIBRIN.]

Albumen is found very extensively in the human body, forming the chief ingredient in the serum of the blood, chyle, lymph; and enters largely into the composition of the brain and nerves. The white of eggs is liquid albumen. It unites with alkalies and metallic oxides, forming albuminates. It is precipitated from its solutions by nitric acid, heat, corrosive sublimate, and metallic oxides generally. The following is its composition:—

	From Actual Analysis.	Calculated Atoms.
Carbon	54.38	54.44—C. 48
Hydrogen	7.14	6.99—H. 37
Nitrogen	15.92	15.88—N. 6
Oxygen	22.56	22.69—O. 15

100

100

Casein is the basis of the various kinds of cheese, and closely resembles albumen in many properties. It is insoluble in water, but a small portion of alkali renders it soluble; it may be prepared by adding dilute phosphoric acid to fresh milk warmed; a coagulum is produced, which after being washed is to be dissolved in a weak solution of carbonate of soda, and this is to be kept in a warm place to allow of the separation of the butter; these re-solutions in carbonate of soda and precipitations are to be repeated several times, and the insoluble casein is then to be washed with boiling water, and treated with ether, to remove any remaining butter or fatty matter.

Casein thus prepared is a curdy white substance, insoluble in water or alcohol, but soluble by water containing an alkali or its carbonate; dilute acids also dissolve a small portion of it. When moist, it reddens litmus-paper, and leaves about 0.3 per cent. of ashes by incineration. Casein is coagulated by certain animal membranes, as is shown in the process of making cheese, in which, by the action of a piece of the stomach of the calf, milk is separated into a yellowish liquid termed whey, and a solid white coagulum which contains all the casein of the milk with portions of some of its other principles.

According to the analysis of Mulder, casein consists of

Carbon	54.96
Hydrogen	7.15
Azote	15.80
Oxygen	21.73
Sulphur36

—100

The following are also formula for these substances:—

Fibrin from blood $10(C_{40}H_{31}N_5O_{12}) + SP$, or $10\overline{Pr} + SP$; that is to say, every atom or equivalent of fibrin contains 10 atoms or equivalents of Protein with one each of sulphur and phosphorus.

Albumen from the serum of the blood is represented by $10(C_{40}H_{31}N_5O_{12}) + S_2P$, or $10\overline{Pr} + S_2P$; that is to say, it differs from fibrin in containing one atom more of sulphur.

Casein from cow's milk, $10(C_{40}H_{31}N_5O_{12}) + S$, or $10\overline{Pr} + S$.

Crystallin, the substance that forms the principal constituent of the lens, $15(C_{40}H_{31}N_5O_{12}) + S$, or $15\overline{Pr} + S$.

These are all the Protein-Compounds of the animal body yet known. The muscular fibre is for the most part composed of a Protein-Compound, fibrin, which likewise exists in the circulating fluids; and albumen occurs in the brain, liver, kidney, and many other organs, as well as in the blood. The above compounds of Protein enter into some very important combinations, a few of which, from their physiological bearings, we shall here notice. The combinations of the leading Protein-Compounds, fibrin, albumen, and casein, with alkalies, acids, and salts, are especially remarkable. Protein is soluble in weak alkalies, and according to Mulder it exists in the blood as a proteate of soda with sulphur and phosphorus. Enderlin and the Giessen school, on the other hand, deny that it exists in that fluid as proteate of soda. They assert that the cause of the alkalinity of the blood is the presence of the ordinary tribasic phosphate of soda—a salt which has the power of dissolving the Protein-Compounds: the question whether Mulder or Enderlin be correct is still undecided.

On neutralising a weak alkaline solution of Protein by an acid, its solubility is greatly diminished; a fact which Mulder regards as elucidating the medical properties of certain acids. The sulphuric and phosphoric acids, for instance, possess the property of stanching blood; acetic acid, on the contrary, by which Protein is readily dissolved, is destitute of that property. Very dilute hydrochloric acid occurs in the stomach, and as it possesses the property of dissolving Protein, it doubtless renders the food (at least the portion consisting of Protein-Compounds) tender, and thus assists digestion. Some acids enter into combination with the Protein-Compounds, producing comparatively insoluble bodies. For this reason certain acids (sulphuric and hydrochloric) are very efficacious in putrid fevers, scurvy, &c. As an illustration of the combinations of the Protein-Compounds with salts, we may notice that of bone-earth with casein. Bone-earth is a phosphate of lime whose composition is represented by the formula $3P_2O_5 + 8CaO$. In casein, and therefore in milk, it exists in great quantity, and this seems to supply a large amount of earthy matter to the tender bones of young animals.

In addition to albumen and fibrin, a third Protein-Compound exists in the blood, constituting the cell-wall of the corpuscles. It is termed Globulin. Its real composition is unknown; Simou regards it as casein. All these Protein-Compounds contain more or less phosphate of lime, which thus finds its way to the bones.

Two other very important Protein-Compounds exist in the animal body, namely the binoxide and tritoxide of Protein. They both exist to a large amount in the blood in inflammatory diseases, and to a small amount in healthy blood. The latter is soluble in water, the former is not. At every respiration a small amount of them is produced in the blood, and Mulder (who must be regarded as the highest authority in all that relates to Protein) believes that they form around the blood-corpuscles a thin layer, having the same composition as the buffy coat or inflammatory crust. Gelatin is a degraded form of Protein. [GELATIN.]

PROTELES. [AARD-WOLF.]

PROTEOSAURUS. [ICHTHYOSAURUS.]

PROTEUS, Laurenti's name for one of the genera of Perennibranchiate Batrachians, namely, those Batrachians which preserve their branchiae throughout life, whereas the Caducibranchiate Batrachians only possess them during their early or tadpole state. [AMPHIBIA.] This preservation of the branchiae does not interfere with the presence of true lungs, so that these *Perennibranchiata* may, as Cuvier observes, be regarded as the sole vertebrated animals that are truly amphibious. Cuvier says, "The simultaneous existence and action of branchial tufts and lungs in these animals can no more be contested than the most certain facts of natural history; I have before me the lungs of a *Siren* of three feet in length, where the vascular apparatus is as much developed and as complicated as in any reptile: nevertheless this *Siren* had its branchiae as complete as the others." [SIREN.] Cuvier further observes that whilst the branchiae subsist, the aorta, in coming from the heart, is divided into as many branches on each side as there are branchiae. The blood of the branchiae returns by the veins, which unite towards the back in a single arterial trunk, as in the fishes; it is from this trunk, or immediately from the veins which form it, that the greatest part of the arteries which nourish the body, and even those which conduct the blood for respiration in the lung, spring. But in the species which lose their branchiae naturally, the branches which go there become obliterated, except two which unite in a dorsal artery, and of which each gives off a small branch to the lung. "It is," adds Cuvier, "the circulation of a fish metamorphosed into the circulation of a reptile."

The *Proteus* of Laurenti (*Hypochton* of Merrem) has four feet. There are three toes on the anterior feet and two only on the posterior feet. The skeleton bears considerable resemblance to that of the Salamanders; indeed, Cuvier, we believe, has somewhere termed the fossil *Salamandra gigantea*, the *Homo diluvii testis* of Schuechzer, *Protée Gigantesque* [AMPHIBIA]; but *Proteus* has many more vertebrae than the Salamanders, and less of the rudiments of ribs, and its bony head is entirely different from theirs in its general conformation.

But one species of *Proteus* appears to be known, the *Proteus anguinus* of authors, *Hypochton Anguinus*. Cuvier describes it as more than a foot long, of the size of a human finger, with a tail vertically compressed, and four little legs; the muzzle elongated and depressed; both of its jaws furnished with teeth; the tongue with but little motion, but free in front; the eyes excessively small and hidden by the skin, as in the Rat-Mole (*Spalax*); the ears covered by the flesh, as in the Salamander; its skin smooth and whitish.

a, Skull, &c., and first three vertebrae, of the *Proteus*. b, Same seen from above, eight times larger than nature. (Rusconi.)

Several specimens of these animals have been brought to this country.

In November, 1837, Dr. Martin Barry exhibited one living, to the Zoological Society of London, and read the following communication from Professor Rudolph Wagner, of Erlangen in Bavaria:—

"I was so fortunate," says Professor Wagner, "at the end of last summer, as to obtain three living *Protei*; of which I have examined two, just killed, that proved to be a male and female, and have given the third, alive, to my friend Dr. Barry, who may perhaps have an opportunity of bringing it forward at a meeting of the Zoological Society. The results of my examination correspond perfectly with the statements of Cuvier, R. Owen, J. Müller, and others, on the *Proteidea*; but are opposed to several of the views lately put forth by Rusconi. ('Observations sur la Sirène,' 1837.) I have, for instance,

no doubt that the pulmonary sacs or vesicles really perform the function of lungs. Each lung contains a large artery and a still larger vein, which are connected together by means of large and

Skeleton of *Proteus*, seen from above. a, bones of interior foot, magnified. b, bones of posterior foot, magnified. (Rusconi.)

numerous vessels. To me the most important point was the examination of the blood-globules and the generative organs. I conjectured, on various grounds, that the *Proteidea* would be found to have, of all

*Proteus anguinus.*

animals, the largest blood-globules:—first, because the size of the latter in the naked *Amphibia* in general is the largest in the animal kingdom; secondly, because, remarkable as it is, the blood-globules are here (in the naked *Amphibia*) so much the larger, the longer the gills continue in the larval state; hence the land and water salamanders have much larger blood-globules than the frog. I conjectured also that the *Protei* (probably also the *Siren*, &c.), because they permanently have both gills and lungs—being therefore permanently larvæ—would be found to have the largest blood-globules. The latter are indeed gigantic; flat, oval, resembling those of the salamander, and from 1-30th to 1-40th of a Paris line in length; hence, as minute points, visible to the naked eye. They are from once to twice the size of the blood-globules of the salamander, nearly three times as large as those of the frog, and about twelve or fifteen times the size of those of man. In a female I found the ova very beautifully developed; their structure, as well as that of the ovary, corresponding perfectly with that of the other naked *Amphibia*, especially the *Triton*. The smallest ova consist of a delicate chorion, yellow yolk, large germinal vesicle, and a manifold germinal spot. I regret to say that in the otherwise tolerably developed testes of the male there were no spermatozoa. I conjecture however that the spermatozoa of this animal resemble those of the *Triton*. I would just remark, that the form and size of the blood-globules, the formation of the ova, and the form of the spermatozoa, in different animals, have a great zoological and physiological interest. Already is it in my power from a drop of blood or semen placed before me, to determine with the microscope, not only the class, but frequently the genus and the species from which these fluids have been taken."

Sir Humphrey Davy, in his 'Consolations in Travel,' gives a very graphic account of finding these subterranean animals in Illyria. [SIREX.]

PROTOCOCCUS, a genus of Plants belonging to the natural order *Conservaceæ*. It is made the type of a tribe *Portococcidæ*, belonging to the sub-order *Palmellaceæ*. The *Palmellaceæ* are plants of the simplest kind, consisting of single cells somewhat globose or elliptical, and either free or connected together by a slimy mucus or frond. The latter forms constitute the tribe *Coccochloridæ*, whilst the former are the *Protococcidæ*. In this tribe are included the genera *Protococcus*, *Hematococcus*, *Chlorococcus*, *Pleurococcus*, *Hormospora*, and *Stereococcus*. Of these genera *Protococcus* is the most interesting, as affording the red cells, which, frequently occurring on snow, have got for it the name of the Red-Snow Plant. The genus is thus defined:—Plant consisting of aggregated naked globules filled with minute granules, and sessile on a gelatinous transparent mass. [SNOW, RED.]

PROTOMEDEA. [ACALEPHÆ.]

PROTONOPSIS. [AMPHIBIA.]

PROTOPTERIS, a genus of Fossil Plants, from the coal formation, including *Stigillaria punctata* of Brongniart. (Presl.)

PROTOPTERUS. Under this name Professor Owen, in the manuscript catalogue of the Museum of the College of Surgeons, in June, 1837, recorded the principal characters of an extraordinary animal which he supposed to belong to the Malacopterygious Fishes. In the same year, Dr. Natterer published an account of a nearly allied animal under the name *Lepidosiren paradoxa*. This account appeared in the annals of the Museum of Vienna, and is drawn up from two specimens discovered by the author of the paper in South America. The memoir of Dr. Natterer on the South American *Lepidosiren* was followed by one from Professor Owen, in the 'Linnæan Transactions' (vol. xviii. part 2, p. 327), in which that anatomist describes in detail both the external characters and internal anatomy of the *Protopterus* above mentioned; and as he found this animal must be referred to the same genus as that discovered by Dr. Natterer, he adopted his generic term, and applied the name of *Lepidosiren annectens* to the species. The last-mentioned animal, says Professor Owen, "was presented to the Royal College of Surgeons, June, 1837, by Thomas C. B. Weir, Esq., together with a smaller dried specimen inclosed in indurated clay baked hard by the sun. Several species of insects peculiar to the Gambia, or African forms, accompanied these specimens. It is a female, with the ovaria well developed, and measures twelve inches eight lines in length; its greatest circumference is four inches and a half. The head commences by an obtuse muzzle, and gradually enlarges in all its dimensions to the gill-openings, which are situated immediately anterior to the base of the pectoral extremities: the length of the head, from the snout to the gill-opening, is one inch

eleven lines. The anus, or rather the cloacal vent, is a small elliptical aperture marked with radiating lines, which is situated three lines behind the ventral filaments, and offers the same peculiarity as does that of the *Lepidosiren paradoxa* in not being situated on the median plane; in the present specimen it was on the right side of a longitudinal fold of integument which occupied the middle line. This distance from the vent to the end of the tail is five inches. The trunk gives a wide elliptical transverse section, and maintains a pretty uniform size, slightly decreasing in breadth to the ventral filaments. Beyond these the tail becomes more rapidly compressed, and after a short distance diminishes also in vertical dimension, till it ends in a thin point. A membranous dorsal fin commences at the distance of four inches from the snout, and, gradually increasing to the height of five lines, is thus continued into the caudal membranous expansion.

*Lepidosiren annectens.*

This fin is supported by numerous soft, elastic, transparent rays, articulated to the extremities of the superior and inferior peripheral spines of the caudal vertebrae; the under part of the caudal fin commences about one inch behind the vent. The entire body is covered with cycloid scales, which are relatively larger, but have the same general structure and disposition as in the *Lepidosiren paradoxa*. They present a subcircular form, with a diameter of about three lines; their posterior margin adheres to the strong cuticle with which they are removed, as in other fishes; the anterior lies freely in a corresponding groove of the chorion. The disposition of the mucous pores and ducts upon the head is very similar in the two species of the *Lepidosiren*, judging from this figure given by Dr. Natterer. A linear series of mucous pores encircles each eye, and from the posterior angle of this series the lateral line commences. This line extends backwards nearly parallel with the dorsal line, situated a little more than one-fourth of the vertical diameter of the body of that line, until it nearly reaches the ventral extremities, where it bends down to midway between the dorsal and ventral margins, and so continues to the end of the tail. The rudimentary filamentary fins, the analogues of the four ordinary extremities in the *Vertebrata*, permanently represent in the present singular animal the earliest embryonic condition of the pectoral and pelvic members. They are round, filiform, gradually attenuated to an undivided point, resembling tentacles or feelers rather than fins or legs, and doubtless restricted to their tactile functions. Each filiform member is supported by a single-jointed, soft, cartilaginous ray. The pectoral tentacles are somewhat shorter and more slender than the ventral ones; the former are two inches, the latter two inches four lines in length. The branchial apertures are narrow vertical slits four lines in extent. The eyes appear externally as two small round flat spots of a lighter colour than the surrounding integument; they are situated seven lines from the end of the snout, and nearly the same distance apart from one another. Each of these simple visual organs measures one line and a half in diameter; it is not defended by any palpebral folds of the skin; the cornea is thin, sufficiently transparent to allow the lens to be visible even in the specimen preserved in spirits. The nostrils are situated at the under part of the upper lip, within the opening of the mouth. They appear as two small perforations leading to blind sacs. About a line behind the lower lip, between it and the teeth, there project six soft papillose processes, of a triangular form. Behind the upper lip there are eight similar papillose processes, four on each side. There are two small, slender, conical, sharp-pointed and slightly recurved teeth, which project downwards from the intermaxillary bone, to which they are attached by ligaments. These teeth, in their paucity, relative size, and mode of fixation to the maxillæ, resemble those of the *Chimæra* and some of the extinct cartilaginous fishes, as *Cochliodus* and *Ceradodus*; but they are unlike these in their microscopic structure, and differ from any known dental apparatus in the class of fishes, in the modifications of the working surface which at once adapt them for piercing, cutting, and crushing. The strength of the jaws, and

the size of the muscles which work them, are proportionate to the size and formidable character of the maxillary dental plates. There are no lingual, palatine, pterygoid, vomerine, or pharyngeal teeth."

The skeleton of this curious fish is partly cartilaginous and partly bony, and the osseous portions are of a green colour, as in the Common Gar-Fish (*Nelone vulgaris*). [BELONÆ.]

In reviewing the principal characters of the skeleton of the Lepidosiren, "we obtain," says Professor Owen, "good evidence of its ichthyic nature. If indeed the species had been known only by its skeleton, no one could have hesitated in referring it to the class of Fishes; but in that class it would have offered a most singular and interesting combination of the cartilaginous and osseous types.

"The central elements of the vertebral column, the basis of the skeleton, exhibit a persistence of its primitive embryonic condition, such as has hitherto been witnessed only in the sturgeon and cyclostomatous fishes; but the superior arches and spinous appendages, instead of retaining the cartilaginous state, are converted into the tough elastic fibrous texture characteristic of the skeleton of fishes. The cranium in like manner presents an extremely novel combination of the cartilaginous and bony states, both as regards its partial ossification and the condition of the ossified parts.

"It is only in the higher cartilaginous fishes, for example, that the maxillary, palatine, and pterygoid bones are blended together to form the simple superior dentigerous arch, or upper jaw. The composition of the lower jaw corresponds with that which characterises most of the osseous fishes, and is more simple than in the *Amphibia*. The confluence of the cranial vertebrae reminds one of the condition of the skull in the siren; but no vestige of a preopercular bone is present in any of the Perennibranchiates. The sphenoid bone, as it exists in the sturgeon, is here seen in its fully ossified state. As the basis of the vertebral column presents a condition analogous to that which characterises the early embryonic periods of the higher *Vertebrata*, so also the extremities retain their simple structure as when they first bud forth, and are devoid of any trace of digital divisions: still the march of development has begun, and we perceive by the numerous joints of the cartilaginous ray that its direction is towards the ichthyic modification of the great vertebral plan."

This animal is regarded by some naturalists as one of the *Amphibia*. In many points of its structure it certainly does approach that group of animals, especially in the condition of its air-bladder or lungs and its branchiæ; but as regards the former, we find considerable advances are made towards the reptilian structure by some other fishes; and it may be remarked that the present animal still differs widely from the *Amphibia* in possessing distinct large scales. There is another character which it appears is of the highest importance in determining the class to which the Lepidosiren belongs, namely, the structure of the nostrils. "In the organ of smell," says Professor Owen, "we have at last a character which is absolute in reference to the distinction of fishes from reptiles. In every fish it is a short sac communicating only with the external surface; in every reptile it is a canal with both an external and an internal opening. According to this test, the Lepidosiren is a fish; by its nose it is known not to be a reptile. In other words, it may be said that the Lepidosiren is proved to be a fish, not by its gills, not by its air-bladders, not by its spiral intestine, not by its unossified skeleton, not by its generative apparatus, nor its extremities, nor its skin, nor its eyes, nor its ears—but simply by its nose; so that at the close of our analysis we arrive at this very unexpected result, that a reptile is not characterised by its lungs nor a fish by its gills, but that the only unexceptionable distinction is afforded by the organ of smell."

In conclusion, the author states—"From every group of fishes however the Lepidosiren is sufficiently distinct to form a type, not merely of a genus, but of a family; and in the natural system it forms a link connecting the higher Cartilaginous Fishes with the Saurian genera *Polypterus* and *Lepidosteus*; and at the same time makes the nearest approach in the class of Fishes to the Perennibranchiate Reptiles."

The South American Lepidosiren (*Lepidosiren paradoxa*) greatly resembles the species above described, but differs somewhat in its proportions. The whole length of *L. paradoxa* includes eleven lengths of the head, measured from the end of the mouth to the gill-openings; in the *L. annectens* the total length of the animal includes little more than six lengths of the head. This species is therefore distinguished from the *L. paradoxa* by the shorter relative length of the trunk as compared with the head.

PROTOROSAURUS, Meyer's name for the Fossil Monitor of Thuringia.

PROTOZOA, a term applied by Oken to the lowest forms of animal life. *Protozoa* has been applied to the same forms of vegetable life. As employed at the present day, it embraces the group of Infusoria termed by Ehrenberg *Polygastrica* [INFUSORIA], the *Rhizopoda* of Dujardin embracing the *Foraminifera* [FORAMINIFERA] and the Sponges. [SPONGIADÆ.] The *Acrita* of M'Leay, and the *Oozoa* of Cuvier, correspond to this section of the animal kingdom.

PROX. [CERVIDÆ.]

PRUNELLA, a genus of Plants belonging to the natural order *Labiata*. It has two inferior stamens; the filaments bifid, one branch barren; the anthers all 2-celled; the corolla ringent, the upper lip

concave, entire; the calyx ultimately closed and compressed, the upper lip flat, truncate, 3-toothed, the lower lip bifid.

P. vulgaris, Self-Heal, is a native of Europe and Asia; very plentiful in America and Australia, and also in England. The leaves are stalked, ovate or oblong, toothed or deeply pinnatifid; the upper lip of the calyx with short truncate mucronate teeth; the lower lip with ovate-lanceolate mucronate teeth, the two longest stamens with a straight spinous root at their apex. The flowers are purple, white, or nearly red. In the British specimens the leaves are nearly entire. This plant is considered astringent, and was formerly used in fluxes and gargarisms for apthæ and inflammation of the fauces. Its reputation is now merely in name.

P. grandiflora has petiolate ovate leaves, quite entire or toothed, the lateral teeth of the upper lip of the corolla lanceolate; the corollas large, more than twice as long as the calyx. It is native throughout Europe in woods and shady places. The flowers are of a purple or violet colour, seldom white.

(Babington, *Manual of British Botany*.)

PRUNUS, a genus of Arborescent Rosaceous Plants, belongs to the Amygdaleous division of the order, and comprehends several of our domestic fruits. The Cherry, Bird-Cherry, Plum, Damson, Sloe, Bullace, and Apricot, are all comprehended in the genus as limited by Linnæus; but in the opinion of some modern botanists, the true Plums require to be separated from the others, and should exclusively constitute the genus *Prunus*, while the others are to be considered as belonging to two other genera, represented by the Cherry and the Apricot. In this view of the subject, each genus is characterised thus:—

Armeniaca, the Apricot.—Drupe woolly outside. Stone blunt at one end, sharp-pointed at the other, with a furrow passing all round it, and an even surface. Young leaves rolled up.

Cerasus, the Cherry.—Drupe smooth, without bloom. Stones roundish, smooth. Young leaves folded flat.

Prunus, the Plum.—Drupe smooth, covered with bloom. Stone sharp-pointed at each end, furrowed all round, and smooth on the surface. Young leaves rolled up.

Of the Plum genus, thus restricted, there is in common use the Garden Plum (*P. domestica*), with all its numerous varieties, the Bullace (*P. insititia*), and the Sloe (*P. spinosa*). These plants are distinguished specifically by botanists, but apparently without reason. It is the opinion of the best experimental physiologists, that the Sloe of our hedges was the origin of the others; and certainly there is not more difference between a Sloe and a Greengage than there is between a German Quetscho and an English White Magnum-Bonum. Several other species belong to the genus, but they are of no moment, with the exception of a plant called *Prunus Coccinilla*, which inhabits the mountains of Calabria, and has a great reputation in Italy on account of the tonic qualities of its bark.

PSALIODUS. [GOAT-SUCKERS.]

PSALIODUS, a genus of Fossil Fishes. [FISH.]

PSAMMA, a genus of Grasses belonging to the tribe *Arundinææ*. It is known by its flower being enveloped in long silky hairs, the lower glume shorter than the upper, and its panicle being spike-like.

P. arenaria, Sea-Reed, Marram, is the only British species. It is found on sandy sea-shores, where its roots assist in binding the shifting sands.

PSAMMO'COLA, M. De Blainville's name for a genus of Conchifers (*Psammobia* and *Psammotæa*, Lam.) belonging to Lamarck's family *Nymphaeææ*.

PSAMMO'DROMUS, a genus of Saurian Reptiles.

PSAMMODUS, a genus of Fossil Fishes. (Agassiz.) [FISH.]

PSAMMOSAURUS. [MONITORIÆ.]

PSARIS. [MUSCICAPIDÆ.]

PSELAPHUS (Herbst), a genus of Coleopterous Insects, but now regarded as a family, to which the name *Pselaphide* is applied. The *Pselaphi* are very minute insects, and most remarkable in their structure. By some entomologists they are arranged with the *Brachelytra*, owing to their having the wing-cases short and truncated; and by others they are placed in the section *Trimera*, their tarsi having but three joints: in the classification of Latreille they constitute the last family of Coleopterous Insects, being placed at the end of the *Trimera*.

Scarcely any of the known *Pselaphi* exceed one-twelfth of an inch in length, and the greater portion of them are under that size; they prey upon other insects still smaller than themselves, and are found under stones, and amongst herbage, especially in damp situations. Some species are found under the bark of trees, and in putrid wood, and the species of one of the genera are found in ants' nests (the genus *Claviger*). They are often collected during the winter months by shaking the moss from the roots of trees, or from old walls, over a piece of white paper or cloth. They are probably found in all parts of the world. The principal characters of the group are as follows:—

Head moderately large, exerted, and most commonly of a triangular form, being broad at the base and attenuated in front; the eyes moderately prominent, sometimes wanting; palpi usually large and generally 4-jointed; antennæ usually 11-jointed, sometimes with 6 joints, and in one genus apparently having but one large joint, generally equal to about half the length of the insect, and increasing

in thickness from the base to the apex. Thorax usually not much broader than the head, sometimes nearly cylindrical, but most commonly dilated in the middle; elytra broad, much shorter than the abdomen, and truncated behind, destitute of striae, if we except one on each elytron near the suture, and an abbreviated stria at the base about mid-way between the suture and the outer margin—these are almost constant. Abdomen broad, obtusely terminated, and without appendages as observed in the *Brachelytra*; usually four or five joints are visible beyond the elytra. Legs rather long; tibiae curved; tarsi 3-jointed, the basal joint small, and the terminal joint furnished either with one or two simple claws.

The *Pselaphidae* are composed of the following 13 genera, which may be most briefly characterised by throwing them into a tabular form, as in M. Aubé's Monograph, published in Guérin's 'Magasin de Zoologie' for the year 1834.

Section 1. Antennae two-jointed.

Division 1. Tarsi with two claws.

1. *A.* with the claws unequal.—*Metopias*.

1. *B.* with the claws equal.—*Tyrus*, *Chennium*, *Ctenistes*.

Division 2. Tarsi with a single claw.

Pselaphus; *Bryaxis*; *Tychus*; *Bythinus*; *Trimium*; *Batrius*; *Euplectus*.

Section 2. Antennae six-jointed.

Claviger.

Section 3. Antennae with but one large and elongated joint.

Articerus.

Examples of most of these genera are found in this country. Of the genus *Metopias* only one species is known; it inhabits Guyana. The genus *Tyrus* is found in Sweden and Germany, and perhaps in England. Of the genus *Chennium* but one species is known: it is found in the south of France. The curious genus *Claviger* has been discovered in England by Mr. Westwood: it is found in the nest of a species of ant (*Formica flava*). On the Continent it has been long known.

Owing to their remarkable appearance, and the curious forms displayed by the various species, the *Pselaphidae* have been more carefully studied perhaps than any other group of minute insects, and have given rise to several monographs—see the 'Monographia Pselaphidorum et Seydmenidarum Britanniae,' by H. Denny, Norwich, 1825, 1 vol. 8vo.; 'Monographia Pselaphorum,' H. F. L. Reichenbach, Lipsia, 1816, 1 vol. 8vo. P. W. J. Müller has published a monograph on the *Pselaphi* in the third volume of the 'Magazin der Entomologie, von E. F. Germar.' M. C. Anbé has likewise published an excellent monograph on the same group, which has been quoted in the former part of this article.

PSEUDOBDELLA. [ANNELIDA.]

PSEUDOCARCINUS, M. Milne-Edwards's name for a genus of *Crustacea*.

The general form is that of many *Xanthi*. [XANTHUS.] The carapace is slightly convex, and a little embossed near the front, which is nearly horizontal; latero-anterior borders moderately curved, and armed with more or less projecting teeth; posterior portion of the carapace nearly of the same extent as the anterior, with its lateral borders straight, and directed very obliquely backwards. The basilar joint of the external antennae is very small, the second hardly reaches the front, and the third, which is lodged in the orbital gap, does not fill it, so that the antennary fosses are not completely separated from the orbit; the terminal stem of these appendages, instead of being very short, is more than twice as long as its peduncle. The species are found in the Indian and Southern Oceans.

PSEUDOCORYSTES, M. Milne-Edwards's name for a genus of Brachyurous Crustaceans belonging to his tribe of Corystians, and bearing much analogy to *Corystes* [CORYSTES], and especially to *Navtilocorystes*.

General form approximating to *Corystes*, but the feet natatory, as in *Navtilocorystes*: jaw-feet differing from those of both.

PSEUDOGRAIPSUS. [GRAPSIDAE.]

PSEUDOLIVA, a genus of *Gasteropoda*.

PSEUDOPODIA. [INFUSORIA.]

PSEUDORHOMBILA. [GONOPLACIDAE.]

PSEUDOCARIA, a term proposed by De Blainville to include plants, many of which have been ranked with the *Polyparia*. It is subdivided into two classes: *Calciphyta*, which are principally composed of the genus *Corallina*, Linn.; and *Nematophyta* (also called *Nematozoaria*), which include *Conferva*, *Oscillatoria*, *Byssus*, &c. [ALOE; CORALLINACEAE.]

PSIDIUM (from *ψιδιον*, the Greek name for a pomegranate), a genus of Plants belonging to the natural order *Myrtaceae*. The tube of the calyx is ellipsoid or obovate, usually contracted at the apex; the limb ovate, undivided, but afterwards from 1- to 5-cleft. There are five petals and numerous free stamens inserted in a broad circle, almost through the whole undivided part of the limb; the style is filiform, the stigma capitate; the ovules are numerous, horizontal, and fixed to the margin of the placenta; the berry is many-seeded, corticate by the tube of the calyx, and crowned by its lobes. The seeds imbedded

in the pulp in the mature fruit with a bony testa. The species are trees or shrubs, natives of America within the tropics. The fruit is edible, and is known by the name of Guava. It has a fragrant but peculiar odour and very sapid taste, and is eaten both raw and when made into jelly.

P. pomiferum, Apple-Bearing or Common Red Guava, has tetragonal branches, oval or oblong lanceolate leaves, pubescent beneath, from 3 to 8 peduncles, or many-flowered. The fruit is globose, yellow, and somewhat astringent, with an agreeable odour; the root and young leaves are astringent; and are esteemed strengthening to the stomach. It is a native of the West Indies, Mexico, and South America.

P. montanum has tetragonal branches, oval-oblong leaves, acuminate and quite glabrous; the peduncles many-flowered, and the fruit roundish. It is a native of Jamaica on the mountains. The fruit is small, acid, and smells strongly like bitter almonds, hence it is called *Almandron*. The wood is very hard and of a fine colour and grain. It works well, takes a fine polish, and is much esteemed for ornamental purposes.

PSILOSTOMATINA. [CHEIROPTERA.]

PSILOMELANE. [MANOANESE.]

PSILOPOGON. [PICIDÆ.]

PSILOMATA, M. De Blainville's name for his third family of his order *Aporobranchiata*, and placed by him at the end of that order and immediately before the order *Polybranchiata*, which contains the genus *Carolina*. [POLYBRANCHIATA.]

The only genus of *Psilosomata* recorded by M. De Blainville is *Phyllirice*.

Body free, naked, very much compressed, or much higher than it is thick, terminated behind by a sort of vertical fin; cephalo-thorax small, and provided with a pair of natatory appendages, which are triangular, compressed, and simulate a kind of long tentacles or branchiae; mouth subterminal, of a horse-shoe shape, with a short retractile proboscis; anus on the right side of the body; orifice of the organs of generation unique, on the same side, and more anterior than the anus. Organs of respiration (?).

Ex. *Phyllirice Bucephalum*.

This species was discovered in the Mediterranean Sea by Péron and Lesueur.

PSITHYRUS, Saint Fargeau, a genus of Hymenopterous Insects belonging to the section *Anthophila* (Latreille) and family *Apidae*. The insects of this genus so closely resemble the Humble-Bees (*Bombus*), that till recently they were by all authors confounded with them. The *Psithyri* however differ widely from the Humble-Bees, inasmuch as they make no nests of their own, neither do they collect food for their young, but, like the Cuckoo among birds, they deposit their eggs in the nests of others, and leave their young to be hatched and reared by them. It is the nests of the Humble-Bees that they select for this purpose. Mr. Newman considered these facts relating to their economy so important, that he established an order among Hymenopterous Insects, to which he gave the name *Apathites* (from *α*, without, and *πάθος*, affliction), for the reception of the present insects, which, according to him, constitute the genus *Apathus*, and some other genera of bees. The characters of the order *Apathites*, given by the author, are as follows:—Larva hatched from an egg, deposited by its parent in the nest of other *Apidae* at the time when their own eggs are laid; when it hatches, being stronger and larger than the rightful possessor of the cell, it consumes the food provided for its companion, and starves it to death; and in those instances in which fresh supplies of food are daily provided, it continues to receive and appropriate them as its own. Pupa changes in the same situation, in a silken cocoon, spun by the larva. Imago has no apparatus either on the body or legs for collecting honey; in other respects it resembles in structure each of the other orders of *Apidae*. It enters their nest with perfect familiarity, and seems to be quite unsuspected of intrusion. It collects no pollen or honey, never builds a nest of any kind, nor takes any care of its young, but spends its time among flowers, or hovering about sand-banks in which other bees have fixed their habitations. The genera included in this order are—*Apathus* (or *Psithyrus*), *Celiocorys*, *Melecta*, *Stelis* (?), *Epeolus*, *Nomada*, and *Hylaeus* (?). ('Entomological Magazine,' vol. ii. p. 404.) The order *Apathites* however is very objectionable in many points of view; it is founded upon the habits of the species, whilst in fact the habits of the individuals composing the very genera placed by the author in his order are in many cases but partially known: the order moreover comprises genera agreeing in no positive points of structure.

The species of the genus *Psithyrus* may be distinguished from those of *Bombus* by the structure of their hinder legs. In *Bombus* the hinder tibia is compressed, smooth, and somewhat concave on the outer side, and is furnished on its edges with a fringe of stiff curved hairs, which serve to retain on the outer side of the shank the pollen collected by the insect to feed its young. The *Psithyri* have the tibia narrower and covered throughout with hair. They have no basket for the purpose of carrying pollen.

Four or five species of *Psithyrus* are found in England, and these are well described by Kirby in his 'Monographia Apum Angliae.' They are arranged by that author in his genus *Apis*, section **, c. 2, which section also includes the true *Bombi*.

Psithyrus rupestris very closely resembles the Red-Tailed Humble-

Bee (*Bombus lapidarius*), but may be distinguished by the dark (almost black) colour of its wings. The *Apis Albinella* of Kirby is no doubt the male of this species.

P. campestris is black, has a yellow band on the fore part of the thorax, yellow hair on the scutellum, and a patch of yellow on either side of the abdomen at the apex. *Apis Rossiellus* of Kirby is no doubt the male of this species.

P. Barbastellus is black, has the fore and hinder portion, the thorax, and the base of the abdomen yellow; the apex of the abdomen is white.

Apis subterraneus and *A. vestalis* of Kirby's monograph also belong to this group.

PSITTACIDÆ, an extensive and highly-interesting family of Birds, including those commonly called Parrots. They are remarkable for their beautiful colours, their powerful bill, their fleshy tongue, and their power of imitating the human voice. The articulation of some of the species is so perfect, that when the bird is unseen it is difficult to suppose that the words pronounced do not proceed from the mouth of man.

That several of these birds were known to the ancients, both Greek and Roman, we have abundant evidence. Not to weary the reader with quotations, we shall here only refer to Ctesias ('Indic,' 3; Phot. 'Bibl.' lxxii.); to Aristotle ('Hist. Anim.,' viii. xii.), where he notices the *Vitrax* as the Indian Bird, and refers to its powers of mimicry; to Arrian, who speaks of the *Sitracos*, and its imitation of the human voice ('Hist. Ind.,' c. xv.); to Plutarch, who alludes to the same quality in his treatise, 'De Solertia Animalium' (vol. x., p. 51, ed. Reiske; vol. iv., p. 972, Lut. Paris, 1724); to Ovid ('Amor.,' ii. 6); Persius, in the prologue to his 'Satires' (line 8); and Martial's delicate flattery (xiv. ep. 73)—

"Psittacus, à vobis aliorum nomina discam;
Hoc didici per me dicere, Cæsar ave."

These, with the exception of the passage in Ctesias, and many more examples, will be found in the learned treatise by Mr. Vigors, 'On a group of Psittacidae known to the Ancients' ('Zool. Journ.,' vol. ii.), where he reminds us that the ancient writers are unanimous in informing us that the Parrots known to their times came exclusively from India. "We are informed by Ælian," continues Mr. Vigors, "that they were the favourite inmates of the palaces of the princes; and were looked up to as objects of sacred reverence by the religious feelings of the people. From thence they were introduced into Europe at the time of the Macedonian conquest; and the specific name of *Alexandri*, applied by modern science to the type of the group, in honour of the first European discoverer of it, serves to perpetuate the name of a warrior who is said to have valued the conquests that extended the boundaries of his empire chiefly as they served to extend the boundaries of science. It was not until the times of Nero that the Parrots of Africa became known to the Romans. (Pliny, 'Hist. Nat.,' vi. 29.) Some of these birds were among the discoveries made in the course of an expedition sent out by that prince. They came apparently from the neighbourhood of the Red Sea; and it is probable that, as that country became more known, numbers of the same race were imported from it into Rome, and formed the chief part of those victims of the Parrot tribes which in after-times are said to have supplied the inordinate luxury and wantonness of Heliogabalus. The Indian group, thus familiar to the ancients, may be identified with those beautiful birds, equally the favourites of our modern times, which are brought to us from the same country, and which are distinguished by the rose-coloured collar round their neck, the brilliant emerald of their body, and the deep ruby of their bill. Pliny ('Hist. Nat.,' x. 42) points out distinctly the former character. Solinus, in general the servile copier of Pliny, confirms this description, though with a slight variation as to colour. ('Polyhist.,' c. 23.) Apuleius again alludes to the same characters, but more immediately and forcibly distinguishes the varying tints of the collar round the neck. ('Florida,' lib. ii.) Oppian gives the bird an epithet (Ποσειχρὸν ὄρνις, 'Grass-coloured bird,' 'De Venat.,' vii. 488); while Ovid, in like manner, particularises both the emerald plumage and the deep red bill. ('Amor.,' ii. vi.) To this group Mr. Vigors has assigned the name of *Palæornis*.

The upper mandible, which is immovable in mammals, has more or less motion in birds. [Birds.] Some birds indeed, for instance the capercaillie and rhinoceros birds, are not gifted with this motion; but mobility of the upper mandible is the rule in this class, and the want of it the exception. In the *Psittacidae* this power is highly developed; for the upper mandible is not connected into one piece with the skull, by yielding and elastic bony plates, as is the case with birds in general, but constitutes a particular bone, distinct from the rest of the cranium, and articulated to it.

The advantages derived to the animal from this conformation are obvious to any one who watches a parrot taking its food or using the bill as a third extremity to assist it in climbing about its cage. In most birds there is a progressive increase in the number of the phalanges of the toes: thus the great toe has two, the next three, the middle toe four, and the outer toe five. The parrots possess a peculiar cross-bone belonging to the great toe. In common with the pigeon and some other birds, they are destitute of a gall-bladder. Their intestines are very long, and are without cæca. The soft thick tongue

so characteristic of this tribe must be a highly sensitive organ of taste. It is covered with papillæ, and moistened with a salivary secretion, so that they are able to taste and select different articles of food. In some of the forms, the *Trichoglossi* for instance, which feed on the nectar of flowers, the brush-like tongue is fringed with tubular pro-

Skull of Macaw.

cesses, in conformity with the suctorial mode of feeding adopted by these birds. One of them kept by Mr. Caley, on seeing the coloured drawing of a plant, made an attempt to suck the flowers, and evinced the same disposition towards a piece of printed cotton furniture. The accurate observer last mentioned supplied the *Psittacus pusillus*, Lath., a species of the same genus, with honey and moistened sugar, which it sucked with ease and apparent pleasure by means of its brush-like tongue. The tongue is short, thick, and fleshy, as in most of the parrot tribe; but it is further distinguished by terminating in a number of very delicate and close-set filaments, which can be protruded and expanded like a brush. The plumage of this extensive family is of the most rich and varied description, embracing almost every colour and gradation of tint. The Zoological Society of London possesses one of the finest living collections of these splendid birds in the world. The quantity of mealy dust discharged from the skin by the cockatoos, and other species of parrots, particularly at pairing time, is remarkable; though the separation of this peculiar matter from the skin is not confined to this family, but is effected in many birds of different orders, eagles and herons for instance. The characters of the powerful bill, and the grasping scansorial foot, which last is so constructed as also to convey the food to the mouth, will be seen below.

Head of Macaw.

Foot of Macaw.

This large, hard, and solid bill, rounded throughout, and surrounded at its base with a membrane wherein the nostrils are pierced, together with the thick fleshy and rounded tongue, gives the *Psittacidae*, as Cuvier observes, the greatest facility in imitating the human voice, a facility to which their complicated lower larynx, with its three peculiar muscles on each side, contributes. Their strong mandibles, formed for shelling and cracking the hardest fruits, are worked by more numerous muscles than those of other birds.

The Parrot tribe are found in great numbers in warm climates, and principally in the torrid zone. They are however abundant in the southern hemisphere, and occur even in high latitudes, whilst in the north they do not appear to be represented beyond the tropics by any species, except perhaps in India by *Palæornis*. Parrots occur in the southern extremity of America, throughout Australia, in Van Diemen's Land, New Zealand, and even in Macquarrie Island, in 52° S. lat. They are monogamous, and make their nests in the holes of trees, which they climb with their feet and bill. The shortness of their wings not permitting them to pass wide seas, the old and new continents, and even some of the large islands, have their particular species. Their food consists of fruits of almost every kind, and their natural voice is loud, harsh, and grating almost beyond endurance.

Brisson places the Parrots in his thirteenth order of birds, consisting of those with two anterior and two posterior toes. This order he divides into four sections: the first, with a straight bill, includes the Wryneck, Woodpecker, and Jacamar as generic forms; the second, with the bill rather curved, the Barbets and Cuckoos; the third, with the bill short and hooked, the Trogons, Crotophaga, and the Parrots; and the fourth, with the bill long, and of the size of the head, the Toucans.

Linnaeus placed the genus *Psittacus* at the head of his order *Pica*, with the following definition:—Bill hooked; upper mandible moveable, furnished with a cere. Nostrils situated in the base of the bill. Tongue fleshy, obtuse, entire. Feet scansorial.

He divided the genus, which is preceded by *Lanius* (the Shrikes), and immediately followed by *Ramphastos* (the Toucans), into the following sections:—

* *Macrouri cauda cuneiformi*.

This division contained the Maccaaws.

** *Macronri minores*.

This division contained *Psittacus Alexandri* and the Parrakeets generally; but both in this and the former division we find Parrots that can hardly be called 'long-tailed.' Thus in the first division we have *Psittacus nobilis* with the synonyms of '*Psittacus viridis alarum costa superne rubente* of Aldrovandi (vol. i., t. 669), Sloane, Jam., 2, p. 297,' '*Psittacus Amazonicus*, Briss., and *P. medicæ magnitudinis*, Will., t. 16:' whilst in the second we find the *P. agilis*, *P. minor viridis* of Edwards.

*** *Brachyuri cauda æquali*.

This contained the Cockatoos, Lories, and true Parrots.

Cuvier places the *Psittacidae* between the Toucans and the Touracos; they consist of the *Aras* (*Ara*, Kuhl); *Perruches* (*Conurus*, Kuhl), divided by Le Valliant into *Perruches-Aras*, which have naked cheeks (*Psittacus Guyanensis*, &c.); *Perruches à Queue en Flèche* (*Palæornis*); and *Perruches à Queue Élargie vers le Bout* (*Platyercus*); Cockatoos (*Ptyctolophus*); True Parrots; Lories; Short-Tailed Parrots (*Psittacula*, Kuhl); and Parroquets à Trompe, Le Vaill. (*Microglossus*, Vieill.), of which last Cuvier thinks that the *Perruches Ingambes* (*Pezoporus*, Ill.) may be made a sub-genus.

Mr. Swainson is of opinion that the Parrots constitute the sub-typical division of the *Scansores* wherein the powers of climbing are less developed. "If," says Mr. Swainson, "any group in nature be isolated, it is this. Possessing in themselves the strongest characteristics, there is no bird yet discovered which presents any point of connection to them: approximations indeed are certainly made towards them by the tooth-billed Barbuts (Barbets, *Pogonias*); but there is still a gap, which no genus yet discovered is calculated to fill up. On considering the relative difference between the Barbuts and the Parrots, we should say, theoretically, that of all the five groups among the latter, one only remains to give the typical structure." As the Parrots appear to Mr. Swainson to form a group precisely equivalent to the true Woodpeckers, he arranges them under five genera: the Maccaaws, the Parrots, the Cockatoos, the Lories, and the Ground Lories (*Platyercus*, Vig.). In the synopsis at the end of the work ('Classification of Birds') we find the following arrangement:—

Psittacide.

Bill very short: the upper mandible greatly curved over the lower, which is considerably shorter.

Sub-Family *Macroercina*. Maccaaws.

Upper mandible greatly hooked; lower mandible much higher than broad. Tail very long, cuneated.

Genera: *Macroercus*, Vieill.; *Conurus*, Kuhl; *Leptorhynchus*, Sw.; *Palæornis*, Vig.

Sub-Family *Psittacina*. Parrots.

Upper mandible very distinctly toothed; lower mandible longer than it is high. Tail short, even, or rounded.

Genera: *Erythrostomus*, Sw.; *Chrysotis*, Sw. (Amazonian Parrots); *Psittacus* (Parrot of the Old World—most typical of this sub-family); *Agapornis*, Selby; *Poicephalus*, Sw.

Sub-Family *Ptyctolophina*. Cockatoos.

Head large, ornamented with a folding or procumbent crest. Bill short, very broad; the culmen remarkably curved. Tail rounded, lengthened, broad; the feathers not narrowed.

Genera: *Ptyctolophus*, Vieill. (subtypical); *Licmetis*, Wagl.; *Microglossus*, Geoff.; *Centrourus*, Sw.

Sub-Family *Loriance*. Lories.

Bill but slightly curved; the margin of the upper mandible situated; the notch obsolete; lower mandible slender, conic, much longer than high; the gonys (typically) straight.

Genera: *Brotoeris*, Vig.; *Psittaculus*, Kuhl; *Trichoglossus*, Vig.; *Lorius*, Brisson; *Pyrrhodes*, Sw.

Sub-Family *Platyercina*. Loriets.

Tail long, very broad, considerably cuneated. Bill strong, thick, toothed: the culmen very convex. Under mandible deep, but very short: the gonys curved. Feet and toes slender. Tarsus longer than the hallux.

Genera: *Vigorsia*, Sw.; *Platyercus*, Horsf. and Vig.; *Nanodes*, Horsf. and Vig.; *Leptolophus*, Sw.; *Pezoporus*, Ill. (Swainson.)

The family is placed by Mr. Swainson between the *Rhamphastidae* and the *Picidae*.

Mr. G. R. Gray ('List of the Genera of Birds') also arranges the *Psittacidae* between the *Ramphastidae* and the *Picidae*.

We proceed to lay before the reader some of the forms here mentioned.

Macroercus.—The Maccaaws are all natives of America, and principally of its southern portion. The Carolina Arara (*Psittacus Carolinensis*, Linn.) has been recorded as occurring in the United States as high as 42° N. lat., though, according to Audubon, few are now to be found higher than Cincinnati; but the true Maccaaws are natives of much warmer latitudes. Though the tongue is thick, fleshy, and soft, their powers of imitation fall far short of those of the true Parrots and Parrakeets, and the harsh tones with which, after much teaching, they not very perfectly articulate a few words, contrast strongly with the assumed musical voice and ready docility of the latter. They are however capable of great attachment when domesticated. Their natural notes are screams of the most discordant and piercing kind. The hollows of trees are the places selected for their nests, and the number of eggs laid amounts to two, which are said to undergo the incubation of the male as well as the female.

Blue and Yellow Macaw (*Macroercus Ararauna*).

The Great Green Macaw (*Psittacus militaris*, Auct.), inhabiting the warmer districts of the chain of the Andes, where it is found as high as about 3000 feet, in Mexico and Peru; the Hyacinthine Macaw (*Macrocerus Hyacinthinus*); the Red and Blue Macaw (*M. Aracanga*); and the Blue and Yellow Macaw (*M. Ararauna*), are known to most admirers of this gay race; though the Hyacinthine Macaw is rarely seen alive in this country, and is not common even in museums.

The genus *Macrocerus* has the following characters:—Size large. Orbits and sometimes the face destitute of feathers. Nostrils concealed. Notch in the upper mandible obsolete; the under remarkably short, but very deep. (Sw.)

M. Ararauna has the bill black, largely and strongly developed. The upper mandible, which not unfrequently measures from the forehead to the tip $3\frac{1}{2}$ inches, is much deflected: the under mandible is short, deep, and very stout. Cheeks white, naked, with three fine narrow lines of black plumelets under the eyes, the irides of which are yellowish. Beneath the under mandible a broad black band extending upwards to the ears behind a great part of the white naked patch. Plumage rich blue above, blending into green on the forehead, crown, some of the smaller wing-coverts, and rump. Greater quills and tail nearly violet. Wings and tail, beneath, yellow. The rest of the under parts rich saffron. Legs and feet blackish-gray. Total length about 39 inches, of which the tail measures some 24 inches.

It is a native of tropical America, the Brazil, banks of the Marañon, or Amazon River, Guyana, Surinam, &c.

Though generally living in pairs, the Blue and Yellow Macaws sometimes assemble in large flocks, their favourite haunts being swampy woods where a species of palm on whose fruit they principally feed is abundant. They fly well and often very high, showing a great command of wing, especially before they alight on the top of the lofty trees which they select for their resting-place. The two eggs, which are laid in the hollows of decayed trees, as well as the young, are said to receive the parental care of the male as well as of the female, which have two broods a year generally.

Psittacara.—Between the Macaws and Parakeets (*Palæornis*) comes the genus *Psittacara* (Vig.). "These birds," says Mr. Vigors, "although their cheeks are covered with feathers, and they are thus brought within the circle of the Parakeets, have yet the bill of the Macaws; and by a greater or less nakedness of the orbits round the eyes they still further assert their affinity to them. From their osculant situation between the two groups, thus strikingly apparent, the species that exhibit these characters have received the familiar name of Parakeet-Macaws in our language, and of Perruche-Aras among the French ornithologists. Like the true Macaws, they are exclusively natives of the New World." (*Zool. Journ.*, vol. ii.) Mr. Vigors adds in a note, that a species nearly allied to both these groups had then lately been brought to this country.

It has the following characters:—Head feathered, space round the eye naked. Bill thick, rather short; upper mandible compressed at the apex, the lower mandible very short inclining inwards, deeply

emarginate. Wings moderate; first and fourth quills equal, third rather longer, second longest; internal web of the first slightly notched near the middle, external webs of the second to the fifth inclusive gradually broader in the middle. Feet rather strong, tarsi short. (Vigors.)

P. leptorhyncha. Green; space round the eye white; interocular band and frontal fillet red; tail cinnamon red.

The sub-family *Palæornina*, as it appears in Mr. Vigors and Dr. Horsfield's 'Description of the Australian Birds in the Collection of the Linnean Society' ('*Linna. Trans.*' vol. xv.), consists of the genera *Nanodes*, *Platycercus*, *Pezoporus*, *Palæornis*, and *Trichoglossus*.

Palæornis.—The Parakeets forming this group belong to continental India and some of the neighbouring islands in the Indian Ocean and Africa, with the exception of *Palæornis Barrabandi* (*Polytelis* of Wagler), which is a native of Australia. India and its islands must however be considered as the principal locality of the species, which, according to Wagler's monograph, amounts to eleven, including *Palæornis inornatus*, which he adds to the group with doubt.

These Ring Parakeets, as they are generally termed, are justly held in high estimation for the symmetry of their form, the grace and elegance of their movements, the beauty of their colours, their great docility and powers of imitation, and their fond attachment to those with whom they are domesticated and who treat them with kindness. They were not less prized, as we have seen, by the ancients; and it becomes a not uninteresting inquiry to endeavour to ascertain what were the species known to them. Some suppose that *Palæornis Alexandri* was the only one: but though that species may have been and was probably the first introduced into Europe, we think that it will appear that those who confine the Parakeets known to the ancients to that bird have taken too narrow a view of the subject.

Ring Parakeet (*Palæornis Alexandri*).

This genus has the following characters:—Bill rather thick; the upper mandible dilated, the culmen round, the lower mandible broad, short, and emarginate. Wings moderate; three last quills (extimæ) nearly equal, longest; external webs of the second, third, and fourth gradually broader in the middle. Tail graduated; the two middle very slender feathers much exceeding the rest in length. Feet with short and weak tarsi; the claws moderate, rather slender, and falcate. Body slender and neat. (Vig.)

Mr. Vigors divides the genus into the following sections:—

• Lower mandible short.

P. Alexandri, *P. torquatus*, *P. flavitorquis*, *P. bitorquatus*, *P. xanthosomus*, *P. Malaccensis*, *P. erythrocephalus*, *P. Bengalensis*, *P. Pondicervianus*, *P. Barrabandi*.

Psittacus leptorhyncha.

** Lower mandible elongated.

P. Papuensis.

Platyercus (Loriets).—Bill rather short, the upper mandible rounded and dilated, the lower one short, deeply emarginate, with the apex squared. Wings rounded; the first quill shorter than the second and equal to the fifth; second and third longest; the external webs of all except the first abruptly notched towards the middle. Tail broad, depressed, rather rounded or sub-graduated; the tail-feathers rounded at the apex. Feet with elevated tarsi; the toes slender and elongated, and the claws long and but little falcated.

P. scapulatus, Tabuan Parrot, or King's Parrot.

Male.—Green; the head, neck, and body beneath scarlet; nuchal lunula and rump lazuline; longitudinal scapular line pale-green; cerulean; tail-feathers black, with brilliant green reflections.

Female.—Head and neck green.

It is a native of Australia.

Tabuan Parrot (*Platyercus scapulatus*).

Mr. Caley seldom noticed a full-coloured specimen, that is, red. He states that, when the Indian corn is ripe, they may be seen in large flocks on the farms, clinging on the stalks and occasioning much mischief to the corn. He apprehends that the greater part of these flocks are young birds, as it is rare to see a bright-red one among them. The natives told him that this species breeds chiefly in a white gum-tree (a species of *Eucalyptus*), making its nest of a little grass, and lining it with feathers. It has, he adds, as many as twelve young ones, and the eggs are of a dirty-white with black specks; the nest is found by its enlarging the hole at which it creeps in; this process gives the surrounding part a reddish appearance, which forming a contrast with the whiteness of the other parts, renders it conspicuous.

Nymphicus.—Bill distinctly toothed; culmen slightly carinated; nostrils thick, tumid, naked; head crested. Wings very long; outer web of the quills not sinuated. Tail very broad, cuneated; the two middle tail-feathers conspicuously longest and pointed. (Sw.)

N. Novæ Hollandiæ. Male.—Forehead, crest, and cheeks lemon-yellow; ear-coverts rich reddish-orange; back of the neck, two centre tail-feathers, and the external margins of the primaries brownish-gray; back, shoulders, and all the under surface and outer tail-feathers grayish chocolate-brown, the shoulders and flanks being the darkest; a white mark extends from the shoulders lengthwise down the centre of the wing; bill and bare space round the eye brownish-gray; feet blackish-brown.

The Female differs from the male in the colour of the face and crest being of a dull olive-yellow, the latter becoming still darker at its extremity; the throat grayish-brown and the back lighter than in the male; the lower part of the abdomen, upper tail-coverts, and tail-feathers, yellow, except the four middle ones, which are gray; the whole transversely and irregularly barred with lines of brown. Total length 12 inches.

Mr. Gould, whose accurate description we have given from his grand work on the 'Birds of Australia,' states that this species has many of the actions of the *Platyercus*, being extremely active, and running round its cage with surprising agility, in which particular it is only equalled by the most terrestrial members of the family. To give

NAT. HIST. DIV. VOL. IV.

some idea of the immense flocks of this beautiful bird, which inhabit the interior of Australia, the same author informs us that his brother-in-law, Stephen Coxen, Esq., procured more than 200 examples during a single excursion into the interior.

Nymphicus Novæ Hollandiæ.

Euphemia, Wagl. (*Nanodes*, Vig.).—Bill short; the culmen rounded, higher than it is long, being very like that of *Macrocerus*, the lower mandible very short, inclining inwards, and emarginate. Wings moderate, sub-acuminate; first and second quills, which are nearly equal, longest; the external webs of the second and third slightly emarginate towards the apex. Feet moderate; tarsi and toes rather slender. Tail gradually cuneated; tail-feathers slender towards the apex. (Vigors.)

E. undulata. Male.—Crown of the head and throat pale yellow, the latter ornamented on each side with several rich blue spots, a row of which, but of a darker tint, crosses the throat in the form of a

Euphemia undulata.

creescent; sides and back of the head, back of the neck, upper part of the back, scapulars, and wing-coverts olive-brown, each feather having a crescent-shaped mark of black near its extremity, and margined with yellow; primaries green on their outer edges, the tip and internal

web brown; secondaries crossed by a broad band of yellow, which is continued, but much narrower, across some of the primaries; breast, all the under surface, lower part of the back, and the tail-coverts, fine pale green; two centre tail-feathers deep blue at the base, passing into deep green at the tip; the remainder of the tail-feathers bright yellow, tipped with dark green; bill horn-colour at the base, passing into pale yellow at the tip; feet flesh-colour.

The Female differs in being less brilliant in all her markings, and in having the blue spots on the throat less defined and irregular in form. Total length $7\frac{1}{2}$ inches. (Gould, 'Birds of Australia.')

It is found in the interior of New South Wales.

Captain Sturt discovered this species in great abundance in the interior of New South Wales. He informed Mr. Gould that on the extensive plains bordering the Morumbidges he met with it in immense flocks, feeding upon the seeds and berries of the low stunted bushes called scrubs. Mr. Gould also received several from Mr. Coxen, which the latter had procured to the north of Hunter's River. Mr. Gould adds that they are quick and active, and run on the ground with great facility, much after the manner of the true *Platyercus*, or Ground Parrakeets, to which he is of opinion they are closely allied.

Trichoglossus (Lorikeets).—Bill somewhat elongated, rather compressed; lower mandible nearly straight, the margin entire, longer than it is high; tongue furnished below with many marginal bristles at the apex. Wings moderate; first quill longest, second and third a little shorter; webs entire. Feet rather short; tarsi somewhat covered with the femoral feathers; acrotarsi a little feathered below the knee; toes rather strong, depressed; claws strong, falcate. Tail graduated; the tail-feathers rather narrower at the apex. (Vigors.)

It is a native of Australia.

The natural and acquired habits of the species of this genus require some notice. Mr. Caley informs us that the Blue-Mountain Parrot, War'rin of the natives (*T. hæmatodus*), is remarkable for its docility

Blue-Mountain Parrot (*Trichoglossus hæmatodus*).

and attachment to some people, whilst it is a perfect scold to others who may have teased or offended it. "Flocks of these birds," says this accurate observer, "may be seen in the *Eucalypti* trees when in flower, in different parts of the country, but in the greatest number near their breeding-places. It does not eat any kind of grain, even when in a domesticated state. It is much subject to fits, which generally prove fatal; and it is rare to find an individual kept alive above a couple of years. One that I kept, on being shown a figure of a coloured plant, used to put its tongue to the flowers, as if with the intent of sucking them; and I have seen it make the same attempt with a piece of cotton furniture. The flesh of this bird is very good eating." Again, speaking of the Crimson-Fronted Parrakeet, Coolich of the natives (*T. concinnus*), Mr. Caley states that it may be observed in large flocks sucking the *Eucalypti* flowers. He adds that, like the Blue-Mountain Parrot, it is subject to fits, which generally prove fatal, that it is seldom kept alive, and that its breath, or some part about its head, emits a very sweet odour. The natives told him that this species breeds in the hollow boughs of trees, scraping out the decayed mould, and making its nest of it. The eggs, he informs us, are green,

without spots, and the number of young two. Of the Small Parrakeet, Jerryang of the natives (*T. pusillus*), he observes that this, like the Coolich, is seen in very large flocks in the *Eucalypti* trees when in blossom. "The natives," says he, "now and then bring in the young ones, but they seldom live long. I had three young ones for some time, which used to huddle together, and give out a very pleasing note. They all died, strongly convulsed, and nearly at the same time; the limbs were as stiff the moment life was extinct as if the body had become cold. The natives tell me that it builds in the hollow limbs of trees, making no other nest than of the decayed wood. It has four young ones. The eggs are white, and without spot."

Mr. Caley also learned from the natives that the nest of this species, of the Ground Parrot (*Nymphicus pulchellus*), of the Dulang (*Platyercus Pennantii*), and of the Coolich (*T. concinnus*), smell very strong and offensive of dung.

T. hæmatodus, Vig. (*T. Swainsonii*, Jardine and Selby). Green Head, middle of the body, and bands on the sides, azure-blue; throat, breast, and flanks, orange-crimson. (Sw.)

Lorius.—The true Lories are remarkable for the elongated and weak form of the bill, and also for a formation of the tongue, similar to that in *Trichoglossus*. [See, col. 476.] They are inhabitants of the islands of the east, and are considered by Mr. Vigors to be the aberrant group of the family. Their colours are of the most rich and mellow description, and the birds are highly prized, not only for their beautiful plumage, but for their lively, active, and affectionate disposition, and their great docility in the articulation of words and even sentences. The genus has the following characters:—Bill elongated, weak. Wings pointed, two first quills longest. Tail moderate, rounded or graduated; the feathers broad, and hardly narrow at their tips.

L. Domicella. Rich scarlet; upon the upper part of the breast a yellow collar; crown of the head blackish-purple in front, passing into violet-purple behind; upper surface of the wings green, violet-blue at the bend and margins, as are the under wing-coverts; thighs externally azure, greenish at the base; bill orange-yellow. Length between 11 and 12 inches.

It is a native of the Moluccas and other Eastern islands.

Lorius Domicella.

The *Ptyctolophinae*, or Cockatoos, are natives of Australia and the Indian Islands, inhabiting the woods, and feeding upon seeds and soft and stony fruits, which last their powerful bill enables them to break with ease. Like others of their congeners, they make their nests in decayed trees, and are easily tamed when taken at an early age. They become familiar and even attached, but their imitative powers seldom go beyond a very few words, added to their own cry of 'Cockatoo.'

Ptyctolophus, (True Cockatoos).—Bill strong, short, very broad; culmen much curved; head with a folding crest; base of the under mandible frequently concealed by feathers. Wings long; secondaries, tertials, and the tail-feathers sometimes mucronate.

P. galeritus, Crested Cockatoo (White). White; crest, and internal webs of the lateral tail-feathers, yellow; under wing-coverts sulphureous.

It is found in Australia.

Mr. Caley's notes contain the following observations on the Crested Cockatoo:—"This bird is called by the natives Car'way, and also Curriang. I have met with it in large flocks at the conflux of the Grosse and Hawkesbury rivers, below Mulge'ey on the former river,

and in the long meadow near the Nepean River. They are shy, and not easily approached. The flesh of the young ones is accounted good eating. I have heard from the natives that it makes its nest in the rotten limbs of trees, of nothing more than the vegetable mould formed by the decayed parts of the bough; that it has no more than two young ones at a time, and that the eggs are white without spots. The natives first find where the nests are by the bird making 'Co'tora'

Crested Cockatoo (*Ptilinopus galeritus*).

in an adjoining tree, which lies in conspicuous heaps on the ground. Co'tora is the bark stripped off the smaller branches, and cut into small pieces. When the young are nearly fledged, the old bird cuts a quantity of small branches from the adjoining trees, but never from that in which the nest is situated. They are sometimes found to enter the hollow limb as far as two yards. The nests are generally formed in a Black-Butted Gum-Tree; and also in Coroy'bo, Cajim'hora, and Yarrowa'ry tree (species of *Eucalyptus*). Their breeding-places appear to be local."

Mr. Vigors divides the genus into the following sections:—

* *Crista plicatili, acuminata, antrorsum torta.*

Of this division he gives *Ptilinopus galeritus* above described as the example.

** *Crista rotundata, retrorsum incumbens.*

Of this section he gives *Ptilinopus Eos, Psittacus Eos* (Kuhl), the Rosalbin Cockatoo, as the example.

P. Leadbeateri, Vig., *Cacatua Leadbeateri*, Wagl., the Tricolour-Crested Cockatoo, also a native of Australia, is the most splendid species yet discovered. Nothing appears to be known of its habits.

In the same family of *Ptilinopinae* Mr. Vigors places his genus *Calyptrorhynchus*, the chief difference between which and *Ptilinopus* consists in the greater elevation and comparative shortness of the bill.

C. funeraria, the Funeral Cockatoo. Mr. Caley says, "Its native name is Wy'n, so called from the similitude of that word to the sound which it makes. I have never seen them together in any numbers, not more perhaps than half-a-dozen at a time; but I have met with them in many different places. Sometimes they come within half a mile of the centre of Paramatta, where I have shot them in the trees. The natives told me it made its nest in Yar'ro-Trees (a species of *Eucalyptus*), using only the vegetable mould. It makes no Co'tora, but cuts off the small branches of apple-trees (a species of *Angophora*). It has two young ones."

Psittacus (True Parrots).—Mr. Vigors is of opinion that the group of the *Psittacidae*, to which the name of *Psittacus* should be applied, may perhaps be considered to be that which comprises the *P. Ama-*

zonicus of Brisson and some allied species. That at least, he observes, is the group best known under the old scientific term, and at the same time under the familiar names of Parrot in our language, and Perroquet in the French, which correspond with it.

These True Parrots are for the most part inhabitants of Tropical America, and their prevailing colour is green. The ash-coloured or Gray Parrot, *Psittacus erythacus*, Linn., is a native of Africa. This group excels all others in docility and power of imitation.

Mr. Swainson divides the True Parrots into two genera, namely:—

1. *Chrysotis* (Amazonian Parrots), which he thus characterises:—Face plumed. Wings rather short; the first and second quills graduated, and shorter than the third and fourth, which are the longest; all these have the inner web sinuated in the middle; tertials very long. Tail short, longer than the wings, broad, with the tips rounded.

The species of these Green Parrots are numerous. Among them the Festive Parrot (*P. festivus* of authors) and the Amazon's Parrot (*P. Amazonicus* of authors) are perhaps the best known; the latter particularly, which is often brought to Europe on account of its superior mimic propensities. The former, which exceeds the Amazon's Parrot in size, inhabits Guyana and the Brazils, the banks of the Marañon, or river Amazon, particularly, living in the forests upon seeds and kernels of fruits. It articulates, with great clearness and precision, words, and even sentences. The smaller Amazon's Parrot is common in Guyana and Brazil, and more especially near the banks of the river from which it takes its name. Fruits form its food, particularly those of the *Rhizophora* Mangle, or Mangrove-Tree, and in its decayed trunks the bird deposits its eggs. It is considered very destructive to orange plantations. In captivity it may be taught to repeat many words and short sentences, which it learns with great facility.

Sloane, in his account of the Common Parrot of Jamaica, says that it is less than those of the mainland, and has a reddish-coloured neck, being everywhere else of a green colour; that it has a short broad tail; speaks very articulately; and that it is eaten baked in pies, tasting like pigeons.

2. *Psittacus*.—Wings lengthened, nearly as long as the tail. Face naked. Tail even; the feathers rounded. It inhabits the Old World.

P. erythacus, the Common Gray Parrot, is generally considered to be superior to all others in docility and mimicry: its imitation of the human voice, when well taught, is complete, and its articulation most clear. Very high prices have been given for clever and well-taught birds. The parrot for which the Roman cardinal gave a hundred gold pieces had, it is said, learned to repeat with clearness, and without hesitation, the whole of the Apostles' Creed, a wonderful instance of memory and imitation. This species is very long-lived. Le Vaillant mentions one that he saw which had been domesticated 93 years: it was indeed then in a state of decrepitude, and both sight and memory were gone.

Wagler's genera, *Electus*, *Pionus*, and *Psittacodis*, vary in some points from *Psittacus*; the former, *Electus grandis* (Moluccas and New Guinea), approaches the Lories.

The Australian genus *Nestor*, of the same author, is pointed out as forming a connecting link between the Parrots and the Cockatoos, and is thus characterised:—Bill elongated; upper mandible compressed, hooked; the tomia sinuated, but not distinctly toothed; the tip projecting, with its under surface sulcated and deeply excavated for the reception of the tip of the under mandible; under mandible narrow, compressed, slightly convex, or forming, when closed, an obtuse angle with the upper; wings rather long, ample; tail of moderate length, and even at the end; tips of the shafts bare, and slightly projecting beyond the feathered parts.

N. productus, Long-Billed Parrot (Gould). General colour of the upper surface brown; beak elongated; head and back of the neck tinged with gray; the feathers of these parts, as well as of the back, margined with a deeper tint; rump, belly, and under tail-coverts, deep red; cheeks, throat, and chest, yellow, the former tinged with red; shoulders, on their inner surface, yellow, tinged with rufous-olive; tail-feathers banded at the base with orange-yellow and brown, the inner webs of the quill-feathers at the base and beneath with dusky-red and brown; bill brown; feet blackish-brown. Total length 15 inches. (Gould, 'Birds of Australia'.)

This species inhabits Norfolk Island and the most eastern portions of New South Wales.

"Like all the other members of this extensive family," says Mr. Gould, "it bears captivity remarkably well, readily becoming cheerful and contented; at least such is the case with an individual in the possession of Sir J. P. Millbank, Bart.; and, as might have been reasonably expected, the variation in the form of the mandibles, which renders these birds so conspicuous, is accompanied by a marked difference in the nature of their food, the powerful bills of the other members of the family enabling them to feed upon hard seeds and stony fruits, while, from the elongated form of this organ in the present birds, this power is denied to them, and we find that they give a decided preference to the leaves of succulent plants and the softer kinds of fruit. Sir J. P. Millbank informed me that the bird in his possession evinced a strong partiality to the leaves of the common lettuce and other soft vegetables, and that it was also very fond of the juice of fruits, of cream, and butter. Its voice was hoarse and

inharmonious, frequently resembling the barking of a dog; and in Yates's 'New Zealand' we are informed that the *Nestor hypopolius*, known there by the name of Kaka, is 'capable of learning to imitate the human voice to a remarkable degree. . . . The cry of this bird, when ranging at large in the woods, is harsh and disagreeable in the extreme.' Although I cannot assert it for a certainty, I have every reason to believe that both these birds frequently descend to the ground and grub up with their lengthened bills the bulbous and other roots which form a portion of their food, particularly as I have found earth still adhering to the mandibles of the specimens I have examined; besides which, I have been informed by Captain Sturt that a parrot inhabiting Australia, having a similar bill, but belonging to another group, is frequently in the habit of so doing."

Long-Billed Parrot (*Nestor productus*).

The genera *Psittacula* and *Agapornis* appear to be the most diminutive of this extensive and interesting tribe. The latter, a ready example of which occurs in the Love-Birds, so extensively petted, and remarkable for their sexual attachment, was separated from *Psittacula* by Sir W. Jardine and Mr. Selby.

The following cut will give some idea of the form of *Psittacula* (*Poicephalus* of Swainson).

Love Bird (*Psittacula Tarenta*).

The student should carefully consult the monograph of Kuhl, and that of Wagler; and of illustrated works should direct his attention more particularly to Le Vaillant's 'Perroquets,' with figures after the celebrated Barraband; Lear's 'Parrots;' Swainson's 'Zoological Illustrations,' 1st and 2nd series; and Selby's 'Parrots,' containing many beautiful figures after Lear, though on a small scale, and forming the 6th volume of the 'Ornithology' of the 'Naturalists' Library.

Those who keep birds belonging to this group would do well to study their natural habits, if they wish to keep them in health. Some, as we have seen, live upon the nectar of flowers, others on soft fruits, and others again on hard fruits, for breaking which they are gifted with a powerful vice of a bill. We have known a case where

the upper mandible of the bill of a parrot of this last description, which had been kept upon soft food, grew to such a length as to begin to penetrate its throat. To such a moderate proportion of hard food, such as almonds, and even harder food, should be presented. Some of the tribe have bred in captivity; and there is little doubt that if pairs were kept in good roomy cages, with a part of them so fitted up as to remind them of their favourite hollow trees, and furnished with dry rotten wood or vegetable earth, the instances would be comparatively frequent.

PSITTIROSTRA, M. Temminck's name for a genus of Granivorous Birds, which he places between the Crossbills (*Loxia*) and the Bullfinches (*Pyrrhula*).

PSOLIDÆ, a tribe of *Echinodermata*, in the order *Holothuriada*. The only British genus, included by the late Professor E. Forbes in this tribe, is *Psolus*, which is thus characterised:—Body irregular, ascidiform; suckers in five rows, three only of which are developed and placed on a soft foot or disc; tentacula ten.

P. phantapus (*Holothuria phantapus*, Linnæus), the Snail Sea-Cucumber, is an inhabitant of the British Seas. It is of a brown colour, has the head reddish-white with orange spots and orange tentacula, the body covered with pectinated scales, or rugæ. It adheres to substances with great firmness by means of its ventral disc. "So powerfully does it adhere," says Professor E. Forbes, "that I have known the head of the animal carried away by the dredge when it brought up entire every other fixed animal which it came in contact with." It is found in European seas, and the genus ranges to the Indian seas. Professor Forbes says, "The *Psolus ternaria* of Jäger and Lesson, should form the type of another genus, distinguished by its twenty tentacula. The genus *Cuvieria* of Peron should be united with *Psolus*."

(Forbes, *History of British Star-Fishes*.)

PSOLINUS. [PENTACTÆ.]

PSOPHIA, a genus of Birds. The *P. crepitans*, is called the Agami. [AGAMI.]

PSOPHOCARPUS. [DOLICHOS.]

PSORALEA (so called from the Greek *ψωραλέος*, 'warted,' on account of most of the species being covered with little tubercles), a genus of Papilionaceous Plants belonging to the natural family of *Leguminosæ*, characterised by the tube of the permanent calyx being sprinkled with callous points. Sepals 5, united to the middle; stamens 10, usually diadelphous. Legume indehiscent, 1-seeded, sometimes ending in a beak. Leaves of various forms. Flowers blue, white, or purple. The species, about 60 in number, and natives of different parts of the world, are either herbaceous plants or low shrubs, some of them ornamental, and all of them easy of culture. They may be propagated either by cuttings or seeds, which they produce abundantly.

P. esculenta, the Bread-Root of North America, is cultivated along the banks of the Missouri and in other parts of that country. The roots, which abound in farinaceous matter, are, like the tubers of the potato, employed as food, especially during the winter months. In this climate it will grow in the open air, but requires the protection of a frame to produce abundant crops of roots. *P. corylifolia* is diffused over every part of India, especially in the vicinity of villages, during the rainy and cold seasons. It is employed as a stomachic and deobstruent. Other species are also used medicinally. *P. glandulosa* is called in Chili, Coulen, Cullen, or Cullen. Some of the native tribes make a very intoxicating kind of beer from a variety called Yellow Cullen.

PSYCHOMYA. [NEUROPTERA.]

PSYCHOTRIA, a genus of Plants belonging to the natural order *Cinchonaceæ*. It is characterised by having a calyx 5-parted, somewhat entire; corolla regular, funnel-shaped, 5 (rarely 4) cleft; stamens 5, rarely 4, exserted or included within the throat of the corolla. Stigma bifid. Berry drupaceous, crowned with the limb of the calyx, usually marked with 10 ribs, and containing two nuts. Nuts ribbed; single seeded. Trees or shrubs; rarely herbaceous plants. Some of the species are ornamental in foliage, and one, *P. parasitica*, as its name indicates, is found growing on trees in the West India Islands.

Several of the species are supposed to possess considerable medicinal properties. *P. emetica* is a small under-shrub, a native of New Granada on the banks of the Magdalena, and probably of other parts of South America; the *Cephaelis emetica* of some other authors. The stem is erect, simple, hairy, and tomentose; leaves oblong-acuminate, narrow at the base, membranous, ciliate, rather hairy on the under surface; stipules very short, ovate-acuminate; peduncles few-flowered, axillary, sub-racemose. This species has long been celebrated as yielding the black or Peruvian or striated ipecacuanha, which, analysed by Pelletier gave of emetine 6, fatty matter 2, and of starch and ligneous matter (the latter bearing but a small proportion) 92. *P. herbacea* is an Indian species used for the same purposes. The roots of *P. sulphurea* and of *P. tinctoria* are employed in dyeing.

PSYLLA (Geoffroy), a genus of Insects belonging to the family *Aphide*, which, according to Latreille, forms the second family of the Homopterous *Hemiptera*.

The *Psyllæ* are minute insects, allied to those commonly called Plant-Lice, and live upon trees and plants, from which they derive

their nutriment by suction, and in so doing they often produce excrescences somewhat resembling gall-nuts, particularly on their leaves and buds. They have two joints to the tarsi; the antennæ are composed of ten or eleven joints, the last of which have two bristles; both sexes have wings, and they possess the faculty of leaping. Their larvæ usually have a very flat body, broad head, and the abdomen rounded behind; the legs are terminated by a little membranous vesicle accompanied beneath with two hooks. Four wide and flat pieces, which are the sheaths of the wings, distinguish the pupa state; several of the species in this stage, as well as in the larva state, are covered with a white substance resembling cotton. The species are very numerous, and are often named after the plants which they infest. Mr. Stephens records 26 species as natives of this country.

PSYLLASTOMATINA. [CHIROPTERA.]

PSYLLIUM, a name of a Plant which occurs in Dioscorides, &c., supposed to be so named from Psyllus (Ψύλλος).

PSYTHIRUS. [PSITHYRUS.]

PTARMICA, a genus of Plants belonging to the natural order *Asteraceæ*. It has a campanulate involucre with the scales brown and scarious at the edge. The receptacle is flat or scarcely convex, broad, and psileaceous. The ligulæ from 5 to 20, flat, expanded, much longer than the involucre. The achenia are bald, obcompressed, the outer often somewhat winged at the edge.

P. vulgaris has a widely creeping root, very difficult to extirpate when the soil is moist. Upright stems about two feet high, angular, smooth, hollow, leafy, with small axillary rudiments of branches corymbose at the top. The leaves are sessile, linear, or slightly lanceolate acute, very minutely serrated with bristly teeth; smooth on both sides, and of a dark green. The flowers are milk-white, larger than most others of the same genus. The whole plant is pungent, and provokes a flow of saliva. Its dried leaves produce sneezing, but this is thought to be owing to their little sharp marginal teeth: the root is aromatic. The heads of *P. nana*, *P. atrata*, and *P. moschata* are used in the Swiss Alps as a substitute for tea. *P. moschata* is the basis of the aromatic liqueur called Esprit d'Iva.

(Lindley, *Vegetable Kingdom*; Lindley, *Flora Medica*.)

PTARMIGAN. [TETRAONIDÆ.]

PTERACLIS. [CORYPHÆNA.]

PTERICHTHYS, a singular genus of Fossil Gsnoid Fishes, from the Old Red-Sandstone of Scotland and Orkney. (Agassiz.) [FISH.]

PTERINEA, a fossil genus of *Conchifera*, allied to *Avicula*, and hitherto confined to the Palæozoic, and chiefly found in the Devonian Strata. (Goldfuss.)

PTERIS (from πτέρω, a wing), a genus of Plants belonging to the natural order *Filices*. The thecæ arise from the points of veins placed on a nerve-like receptacle running along the edge of the leaf, forming an uninterrupted marginal sorus; the involucre are continuous with the edge of the leaf, scarious, and opening inwards.

P. aquilina, Common Fern, Bracken, or Brakes, is the most abundant of our British species. It has a long tapering rhizoma, creeping, externally black. The leaves are erect, from one to six feet high, repeatedly compound with horizontally spreading divisions, whose ribs are smooth; the primary leaves are nearly opposite, the lower ones more alternate, pinnatifid segments oblong, obtuse. They are all of a light bright green colour, slightly brown at the edge, which is revolute and crisped, or wavy, sheltering the dense linear masses of tawny thecæ. The main stalks are angular and sharp-edged, wounding the hands severely if plucked incautiously. When cut across, the rhizoma has a branched appearance resembling a spread eagle, whence the Latin name. There is scarcely any wood, heath, or forest in the United Kingdom where this plant does not make its appearance. It is said to be indicative of poor soil, but it is more probable that its absence from cultivated ground is to be attributed to the effects of the hoe and the plough, rather than to the quality of the soil. The geographical range of this species is very extensive; it is included in every European list, and is found also in Asia and Africa. It is used in many parts of England and Scotland for manure, and in the Western Isles the poor people gain considerable profit by collecting the leaves, and selling the ashes to soap and glass makers, on account of the large quantities of alkali contained in them. As a litter for horses, brakes or fern is in great request in Wales, Scotland, and Ireland, and when chopped up with hay they are sometimes fed upon it. In Inverness-shire the poorer classes thatch the tops of their houses with the leaves, and they form a very durable covering. Pigs are fed upon the roots boiled down into a mucilaginous mass. This species is the *Filix femina* of our older authors. It is likewise the *Θηλυπτέρω* of Theophrastus, 'Hist. Pl.' 9. 18, and of Dioscorides, 4. 184. The ancients are said to have used both the rhizomas and fronds of this fern in decoctions and diet-drinks, in chronic disorders of all kinds arising from obstruction of the viscera and spleen. Some modern authors give it a high character for the same purposes, but it is now seldom used by medical practitioners. In Haller's time its reputation was very extensive as a destroyer of worms, and a bed of the green fronds was esteemed a sovereign remedy for rickets in children. The rhizoma is so astringent that in some places it is used for tanning and dressing red and chamois leather. It has been employed as a substitute for hops, and in the Canaries a miserable sort of bread is made by grinding the root with barley.

(Newman, *British Ferns*; Babington, *Manual of British Botany*; Lindley, *Flora Medica*.)

PTEROCARPUS (from πτέρω, a wing, and κάρπος, a fruit, in reference to the pods being girded with a broad wing), a genus of Plants belonging to the natural order *Leguminosæ*. It has a 5-cleft calyx, a corolla with 5 petals, disposed into a papilionaceous form; 10 monadelphous or diadelphous stamens, an irregular indehiscent legume, somewhat orbicular, surrounded by a wing, woody, and often rugose, in the middle 1-3-celled. The leaves are unequally pinnated. The racemes axillary, or forming terminal panicles. The species are unarmed trees or shrubs.

P. Draco, Dragon's-Blood *Pterocarpus*, is a tree nearly 30 feet high, with alternate shining leaflets, about 5 on each side, and an odd one, rather obtuse, entire, veined, smooth, pale green below; the legumes nearly smooth. The wood of this tree is white and heavy, the bark thick and of a rusty gray colour. When first cut it presents no marks of redness, but in a little time red drops of juice begin to collect and exude from the wood. If left in the sun for about ten minutes they become hard and clear, and are collected under the name of *Sanguis Draconis*, or Dragon's-Blood. This resin formerly constituted an extensive article of commerce from Carthage, but from its diminished consumption its collection has ceased, and all the dragon's-blood obtained now in the market is the produce of *Calamus Draco*.

P. Marsupium is a tree with a very high trunk, scarcely ever found straight. The bark has a brown outer coat which is thin and spongy, and falls off in flakes, disclosing the inner bark, which is fibrous, red, and astringent. The branches are numerous, horizontal, and spreading. The leaves sub-bifarious, alternate, pinnate, with an odd one, 8 or 9 inches long. The panicles are terminal and very large, ramifications bifarious. The flowers are very numerous, white, and with a small spot of yellow in the centre. The bracts small, caducous, solitary below each division and sub-division of the panicle. The seed is solitary and kidney-shaped. This tree is thought by Roxburgh to be the one yielding Gum Kino, a well known astringent,—the juice hardening into a dark red and very brittle gum-resin, which, on being powdered, changes to a light brown, not unlike Peruvian bark. Its taste is strong, but simply astringent. The real kino-tree however appears to be the next species.

P. dalbergioides is a native of the Andaman Islands, where it grows to an immense size, and forms a valuable timber-tree, of which the wood is known as Andaman red wood, from its resemblance to mahogany; but it is redder, heavier, and coarser grained, though that of the root is finer than that of the stem. It was introduced by Col. Kyd into the Calcutta botanic garden in 1794, whence it has been spread into the country.

P. erinaceus is a tree 40 or 50 feet in height. It has unequally pinnate leaves, smooth above, downy beneath; from 11 to 15 leaflets, alternate, distant, on short stalks, ovate, oblong, obtuse, or emarginate, wiry at the edge; lanceolate stipules, solitary or clustered racemes, downy from the old wood below, the young branches much shorter than the leaves. The flowers are yellow, the legumes stipulate, compressed, membranous, velvety, serrated, and undulated, prickly on the centre. When the branches are wounded, a clear bright gum exudes from them, which is the gum kino of commerce, and is mentioned as such by Mr. Mungo Park. It is a very powerful remedy in obstinate chronic diarrhoeas and dysenteries, and in all diseases arising from laxity of tissue. Externally it is applied as a styptic to check hæmorrhages from wounds and ulcers, and to diminish discharges.

P. santalinus is a lofty tree having alternate stalked ternate leaves, petiolate alternate leaflets, smooth above, hoary beneath. The racemes are axillary, simple, or branched, and erect. The legume roundish, stalked, falcate upwards, compressed, smooth, keeled on the lower edge, the keel being membranous and undulated. From this tree is obtained the Red Sandal-Wood, a timber chiefly used by dyers and colour manufacturers of the present day, but which is also used to colour several official preparations, such as compound tincture of lavender. Its colouring matter forms beautiful coloured precipitates with many metallic solutions.

P. flavus is the Yellow Sandal-Tree, and is used for dyeing yellow. Its bark is very bitter.

(Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

PTEROCERAS. [STROMBIDÆ.]

PTEROCLES. [TETRAONIDÆ.]

PTEROCYANEA. [DUCKS.]

PTERODACTYLE (*Pterodactylus* of Cuvier; *Ornithocephalus* of Sömmering), a genus of fossil Saurians, whose type is entirely extinct. To Collini, the director of the elector-palatine at Mannheim, we are indebted for the first introduction of this Heteroclit. He described the skeleton of the long-billed species from a specimen, found at Aichstädt near Solenhofen, in that museum, and figured it in the 'Memoirs of the Palatine Academy' (Part. Phys., v. 58, et seq.).

Collini had well made out the head, the neck, the retrograde direction of the trunk, the small tail, the left leg, and the two arms; but beyond this he seems to have been at a loss. He came to the conclusion that the animal was neither a bird nor a bat; inquired whether it might not be some amphibian; and finished by expressing his opinion that the type must be sought among the marine Vertebrata.

Blumenbach took a widely different view of the subject, and referred this extraordinary form to the Palmipede or Web-Footed Birds.

Professor Hermann of Strasburg, who drew upon his imagination for a restoration of the animal, and clothed it in a hairy skin, considered it to be a Mammal, and assigned to it a situation between the mammiferous class and birds, still more intermediate than that occupied by the bats.

Pterodactylus longirostris.

Sömmering also arranged the form among the mammals, in the neighbourhood of the bats, not without an elaborate detail of the reasons which had conducted him to that conclusion.

It was reserved for the penetrating eye and acute but patient investigation of Cuvier effectually to destroy these theories, supported though they were by weighty authorities: the satisfactory reasoning by which he disposes of them one after the other, and proves conclusively from the organization of the animal that it was a Saurian (in which opinion he was supported by Oken), will be found at large in the fifth volume of the last edition of his 'Ossements Fossiles.' Our limits will not permit us to detail the links of the harmonious chain of his proofs; and we must here content ourselves with observing that the form of the os quadratum appears to have been the principal key by which the great French naturalist solved this intricate zoological puzzle, and detected its Saurian character. "Behold," says he, after having built, as it were, the animal before our eyes, "an animal which, in its osteology, from its teeth to the end of its claws, offers all the characters of the Saurians; nor can we doubt that those characters existed in its integuments and soft parts—in its scales, its circulation, its generative organs. But it was at the same time an animal provided with the means of flight—which, when stationary, could not have made much use of its anterior extremities, even if it did not keep them always folded as birds keep their wings, which nevertheless might use its small anterior fingers to suspend itself from the branches of trees, but when at rest must have been ordinarily on its hind feet, like the birds again; and, also like them, must have carried its neck erect and curved backwards, so that its enormous head should not interrupt its equilibrium."

Well may Cuvier remark, that of all the beings whose ancient existence is revealed to us in his great work above alluded to, these Pterodactyles are the most extraordinary; and that if we could see them alive, they would be the most at variance with living forms. Their flight was not performed by means of ribs as in the dragons (DRACONINA); nor by means of a wing without distinct fingers, like that of a bird; nor by a wing leaving the thumb alone at liberty, as in the bats; but by a wing sustained principally on one very elongated finger, whilst the rest preserved their ordinary brevity and their claws.

At the same time these flying reptiles—a denomination almost contradictory—have a long neck, the bill of a bird, everything in short that could conduce to give them a strange aspect. ('Oss. Foss.')

About 20 species of the genus *Pterodactylus* have been described. The following are some of those best known:—

1. *P. longirostris*, Cuv. (*Ornithocephalus longirostris*, Sömm.; *P. cro-*

codilocephaloides, Ritgen). About the size of a woodcock. It is found in Solenhofen.

2. *P. brevirostris*, Cuv. (*O. brevirostris*, Sömm.; *P. netecephaloides* Ritgen). Found in Solenhofen.

Pterodactylus brevirostris.

3. *P. crassirostris*, Goldf. Found in Solenhofen.
4. *P. medius*, Münster. Solenhofen.
5. *P. Münsteri*, Goldf. Solenhofen.
6. *P. macronyx*, Buckland (*O. Banthensis*, Theodori). Size about that of a raven; wings, when expanded, about four feet from tip to tip. Found at Lyme Regis (Buckland); Banz, Germany (H. Von Meyer).
7. *P. grandis*, Cuv. (*O. giganteus*, Sömm.). About four times as large as *P. longirostris*. Found at Solenhofen (f).
8. *P. Bucklandii*, Goldf. Stonesfield.

Dr. Buckland remarks that in *P. macronyx* (Lias at Lyme Regis) there is an unusual provision for giving support and movement to a large head at the extremity of a long neck, by the occurrence of bony

modern Lizards, whose necks are short, and require no such aid to support the head. In the compensation which these tendons afforded for the weakness arising from the elongation of the neck, Dr. Buckland

Pterodactylus crassirostris. (Goldfuss.)

Pterodactylus crassirostris, restored. (Goldfuss.)

tendons running parallel to the cervical vertebræ, like the tendons that pass along the back of the Pigmy Musk (*Moschus pigmæus*), and of many birds. This provision, he observes, does not occur in any

sees an example of the same mechanism in an extinct order of the most ancient reptiles, which is still applied to strengthen other parts of the vertebral column in a few existing species of *Mammalia* and birds.

The same author points out that the three first fingers of the Pterodactyle agree in structure with those of the fore foot of living Lizards; but as the hand of the fossil reptile was to be converted into an organ of flight, the joints of the fourth or fifth finger were lengthened to become expanders of a membranous wing. Thus, in *P. longirostris*, he observes, the fourth finger is stated by Cuvier to have four elongated joints, and the fifth or ungual joint to be omitted, as its presence is unnecessary. In the *P. crassirostris*, according to Goldfuss, this claw is present upon the fourth finger, which thus has five bones, and the fifth finger is elongated to carry the wing. Throughout all these arrangements in the fore foot the normal numbers of the type of lizards are maintained. "If," continues Dr. Buckland, "as appears from the specimen engraved by Goldfuss of *P. crassirostris*, the fifth finger was elongated to expand the wing, we should infer, from the normal number of joints in the fifth finger of Lizards being only three, that this wing-finger had but three joints. In the fossil itself the two first joints only are preserved, so that his conjectural addition of a fourth joint to the fifth finger in the restored figure, seems inconsistent with the analogies that pervade the structure of this and of every other species of Pterodactyle, as described by Cuvier. According to Goldfuss, this species had one more toe than Cuvier assigns to the other species; in this respect it is so far from violating the analogies we are considering, that it adds another approximation to the character of the living Lizards." After referring to the difference manifested in *P. crassirostris* from the other Pterodactyles, in having the fifth instead of the fourth finger elongated, as above noticed, for the purpose of expanding the wing, Dr. Buckland states that it is however probable that the fifth toe had only three joints, for the same reasons that are assigned respecting the number of joints in the fifth finger; and he observes that in *P. longirostris*, Cuvier considers the small bone in the foot to be a rudimentary form of a fifth toe.

The Pterodactyles have been found in the lithographic limestone of the Jura formation at Aichstätt and Solenhofen, which abounds with remains of Fish, and of Brachyurous and Macrurous Crustaceans, and where *Xiphosuri* (*Limulus*) not unfrequently occur. The fish examined by Cuvier belonged, partially at least, to marine genera. He distinguished, for example, a well-characterised species of anchovy, probably *Clupea sprattiformis* (Blainv.). *Libellule* and other insects have also been found in this Solenhofen slate. The other localities are Lyme Regis (Lias), Bantz, and Stonesfield (Oolite).

Cuvier, speaking of the Solenhofen district, observes that there is no doubt that at the time of the deposit of the lithographic slate, there lived in that canton crocodiles, *Limuli*, and other beings whose geographical distribution is now confined to the torrid zone, together with these flying Saurians, which flitted about by means of the membrane sustained by a single finger, suspended themselves and perhaps crept by the aid of the other three fingers, stood upon their hind legs only, and had their enormous gape armed with small pointed teeth, fit only for seizing insects and small animals.

Dr. Buckland thinks it probable that the Pterodactyle had the power of swimming so common in reptiles, and now possessed by the Vampire Bat of the island of Bonin. ('Bridgewater Treatise.') "Thus," says the Professor, "like Milton's fiend, all qualified for all services and all elements, the creature was a fit companion for the kindred reptiles that swarmed in the seas or crawled on the shores of a turbulent planet:—

" 'The Fiend

O'er bog, or steep, through strait, rough, dense, or rare,
With head, hands, wings, or feet, pursues his way,
And swims, or sinks, or wades, or creeps, or flies."

With flocks of such-like creatures flying in the air, and shoals of no less monstrous *Ichthyosaurs* and *Plesiosaurs* swarming in the ocean, and gigantic crocodiles and tortoises crawling on the shores of the primeval lakes and rivers—air, sea, and land, must have been strangely tenanted in these early periods of our infant world." ('Geol. Trans.' new series, iii., part 1.)

In the 'Bridgewater Treatise,' we find the size and form of the foot, and also of the leg and thigh, adduced as showing that the Pterodactyles had the power of standing firmly on the ground, where, with their wings folded, they possibly moved after the manner of birds; and an opinion that they could also perch on trees, and climb on rocks and cliffs, with their hind and fore feet conjointly, like bats and lizards.

Cuvier, as we have seen, conjectured that the food of these flying Saurians consisted of insects and other small animals, and he thought that, from the magnitude of their eyes, they may have been also noctivagous. Dr. Buckland refers to the presence of large fossil *Libellule*, or Dragon-Flies, together with many other insects, in the same quarries with the Solenhofen Pterodactyles, and to the occurrence of the wings of Coleopterous Insects, mingled with the bones of these Saurians in the oolitic slate at Stonesfield, as proof that large insects existed at the same time with them, and that they may have contributed to their supply of food. He adds however that the head and teeth of two species of Pterodactyle are so much greater and stronger than is necessary for the capture of insects, that the larger species of them may possibly have fed on fishes, darting upon the latter from the air, after the manner of Sea-Swallows, or Terns, and

Solan Geese. The enormous size and strength of *P. crassirostris*, he observes, would not only have enabled it to catch fish, but also to kill and devour the few small Marsupial *Mammalia* which then existed upon the land.

A new species has lately been discovered by Mr. Bowerbank in the Kentish Chalk, which seems to have been more colossal than any hitherto described. Some portions of the upper maxilla prove the total length of the head to have been upwards of 16 inches; and the bones of the upper extremity indicate a width of from 16 to 18 feet from the extreme point of one wing to the other.

PTERODICTYUM. [POLYPTERA.]

PTEROGLOSSUS. [RAMPHASTIDÆ.]

PTEROLOBIUM, a small genus of Plants belonging to the natural order *Leguminosæ*, so named from its pod ending in a membranous wing. The genus was first mentioned by Mr. Brown, in the appendix to Salt's 'Travels in Abyssinia,' and from a species, *P. Kantuffa*, which is also named by Bruce, and described by him as being ordered to be cut away from the roads when the king was going to travel. The genus is found in India as well as in Africa, and even the *Kantuffa* occurs there, as it is the *Cesalpinia lacerans* of Roxburgh, but referred to *Mimosa* by De Candolle, and called *M. Kantuffa*; having been ascertained to be identical with the Indian plant, and belonging to this genus, it has been called *P. lacerans*. The genus contains only a few species of trees and climbing shrubs covered with strong sharp hooked prickles.

PTEROMYS. [SCIURIDÆ.]

PTEROPHYLLUM, a genus of Fossil Cycadeous Plants from the Oolite of Yorkshire and beds of the same age in Scania. (Brongniart.)

PTEROPLEURA. [GECOTIDÆ.]

PTEROPODA, a class of *Mollusca* placed between the *Gasteropoda* and *Brachiopoda* by some writers, and by others next the *Cephalopoda*. The number of species is not large. They pass their entire life in the open sea away from shelter, except that which is afforded by the gulf-weed. In appearance and habits they resemble the fry of the other forms of *Mollusca*. They are supplied with a pair of flippers or wings (hence their name), by means of which they pass rapidly through the water. They swarm in tropical and arctic seas, and are sometimes so numerous as to colour the ocean for leagues. They are the principal food in high latitudes of the species of whale and of sea-birds. They are rarely found on the sea-shore, and only one or two species have been accidentally taken in the British seas.

"In structure, the *Pteropoda* are most nearly related to the marine univalves, but much inferior to them. Their nervous ganglia are concentrated into a mass below the œsophagus; they have auditory vesicles, containing otoliths; and are sensible of light and heat and probably of odours, although at most they possess very imperfect eyes and tentacles. The true foot is small or obsolete; in *Cleodora* it is combined with the fins, but in *Olio* it is sufficiently distinct, and consists of two elements; in *Spiralis* the posterior portion of the foot supports an operculum. The fins are developed from the sides of the mouth or neck, and are the equivalents of the side-lappets (*Epipodia*) of the sea-snails. The mouth of *Pneumodermis* is furnished with two tentacles supporting miniature suckers; these organs have been compared with the dorsal arms of the cuttle-fishes, but it is doubtful whether their nature is the same. A more certain point of resemblance is the ventral flexure of the alimentary canal, which terminates on the under surface, near the right side of the neck. The pteropods have a muscular gizzard, armed with gastric teeth; a liver, a pyloric cœcum, and a contractile renal organ opening into the cavity of the mantle. The heart consists of an auricle and a ventricle, and is essentially opistho-branchiate, although sometimes affected by the general flexure of the body. The venous system is extremely incomplete. The respiratory organ, which is little more than a ciliated surface, is either situated at the extremity of the body and unprotected by a mantle, or included in a branchial chamber with an opening in front. The shell, when present, is symmetrical, glassy, and translucent, consisting of a dorsal and a ventral plate united, with an anterior opening for the head, lateral slits for long filiform processes of the mantle, and terminated behind in one or three points; in other cases it is coical, or spirally coiled and closed by a spiral operculum. The sexes are united, and the orifices situated on the right side of the neck. According to Vogt, the embryo Pteropod has deciduous vela, like the sea-snails, before the proper locomotive organs are developed. (Huxley.)

"From this it would appear that while the *Pteropoda* present some analogical resemblances to the *Cephalopoda*, and permanently represent the larval stage of the sea-snails, they are developed on a type sufficiently peculiar to entitle them to rank as a distinct group; not indeed of equal value with the *Gasteropoda*, but with one of its orders.

"This group, the lowest of the univalve or encephalous orders, makes no approach towards the bivalves or acephala." (Woodward, 'Treatise on Shells.')

De Blainville divides this group into two sections, *Thecosomata* and *Gymnosomata*:—

A. *Thecosomata*.—Animal furnished with an external shell; head indistinct; foot and tentacles rudimentary, combined with the fins; mouth situated in a cavity formed by the union of the

locomotive organs; respiratory organ contained within a mantle cavity.

This section embraces two families, *Hyalaideæ* and *Limacinideæ*.

B. Gymnosomata.—Animal naked, without mantle or shell; head distinct; fins attached to the sides of the neck; gills indistinct.

It contains but one family, the *Clidae*. [CLIONIDÆ.]

PTEROPTOCHUS. [MERULIDÆ.]

PTEROPUS. [CHEIROPTERA.]

PTEROSPERMUM (from the Greek word *πτερον*, signifying a wing, and *σπέρμα*, a seed), a small genus of Plants belonging to the natural order *Byttneriaceæ*, which is found in the Indian Isles and the southern parts of India. The flowers being large and the foliage showy, have induced the cultivation of the species as ornamental trees all over India. The calyx is leathery, 5-partite, tomentose outside, hairy within; petals 5, shorter than the calyx; stamens 20 (5 sterile), united at the base into a column with the stalk of the ovary; style slender, club-shaped; seeds winged. The genus is small, but all the species form handsome trees, and, like most of the plants of the nearly allied order of *Malvaceæ*, abound in mucilage.

PTEROTRACHEA. [GASTEROPODA.]

PTERUTHIUS. [LEIOTRICHANÆ.]

PTILINOPUS. [COLUMBIDÆ.]

PTILODICTYA. [POLYPIFERA.]

PTILOGONYX. [LANIADÆ.]

PTILOLEPTUS. [CUCULIDÆ.]

PTILONORHYNCHUS. [STURNIDÆ.]

PTILOPACHUS. [TETRAONIDÆ.]

PTILOPHYRUS. [COLUMBIDÆ.]

PTILORHYNCHUS. [CORVIDÆ.]

PTYLORIS, Mr. Swainson's name for a genus of Birds which he arranges under the *Paradiidae*, or Birds of Paradise.

PTILOSTOMUS, Mr. Swainson's name for a genus of Birds which he places under the sub-family *Glaucopinae* (Wattle-Crows) of the family *Corvidæ*. *P. Senegalensis* (Sw.), the Senegal Pica, is a native of Africa.

PTILOTTIS. [MELIPHAGIDÆ.]

PTILOTURUS. [MELIPHAGIDÆ.]

PTYCACANTHUS, a genus of Fossil Fishes. [FISH.]

PTYCHOCERAS. [CEPHALOPODA.]

PTYCHODUS, a genus of Fossil Fishes. [FISH.]

PTYCHOGENS are Endogenous Plants whose leaves are occupied by veins running side by side from the base to the apex, without irregular division, as in grasses, lilies, &c. The name has been given in contradistinction to *Dietygens*, which are those Endogens that, like *Smilax*, have the reticulated veins of Exogens. [SMILACIDÆ.]

PTYCHOLEPIS, a genus of Fossil Fishes. [FISH.]

PTYCHOPLEURES, the name used by Messrs. DuRoi and Bibron to designate a sub-family of the Chalcidians or Cyclosaurs, the seventh family of Saurians according to their arrangement. [SAURIA.]

PTYCHOTIS, a small genus of Umbelliferous Plants, of which the seeds of some of the species have formed articles of condiment and of medicine from very early times. The genus extends from the south of Europe, through the Oriental region, to all parts of India. The calyx is 5-toothed; petals obovate, bifid, or emarginate, with a long inflexed point. Fruit compressed laterally, ovate or oblong. Seed roundish, or flat before and convex posteriorly. The species are annual or biennial plants. Stem-leaves usually cut into numerous capillary segments. Flowers white, disposed in compound umbels, of which the involucre is many-leaved, and the involucre either wanting or few-leaved.

The European species are not remarkable for any useful properties, but *P. coptica* and *P. Ajowan* probably yielded the seeds which formed the 'Ammi' of the ancients. Botanists and inquirers into the plants, condiments, and medicines of the ancients, have usually sought too exclusively in Europe for what was frequently derived from the East. Dioscorides states that the *Æthiopic Ammi* is called Cumin by some, and that it is thought to be distinct from the royal kind. The seeds of one kind were sent by Forskål to Linneus, who named the plant *Ammi copticum*. This has now been removed to the present genus *Psychotis*. Arabian authors give Nankwah as the synonym of Ammi, and Persian authors consider Ajwain to be a synonym of the former. It is remarkable, according to Dr. Royle, that there is also an Indian plant which is everywhere called Ajwain, and celebrated for its aromatic smell, pungent taste, and for its employment both by natives and Europeans for culinary and medicinal purposes; so much so, that Dr. Roxburgh could not conceive that "this famous Indian plant should be unknown to European botanists." Dr. Royle says, "in Persian works in use in India the Arabic Nankwah is given as a synonym of the Indian Ajwain, as it is also of the Greek Ammi."

The Indian species has been referred by De Candolle to the genus *Psychotis*, and called by him *P. Ajowan*, stating that it was very closely allied to *P. coptica*, which we have seen was considered to be one kind of Ammi—the two kinds described by Dioscorides being *Cuminum Æthiopicum* and *C. regium*. The latter name is translated by the Persians 'Kamoon Mullooke,' or Royal Cumin, and given as a synonym of the Nankwah. The Indian and Egyptian kinds of *Psychotis*, as

ascertained by modern botanists, are therefore most probably the two kinds of Ammi of Dioscorides. These afford interesting instances of the results to be obtained by closely examining the products of nature possessed of any remarkable properties, in the countries where they are produced, and continue to be used, and whence they were probably first obtained by the ancients.

PTYCHOZOON. [GECKOTIDÆ.]

PTYODACTYLUS. [GECKOTIDÆ.]

PUCCINIA, a genus of *Fungi*, well known to farmers under the name of Mildew. It is distinguished from other parasitical genera by its spore-cases being elevated upon long slender stalks and divided internally by one or two horizontal partitions into two or three separate cavities; the spore-cases arise from a spawn or matrix which is dispersed among the living tissue of the plant on which they grow. A considerable number of species have been distinguished by writers on *Fungi*, and 38 are enumerated as inhabitants of this country. They all grow upon the living leaves or stems of plants, and are generated in their interior, bursting through the epidermis when ready to scatter their seeds or spores. By what means the latter are introduced into the tissue has never been satisfactorily explained. Some writers imagine the seeds to be introduced through the stomates from the atmosphere where they float; but it seems more probable that they are absorbed by the young roots, and carried upwards in the current of vegetation, a mode of introduction which their extremely small size renders quite possible. The mildew of corn is the *P. graminis*, which makes its appearance on the straw and leaves in the form of dark gray or black lines and patches, broken in outline in consequence of their running irregularly together. Each line consists of numerous minute spore-cases, which are individually black when quite ripe. The plant appears in all corn-fields in all seasons, but its injurious effects are only observed in wet seasons, or in places where, from whatever cause, the straw becomes very rank; in the latter instance, the spore-cases, from their great abundance, attract from the straw the fluid food which was intended for the support of the grain, intercepting it in its passage upwards, and thus cause the ruin of the crop. In a disease of this kind there seems no hope of discovering a remedy, for the earth is undoubtedly well stored with the spores of *Puccinia* in all places and in all seasons. [FUNGI; ENTOPHYTA.]

PUCCOON. This name is given in the United States of America to a red vegetable pigment employed by the Indians, and hence has been transferred to the plant that produces it. By some it has been ascribed to *Sanguisorba Canadensis*; but Pursh asserts that it is obtained from the root of *Batschia canescens*, a Boraginaceous plant, while the American writers with one accord apply the name to *Sanguinaria Canadensis*, a Papaveraceous plant, whose roots yield, when wounded, a deep orange-red fluid.

PUCHURY. [NECTANDRA.]

PUDDING-STONE. [CONGLOMERATE.]

PUFF-BALL. [LYCOPERDON.]

PUFF-BIRDS. [BARBETS.]

PUFFIN. [AUK; PROCELLARIIDÆ.]

PUFFINUS, a genus of Birds belonging to the family *Laridæ*. [LARIDÆ.] It has the following generic characters:—Bill as long or longer than the head, slender; upper mandible compressed, and curved towards the point; under mandible also slender, and curved at the point; nostrils tubular, opening by two separate orifices. Legs of moderate length, tarsi compressed laterally; toes three in front, rather long, webbed throughout; hind toe rudimentary. Wings long and pointed, the first quill-feather the longest.

P. major, the Greater Shearwater. It is the *P. cinereus* of Selby; *Procellaria Puffinus* of Jernyns; Puffin Major of the French; and Cinereous and Dusky Shearwater of English writers. This bird has only been rarely shot in the British Islands. There are specimens in the British Museum from the coasts of South Africa. M. Temminck says it breeds by thousands on the banks of Newfoundland. Mr. Yarrell says it is probably the Wandering Shearwater of Messrs. Audubon and Nuttall.

P. Anglorum, the Manx Shearwater; *Procellaria Puffinus* of Pennant; the Manx Puffin, Shearwater Petrel, and the Shearwater of English writers. This bird is smaller than the last, its whole length is only 14 inches. The bill is blackish-brown, the iris is hazel, the head, back of the neck, back, wings, and tail uniform brownish-black; chin and neck in front white; breast, belly, and under tail-coverts white; behind the thighs a patch of brownish-black.

This little bird is an inhabitant of the ocean only, seeking the shore for the purposes of incubation. They lay but one egg, and this of dazzling whiteness. They are not so numerous now as formerly on the Calf of Man. They are still found in considerable numbers on the coasts of South Wales. [PROCELLARIIDÆ.]

(Yarrell, *British Birds*.)

PUG, a dwarf variety of the Dog, somewhat resembling a mastiff or bulldog in miniature. The Dutch Pugs have more the aspect of the large varieties last named than the French Pugs, some of which latter are very small. Both are snappish and noisy, but capable of strong attachment to their masters or mistresses. The French Pugs are, docile and may be easily taught many amusing tricks.

PULEX, the name given by Linneus to a group of Insects, of

which the Common Flea may be regarded as the type. The fleas are considered by Latreille, Kirby, and many other entomologists, as constituting an order of insects. They form the group *Suctorio* of De Geer; the order *Siphonaptera* of Latreille, and *Aphaniptera* of Kirby and Spence, by whom they are placed between the orders *Diptera* and *Aptera*. In the 'Règne Animal' they are arranged between the orders *Parasita*, or *Anaplura*, of Leach, and the *Coleoptera*. It is highly probable however that when this group is better known—when the numerous insects allied to the fleas are more common in our cabinets—it will be found that they do not constitute an order by themselves, but are aberrant forms of the other well-established orders; in these there is a certain degree of uniformity, as regards numbers, variety of habits, &c., which can but lead us to doubt the validity of the so-called orders containing only one or two genera, and but few species, such as the present order, and the orders *Aptera*, *Homaloptera*, and *Strepsiptera*. It is moreover worthy of observation that each of these so-called orders is composed of parasitic insects, which necessarily involves a structure very unlike the more typical species of the groups to which we may suppose they belong.

The *Suctorio* have the mouth composed of three pieces, inclosed by two articulated laminae, which, when united, form a cylindrical or conical proboscis, the base of which is protected by two scales. They undergo a complete metamorphosis: the larva is of an elongated cylindrical form, and when about to change into the pupa state, incloses itself in a silken cocoon, and at the end of a few days assumes the imago or perfect state.

In the genus *Pulex* the body is compressed, of an oval form, and protected by a tough coriaceous covering. The head is small and much compressed, and furnished on each side with a small round eye; behind this is a concavity in which the antennae (which are three-pointed) are situated.

On the anterior part of the head are two four-jointed organs, supposed by Latreille to be the antennae, but which must be palpi, the organs situated behind the eyes being now supposed to be the antennae. The legs are large and strong, particularly the hinder pair, by which the insect jumps, and covered with spines; the tarsi are 5-jointed, and the terminal joint is furnished with two elongated claws; the anterior pair of legs are inserted almost under the head, and the rostrum lies between them.

The female flea is said to lay about a dozen eggs, which are of a whitish colour and somewhat viscid: the larvae are long and slender, and have no legs; the head is scaly and has no eyes, but is furnished with two very small antennae: each of the segments of the body is provided with little tufts of hair, and the terminal segment has moreover two hooked appendages at its apex.

The Common Flea (*Pulex irritans*) is but too well known. It is said to attack dogs, cats, and other animals, as well as man; but there are other species which appear to be peculiar to certain birds and quadrupeds, and these have received in most cases the names of the species they attack, such as the Dog-Flea (*Pulex Canis*), the Mole-Flea (*P. Talpæ*), that of the Martins (*P. Hirundinis*), and of the Mouse (*P. Musculi*), &c.

The Chigoe of the West Indies and South America also belongs to this group, being the *Pulex penetrans* of authors. "It is described," says Messrs. Kirby and Spence (vol. i. p. 102), "as generally attacking the feet and legs, getting, without being felt, between the skin and the flesh, usually under the nails of the toes, where it nidificates and lays its eggs; and if timely attention be not paid to it, which, as it occasions no other uneasiness than itching (the sensation at first, I am assured, is rather pleasing than otherwise), is sometimes neglected, it multiplies to such a degree as to be attended by the most fatal consequences, often rendering amputation necessary, and sometimes causing death. The female slaves in the West Indies are frequently employed to extract these pests, which they do with uncommon dexterity." Besides the name Chigoe, they are sometimes called Jiggers, Nigua, Tungua, Pique, &c.

(Duge, *Recherches sur les Caractères Zoologiques du genre Pulex*, in *Annales des Sciences Naturelles*, October, 1832; Westwood, *On the Structure of the Antennae of the order Aphaniptera*, in *Entomological Magazine*, vol. i.)

PULICARIA, a genus of Plants belonging to the natural order *Asteraceæ*. It has an involucre laxly imbricated in few rows. The pappus in two rows, the outer one short, cup-like, membranous, and toothed, the inner one pilose.

P. vulgaris, Flea-Bane, has lanceolate wavy leaves, narrow at the base, and somewhat clasping; the stem much branched and downy; the heads lateral and terminal, hemispherical, with very short rays. It is the *Jwala* of Linnaeus. The heads are small, the florets yellow. It is found on moist sandy heaths in Great Britain. It has obtained its English name from being used to drive away fleas.

P. dysenterica has a creeping root, and is a herb more or less woolly or cottony, glutinous, and with a peculiar and aromatic smell. The stem rises 12 or 15 inches high: it is round, leafy, cottony, corymbose at the summit, with many bright yellow flower-heads, whose disc is of a darker hue than their numerous spreading rays. The leaves are acute, velvety, and wrinkled, or slightly toothed or serrated, from 1 to 2 inches long, sessile, clasping the stem, the under side cottony. The fruit is bristly and obovate, the pappus rough, the receptacle slightly

cellular, unequally toothed or scaly. Linnaeus states, on the authority of General Keith, that this plant cured the Russian army of the dysentery. But Haller speaks contemptuously of the medical virtues of this plant, because he says it abounds in earthy matter. It is found in damp places in Great Britain.

(Lindley, *Flora Medica*; *Vegetable Kingdom*.)

PULMOBRANCHIATA (De Blainville), an order of Gasteropodous *Mollusca*. [MALACOLOGY.]

PULMOGRADA. [ACALEPHÆ.]

PULMONARIA (so named from its being supposed efficacious in disorders of the lungs, or from the spots on the leaves resembling those on some diseased lungs), a genus of Plants belonging to the natural order *Boraginaceæ*. It has a tubular 5-cleft calyx, a funnel-shaped corolla with a naked throat. The stamens included in the tube filaments very short. The style is simple, the nuts smooth, attached by their truncate base with a central tubercle. The species are herbaceous plants with spotted leaves and terminal corymbose racemes of flowers.

P. officinalis, Lungwort, has ovate leaves, roundish or cordate, the upper leaves oblong. The root is thick and black. The corollas are red before expansion and then purple. The whole plant is more or less hispid. It is found in the woods and thickets of England, and is native of Europe and the Caucasus. The leaves, which are the parts of the plant recommended in medicine, have no peculiar smell, but in their recent state manifest a slightly astringent and mucilaginous taste—hence they are supposed to be demulcent and pectoral, and have been prescribed in consumption. All these plants contain nitro in considerable quantities, and when burnt this species yields one-seventh of its weight in ashes. In the north of Europe it is eaten as a potherb, and according to Ray in his time it was brought to table in Scotland.

P. angustifolia has all lanceolate leaves. It is difficult to distinguish from the former species, but is more pubescent, and has narrower spotless leaves. The corolla is purple, and there is a variety with white flowers. It is a native of Europe.

PULMONELLA. [SYNOICUM.]

PULP, a name given in Vegetable Physiology and Botany to such parts of plants as are semifluid. [FRUIT.]

PULSE. [HEART.]

PULVINITES. [MALLEACEA; MARGARITACEA.]

PUMA. [FELIDE.]

PUMICE. [LAVA.]

PUMPKIN is the vulgar name of the fruit of the *Cucurbita maxima* and *C. Pepo*. [CUCURBITA.]

PUNICA, a genus of Plants belonging to the natural order *Myrtaceæ*, sometimes distinguished, in consequence of its having two verticels of capsules developed instead of one, from *Myrtaceæ* under the name of *Granataceæ*. The genus consists of only a single species, the celebrated Pomegranate, with a dwarf variety, which is sometimes considered a distinct species. The pomegranate has from the earliest periods formed an object of attraction in the countries from Syria to the north of India, where it grows in perfection, as well as in the north of Africa; and this, as well from its shining dark-green foliage, as from its conspicuous flowers, of which the flower-cup and petals are both of a crimson colour, while its large red-coloured fruit, filled with juicy pleasant-flavoured pulp, which covers its numerous seeds, makes it an object of desire in hot countries. Thus we find it mentioned in the Bible under the name Rimmon (Numbers, ch. xiii.), and we hence learn that it was cultivated in Egypt and also in Palestine; by the Arab authors it is called Rooman, and by the Persians Anar, and it is probably indigenous all along the mountains from the Caucasus to the Himalayas, where it is described by Dr. Royle as being found in a wild state. Forster describes the Pomegranate as being delicious in most parts of Persia; and Burues states that the famous Pomegranates without seeds are grown in gardens under the snowy hills near the Caubul River.

The Pomegranate was well known to the Greeks, being the 'Poà of Theophrastus and the 'Poà of Dioscorides. Hippocrates mentions it by what is supposed to be its Phœnician name, Side. By the Romans it was called *Punica*, and *Punicum Malum*, from having been introduced from Carthage. Besides the fruit, the parts employed by the ancients were the double flowers, which were called balaustia; the pericarp, from its leathery consistence, called malicorium, was used for its astringent properties; while the bark of the root was considered an efficient anthelmintic. In the East, where so much has remained stationary, the different parts continue to be employed for the same purposes; and Dr. Royle mentions that in India buloositou is given as the Greek name of the double flower. The rind of the wild fruit is much preferred for astringent purposes, and forms in the present day an article of commerce from the Himalayas to the plains of India. The bark of the root, being also still employed in India for the expulsion of intestinal worms, was made known as a recent discovery in India, in consequence of a Mohammedan practitioner having cured a European gentleman thereof of tape-worm with great ease. He had no doubt learned this property of the bark of the pomegranate from the translations of Dioscorides, which are incorporated in most of the Mohammedan works on *Materia Medica*, affording a striking instance of facts once well known being forgotten until they are

rediscovered. It is remarkable that the African slaves in the West Indies are also acquainted with this property of the root of the pomegranate, which they must have learned in their own country, probably from the prevalence there of Mohammedan works on medicine, or of the practice which is inculcated in them. [POMEGRANATE, in ARTS AND SC. DIV.]

PUPA. In Entomology this term is applied to the third stage of existence of an insect, the egg being the first stage, and the larva or caterpillar, the second. [INSECTA.]

PUPA. (Conchology.) [HELIX.]

PUPIL. [EYE.]

PUPIVORA. In Entomology this term is applied by Latreille to his second great section of hymenopterous Insects—a section the species of which are distinguished by their having the abdomen attached to the thorax, in most cases, by a slender stalk, and not, as in the first section (*Securifera*), forming as it were a continuation of the thorax. The females are furnished with a slender bristle-like ovipositor, and in this respect they also differ from the greater portion of the *Securifera*.

The larvæ of the *Pupivora* have no feet, and most of them are parasitical. Latreille divides this section into two groups, the *Evaniales* and the *Ichneumonides*, distinguished chiefly by the insertion of the stalk or basal portion of the abdomen. In the *Evaniales* the stalk is attached to the thorax, and in most cases immediately under the scutellum; they have distinct nervures to the wings, and those of the upper pair form cellules; the antennæ are filiform, or setaceous, and composed either of thirteen or fourteen joints; the mandibles are toothed on the inner side; the maxillary palpi have six joints, and the labial four; the ovipositor is generally exerted, and composed of three slender pieces.

Dr. Leach regarded the present group as constituting a family, and applied to it the name *Evanidae*; compared with the next section of the *Pupivora*, the present one is very limited in species. Mr. Stephens, in his 'Systematic Catalogue of British Insects,' only enumerates five species, and these constitute three genera, *Evania*, *Brachygaster*, and *Fenus*.

In the *Ichneumonides* the abdomen has its origin between the two posterior legs; the nervures of the upper wings form cellules; the antennæ are generally filiform or setaceous, and composed of many joints (sixteen at least); the mandibles are in most cases destitute of denticulations on the inner side, and are bifid at the apex; the maxillary palpi are always distinct, and seldom have more than six joints. Of this group the species are exceedingly numerous. Mr. Stephens states that he possesses 800 British species of this family. The *Pupivora* appear to be destined to prevent other tribes of insects (particularly the *Lepidoptera*) from becoming numerous.

The *Ichneumonidae* may be seen during the summer months in great numbers flying from plant to plant in search of the caterpillars which are suited to furnish the proper food and to rear their larvæ, each caterpillar apparently having its own peculiar parasite, or parasites, for sometimes several species of *Ichneumon* attack the same larvæ. The female *Ichneumon*, by means of her long bristle-like ovipositor, inserts her eggs in the body of the caterpillar in such a manner, and in such parts, that it does not destroy the life of the victim. In most cases these eggs are not hatched until the caterpillar has changed into a chrysalis; they then hatch, and the *Ichneumon* larvæ feed upon the contents of the pupa case, inclose themselves in silken cocoons, and undergo their final transformations, to come forth in proper season, eating their way through the chrysalis case. Instances are not uncommon in which the eggs of the *Ichneumon* hatch in the body of the living caterpillar, and, what is most remarkable, they do not destroy its life. It is not until the larvæ have quitted their abode in the caterpillar that it dies, having the cocoons of the *Ichneumon* larvæ attached to its skin. The caterpillar so abundant on cabbages, and which is that of the common white butterfly, affords a familiar example of this nature. At certain times of the year numbers of these caterpillars may be seen on walls adjoining gardens: on these they usually attach themselves (in some sheltered situation) to undergo the transformation into the pupa state. One of these caterpillars will appear healthy, select a convenient situation, attach itself (as usual before the change into the pupa state) by means of a silken thread around its body, but instead of undergoing the transformation, we shall find it after a short time covered with an immense number of small yellowish silken cocoons spun by the larvæ of the *Ichneumons* as they crawl from its body. These cocoons, which are about one-eighth of an inch in length, are attached to each other, and to the skin of the caterpillar, which then dies. The larvæ of some of the *Ichneumonidae* themselves are infected with parasites.

(Gravenhorst, *Conspectus Generum et Familiarum Ichneumonum*.)

PURPURA. [ENTOMOSTOMATA.]

PURPURIFERA, a family of *Mollusca*. [ENTOMOSTOMATA.]

PURSLANE. [PORTULACACEÆ.]

PUSTULIPORA. [MILLEPORIDÆ.]

PUTCHUK is the name by which a fragrant root is designated in the price-currents of Calcutta and Bombay, whence it is exported to Canton, being highly esteemed by the Chinese as an incense. From the places of export this would appear to be a product of India, but

neither the plant which yields it nor the place where it grows has been discovered until very recently. The discovery is interesting, as the Putchuk is a substance which was known to the ancients. Dr. Royle, while in the north-western provinces of India, obtained a root which formed a considerable article of commerce, and which was said to be brought from still farther north, that is, from Lahore. It was warm and aromatic in taste, fragrant in odour, and frequently called Orris-Root (Iris-Root) by Europeans in India, though by the natives in Northern India it is called Kooth. On comparing specimens of Kooth which he obtained in Northern India with what was called Putchuk in Calcutta, he found that they were identical, and he was subsequently informed by Mr. Beckett, who was long settled as a merchant in Northern India, that what the latter purchased from Umritseer under the name of Kooth he sold in Calcutta by that of Putchuk, so that there can be no doubt of the identity of the two substances; but all that had been ascertained with respect to the place where it was produced was, that it seemed to be to the north of the Sutlej.

Kooth, being used in India as a medicine, as well as exported to China, is described in the Persian works on *Materia Medica* in use in that country, and has assigned to it Kust as the Arabic, Kooshta as the Syriac, and Koostus as the Greek name. Three kinds are described. Dr. Royle states that he was only able to meet with two kinds in India, one called Koost-Hindee, and the other Koost-Arabee. These evidently refer to two of the three kinds of *Costus* described by Dioscorides as the Arabian, Indian, and Syriac. ('*Illust. Himal. Bot.*, p. 360.) There can be little doubt therefore that the Kooth or Putchuk is one of the kinds of *Costus* of the ancients, which was highly esteemed by them, and formed an ingredient in their most famous compound alexipharmic confections, such as the *Theriaca* and the *Mithridatium*. It was also highly esteemed by them as an incense, as, in the line of Propertius—"Ure puer costum Assyrium redolentibus aris"; and is mentioned by Horace as '*Achæmenium costum*.' ('*Od.*, iii. 1.)

The identity of Kooth and *Costus* was however long ago ascertained, though not generally known, as is evident in the following passage from Garcias ah Horto, in Clusius ('*Exot.*, lib. x.) "*Est ergo Costus dictus Arahibus Cost aut Cast; in Malacca, ubi ejus plurimus est usus, Pucho, et inde vehitur in Sinarum regionem.*" In MacCulloch's '*Commercial Dictionary*,' Putchuk is described as "the root of a plant growing in Sindh. When burned it yields a fine smell. The Chinese beat it into a fine powder, which they burn as incense in the temples of their gods." Of the Putchuk, 6697½ bazar maunds, of the value of 99,903 rupees, were exported from Calcutta in the year 1837-38.

On Dr. Falconer's proceeding on his journey to Cashmere, Dr. Royle requested him to make inquiries respecting this substance, and he discovered that it was exported from the valley in large quantities to the Punjab, whence it finds its way to Bombay and Calcutta; and that it is sold in China at an advance of about 3000 per cent. on the price at which it is gathered in Cashmere. Dr. Falconer subsequently found it growing in great abundance all round the elevated summits of Cashmere. From the plants with which it is associated, and the circumstances under which the Koot grows, being one of the *Composite*, or Thistle tribe, with feathered seed, of which when once established the dissemination becomes easy, Dr. Falconer has no hesitation in thinking that it could be produced to an unlimited extent, of the best quality, in the Himalayas at elevations of from 7500 to 9000 feet above the sea, and that the Choor Mountain alone might be brought in a few years to produce thousands of maunds of it. Preparatory to diffusing the Koot, or *Costus*, he has introduced it into the Himalayan nursery attached to the Saharumpore Botanic Garden.

Finding that it belongs to a new genus, he has named it *Aucklandia*, in honour of George, earl Auckland, governor-general of India, "as a distinction well merited by his lordship's services in the cause of Indian Botany."

(Royle, *On the Productive Resources of India*.)

PUTORIUS. [MUSTELIDÆ.]

PUTRANJIVA, an Indian genus of Plants, referred by Dr. Roxburgh to *Nageia*, but which has been separated by Dr. Wallich under the above name, which is a Sanscrit compound, consisting of the words, 'putra,' a son, and 'jeeva,' life, in consequence of the seeds being struck by parents round the necks of children, under the supposition that they will preserve them in health. They are sold in bazaars throughout India for this purpose. *P. Roxburghii*, the only species known, forms a large timber-tree, with an erect straight trunk, and a white close-grained very hard wood. The head is large and shady, composed of numerous spreading branches, with shining dark green leaves arranged on two sides of the branchlets. The flowers are dioecious, the male ones crowded together; the perianth small, calyx-like, 4-5-leaved; corolla none; stamens three; filaments thread-like, all or only two united together, and the third free. The female flowers solitary in the axils of the leaves, with long foot-stalks; perianth 5-leaved; ovary ovate, oblong, 3-celled; cells 2-seeded; styles three, filiform; stigmas crescent-shaped and toothed; drupe 1-seeded. Young plants of this tree have been cultivated in moist stoves in this country. The genus has been referred to the natural family of

Myricææ, but is considered by Eudlicher as more nearly allied to the *Antidæmææ*.

PYCNODUS, a genus of Fossil Fishes. [Fish.]

PYCNOPHYCUS. [FUCACEÆ.]

PYGATHRIX. M. Geoffroy's name for the Douc, or Cochin-China Monkey (*Lasiopyga*, Illiger). It has the following characters:—Head rounded; muzzle moderately prolonged; tail long; cheek-pouches; hands longer than the fore arms and the legs; anterior thumbs very short and slender; no callosities; buttocks fringed with long hairs.

Dental Formula:—Incisors, $\frac{4}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5} = 32$.

P. Nemæus, Geoff. (*Lasiopyga Nemæus*, Ill.; *Simia Nemæus*, Linn., 'Mant.').

This very rare monkey is perhaps the most remarkable of the whole tribe for the variety and liveliness of the colours with which it is marked, and which are the more striking from being distributed in large masses.

The upper part of the head is brown with a dark-reddish chestnut frontal band. The cheeks are clothed with very long and whitish or yellowish-white hairs. The back, the belly, the arms, and the sides are gray with a somewhat greenish cast; the tail is whitish, and so are the rump and the fore arms; the anterior fingers are blackish; the lips and thighs are blackish, and the legs of a brightish-red chestnut; the more exposed parts of the face are of a reddish tint. Length rather more than 2 feet when erect; length of tail about 1 foot 7 inches.

It is a native of Cochin China.

Cochin-China Monkey (*Pygathrix Nemæus*).

PYGODA'CTYLUS. [SCINCOIDEA.]

PYGOPODES, Illiger's name for those Natatorial Birds whose wings are well-developed, and whose feet are placed very far back so as to facilitate their diving, as *Columbus*, *Uria*, *Alca*, &c.

PYGOPUS. [SCINCOIDEA.]

PYLORIDIA, *Pyloriden*, M. De Blainville's name for his ninth family of *Lamellibranchiata*, which he thus characterises:—Body compressed, more and more cylindrical, the mantle more and more closed and prolonged backwards by two long tubes which are ordinarily distinct, with an anterior and inferior aperture for the passage of a very small and ordinarily conical foot; branchiæ narrow, free, and prolonged in the tube. Shell regular, rarely irregular, nearly always equivalve, gaping at the two extremities; hinge incomplete, the teeth gradually vanishing ('*s'effaçant peu en peu*'); ligament internal or

external; two distinct muscular impressions, united by a pallial impression which is very flexuous backwards.

M. De Blainville remarks that all the animals of this family live inclosed in the mud, the sand, or calcareous stone, almost without ever changing their place, always in a vertical position, the mouth below and the anus above. All their shells, he observes (ordinarily white, and covered with an epidermis), hardly ever exhibit any striae from the umbo to the base, but only lines of growth (*stries d'accroissement*).

Section 1. (Ligament internal.)

Pandora.—Animal oval, compressed, rather elongated, with the mantle in form of a case, terminating backwards by two tubes united at their base only, and rather short, opening anteriorly for the passage of the foot, which is large, triangular, thick, and swollen at its extremity; branchiæ large, free backwards, where the two pairs are united and terminate in a point in the siphon; labial appendages rather large, triangular, and not striated. Shell delicate, regular, elongated, compressed; inequivalve, inequilateral, having the right valve flattened and the left more or less convex; umbones but little distinct; hinge composed of a cardinal tooth in the right valve, corresponding with a cavity in the left; ligament internal, oblique, triangular, inserted in a little pit with rather projecting edges; muscular impressions rounded, that of the mantle but little apparent and forming a small excavation. (Rang.)

The *Pandora* live sunk in the sand so deep that it requires some difficulty to get them out. They have been found at depths varying from the surface to 10 fathoms.

Species are recorded from Norway, the European seas, including the Mediterranean, the Pacific, the coasts of Georgia and Florida in North America, and New Zealand. Woodward enumerates 13 recent and 6 fossil species.

P. rostrata has the shell with the anterior side produced, attenuated, rostrated, and angulated in each valve. Dr. Carpenter says of its microscopic structure that the outer layer of regular, vertical, and prismatic cells are 250 times smaller than those of *Pinna*.

It is found on the coasts of England and France, and the Mediterranean.

Shell of *Pandora rostrata*.

a, Interior of deep valve; b, interior of flat valve; c, valves closed.

Soft parts of *Pandora rostrata*.

a, a, a, r, Mantle, opened anteriorly to show the issue of the foot; p, foot; b, rectum; e, liver covered by the ovary; m, adductor muscles; c, c, tubes.

P. obtusa is a more abundant British species.

Anatina.—Animal oblong, rather thick, having the mantle closed by a rather large membranous lamina with a small rounded aperture at the antero-inferior part for the passage of a linguiform foot; two elongated tubes separated deeply at their extremity, the lower being rather greater than the upper; branchiæ narrow, free, and pointed backwards. Shell delicate, sometimes translucent, oval, elongated or oblong, gaping at one or both extremities, equivalve; very inequilateral; umbones placed backwards, the upper anterior border being longer than the posterior; hinge without teeth, but having in their place a horizontal excavated apophysis or spoon-shaped process, receiving the internal ligament, and sustained by a lamina which is oblique and decurrent into the interior of the shell; muscular impressions distant, oval, united by a pallial impression which is but little marked, but having a deep and rounded excavation backwards. (Rang.)

There are 20 living species known. They inhabit India, the Philippines, New Zealand, and Western America. There are 50 fossil from the Devonian and Oolitic Rocks. *Periploma*, *Cochlodæma*, and *Cercomya* are sub-genera.

A. subrostrata has the shell ovate, membranaceous, anterior side attenuated and subrostrated.

It is a native of the seas of Australia. Lamarck adds, the Indian Ocean.

The *Anatine* have hitherto been found for the most part in sands and shallow water.
